BRADBURY AND EVANS, PRINTERS, WHITEFRIARS.

TO

HER MAJESTY QUEEN VICTORIA,

The English Cyclopædia

IS,

WITH HER MAJESTY'S GRACIOUS PERMISSION,

MOST HUMBLY INSCRIBED,

BY HER MAJESTY'S DUTIFUL AND DEVOTED SUBJECT,

CHARLES KNIGHT.

December 10, 1853.

PREFACE.

UPON completing the first two volumes of "THE ENGLISH CYCLOPÆDIA"—namely, one of GEOGRAPHY, and one of NATURAL HISTORY—the Conductor is called upon to say a few words upon the general nature of the work, and its progress to the present time.

"The English Cyclopædia," as announced from the first, is based upon "The Penny Cyclopædia of the Society for the Diffusion of Useful Knowledge." The copyright of that great work being the property of the Conductor, he alone had the power of remodelling it throughout, so as to adapt the original materials to the existing state of knowledge. To accomplish this in the most effectual manner, it was determined to publish "The English Cyclopædia" in FOUR DIVISIONS, each having its own alphabetical arrangement; these Divisions being—I. GEOGRAPHY; II. NATURAL HISTORY; III. SCIENCES AND ARTS; IV. HISTORY, BIOGRAPHY, MORAL SCIENCES, LITERATURE.

During the progress of the publication, the Conductor has become more and more satisfied that the plan of issuing "The English Cyclopædia" in Four Divisions is a judicious arrangement. It has the obvious advantage of completing, in a comparatively short time, large departments of knowledge with the most recent information. Finishing the great branches of Geography and Natural History in two years and a half, the beginning and the end of each Series will not present different aspects—the one somewhat antiquated, the other perfectly fresh. The editorial labour, too, being more condensed, the relations and proportions of each article and subject can be better preserved. The Conductor has no reason to regret that it was resolved to produce a NEW Cyclopædia in a NEW form. The old materials were of the highest value; but the edifice required to be rebuilt.

The amount of literary labour which this remodelling has involved will at once be seen by any one who will compare the articles of the present work with those of the original. That labour has not been confined to revision and correction. Many new articles have been introduced, and many of the old ones supplied by others wholly re-written. The changes which have taken place since the "Penny Cyclopædia" was commenced, twenty years ago, have rendered every branch of information in some degree a new study. That no diligence has been spared to collect every fact not previously recorded; to systematise articles that from the long course of publication of the original work were disconnected; to make the references complete; and truly to present, as far as a "Dictionary of Universal Knowledge" can present, the advanced opinions of our own times;—to this labour, amongst all engaged in the work, the Conductor can bear the most ample testimony. In this Division of the Cyclopædia, his own duties have consisted only in a general superintendence. He is deeply indebted to the exertions of Dr. EDWIN LANKESTER, by whose care the Cyclopædia of Natural History has been brought into a more systematic shape; while every exertion has been made to bring up the articles to the science of the present day, much that was obsolete has been removed. The scientific connexions of Dr. LANKESTER have enabled him, in editing this department, to have access to the opinions of the best living authorities, and to secure the ablest assistance wherever required.

Of the typographical execution of this work, in the essential point of accuracy, the Conductor can confidently speak. Of its other merit, that of mechanical execution, he believes that no work of such remarkable cheapness was ever produced with the beauty that was once considered exclusively to belong to the dearest class of books.

December, 1853.

OOTTERPARAH PUBLIC LIBRARY 1859

THE
ENGLISH CYCLOPÆDIA.

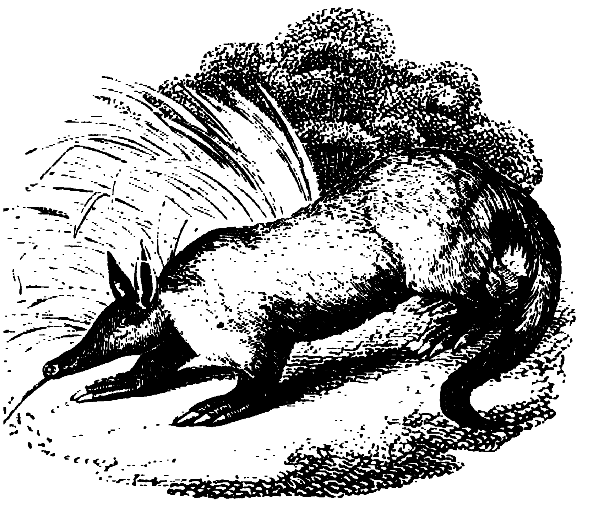
NATURAL HISTORY.

AARD-VARK (*Orycteropus*, Geoffroy), in Zoology, a genus of animals belonging to the class *Mammalia*, and order *Edentata*.

The *Orycteropus* is now separated from the *Myrmecophaga*, or Ant-Eaters of Linnæus, with which it had been formerly associated. In its anatomical structure it bears a much closer relation to the armadillos than to any other quadrupeds, not even excepting the ant-eaters, with which it was formerly associated. Like these animals, the *Orycteropus* is provided with large and powerful claws, for digging up roots and insects, and for forming subterraneous burrows; and, like them, has neither incisors nor canine teeth. Its molar teeth, however, are altogether peculiar, both in form and structure, and have no resemblance to the teeth of any other known animal. Of these there are five large ones on each side (both in the upper and under jaws), which are always permanent; and a variable number of from one to three smaller ones, placed in front of the others, and apparently representing the false molars of ordinary quadrupeds. The first of the large molars is smaller than any of the other four, and of a cylindrical form, somewhat compressed or flattened on the sides; the second is rounder; the third and fourth are each composed of two similar cylinders, as it were, soldered together; and the last is a simple cylinder, like the first and second. Immediately in front of these are the small or false molars, which, falling annually, vary in number according to the individual. Properly speaking, the teeth of these animals are destitute of real roots, and are therefore, like the tusks of the elephant, and the incisors of the rodentia, capable of being indefinitely increased, by the deposit of new matter on the under extremity, to counterbalance the continual wear of the upper surface.

In the form of the extremities the *Orycteropus* resembles the armadillos still more nearly than in the nature of its dental system. The legs are remarkably short and stout; the feet plantigrade (that is to say, the animal walks upon the whole sole of the foot, as man and the bear, instead of bringing the point of the toe only in contact with the ground, as may be observed in the dog, horse, &c.); and the toes, of which there are four on the fore feet and five on the hind, are armed with extremely large and powerful claws, flattened horizontally, and scooped or hollowed out on the under surface, so as to form a most efficient instrument for digging and burrowing beneath the surface of the earth. This process is still further facilitated by the oblique form of the anterior extremities, arising from the unequal length of the toes; the two interior being considerably longer than the others, and the whole diminishing gradually from the index (or toe corresponding with the fore-finger) outwards. In other parts of its anatomy the *Orycteropus* resembles both the armadillos and the ant-eaters, and particularly in the form and structure of the stomach and alimentary canal. The reader who is desirous of further information upon these subjects may consult Cuvier's 'Leçons d' Anatomie Comparée,' and his great work, 'Sur les Ossemens Fossiles,' from which the details here given are for the most part abridged.

The only species of this curious genus with which zoologists are at present acquainted is the Aard-Vark (*Orycteropus Capensis*). It is an animal extremely common in some parts of Southern Africa, though, from its nocturnal habits and extreme timidity, it is not so frequently seen as many others which are in reality scarcer. Its colonial name of aard-vark, or earth-pig, by which it is known among the Dutch inhabitants of the Cape of Good Hope, is derived as well from its habit of burrowing as from the general appearance which it bears, at first sight, to a small, short-legged pig. This animal, when full grown, measures about three feet five inches from the snout to the origin of the tail; the head is eleven inches long; the ears six inches; and the tail one foot nine inches. The head is long and attenuated; the upper jaw projects beyond the lower, and ends, as in the common hog, in a truncated callous snout, having the nostrils pierced in the end of it; the mouth is small for the size of the animal, and the tongue flat and slender, not cylindrical as in the true ant-eaters, nor capable of being protruded to such an extent as in these animals: it is, however, covered in like manner with a glutinous saliva, which firmly retains the ants, upon which the animal lives, and prevents those which once come in contact with it from escaping afterwards. The ears are large, erect, and pointed; and the eyes, which are of moderate size, are situated between them and the snout, about two-thirds of the distance from the extremity of the latter. The body of the aard-vark is thick and corpulent; the limbs short and remarkably strong; the hide thick, tough, and nearly naked, having only a few stiff hairs, of a pale reddish-brown colour, thinly scattered over it, excepting on the hips and thighs, where they are more numerous than elsewhere. The tail is about half the length of the body and head together, and, like the body, is nearly naked; it is extremely thick and cylindrical at the base, but decreases gradually towards the extremity, and ends in a sharp point.



Aard-Vark (*Orycteropus Capensis*).

Thus formed, the aard-vark is in all respects admirably fitted for the station which nature has assigned to it in the grand economy of the animal kingdom. It feeds entirely upon ants, and in this respect fulfils the same purposes in Southern Africa which is executed by the *Pangolins* in Asia, the *Myrmecophaga* in America, and the *Echidna* in Australia.

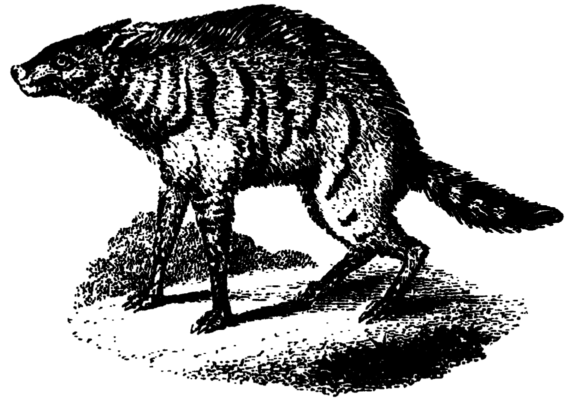
These insects raise mounds of an elliptical figure, to the height of three or four feet above the surface of the ground; and are these gigantic ant-hills in some parts of Southern Africa, that they are frequently seen extending over the plains as far as the eye can reach, and so close together that the traveller's waggon can with difficulty pass between them. They abound more especially in the Zeurevelden, or sour districts, so called from producing a kind of sour grass; are seldom found on the karroos or downs, and never in very dry or woody districts. By constant exposure to the rays of a powerful tropical sun they become so hard and indurated on the outer surface that they easily support the weight of three or four men, and even a loaded waggon will sometimes pass over without crushing them. Internally these mounds are of a spongy structure, something resembling a honeycomb, and are so completely saturated with animal oil that they inflame without difficulty, and are an excellent substitute for wood or coal.

Wherever ant-hills abound the aard-vark is sure to be found at no great distance. He constructs a deep burrow in the immediate vicinity of his food, and changes his residence only after he has exhausted his resources. The facility with which he burrows beneath the surface of the earth is said to be almost inconceivable. We have already seen how admirably his feet and claws are adapted to this purpose; and travellers inform us that it is quite impracticable to dig him out, as he can in a few minutes bury himself at a depth far beyond the reach of his pursuers; and, further, that his strength is so great as to require the united efforts of two or three men to drag him from his hole. When fairly caught, however, he is by no means retentive of life, but is easily dispatched by a slight blow over the snout. The aard-vark is an extremely timid, harmless animal, seldom removes to any great distance from his burrow, being slow of foot and a bad runner, and is never by any chance found abroad during the day-time. On the approach of night he sallies forth in search of food, and, repairing to the nearest inhabited ant-hill, scratches a hole in the side of it just sufficient to admit his long snout. Here, after having previously ascertained that there is no danger of interruption, he lies down, and, inserting his long slender tongue into the breach, entraps the ants, which fly to defend their dwellings upon the first alarm, and, mounting upon the tongue of the aard-vark, get entangled in the glutinous saliva, and are swallowed by whole scores at a time. If uninterrupted, he continues this process till he has satisfied his appetite; but on the slightest alarm he makes a precipitate retreat, and seeks security at the bottom of his subterranean dwelling. Hence it is that these animals are seldom seen even in those parts of the country in which they are most numerous. Like other nocturnal animals, which pass the greater part of their lives in sleeping and eating, they become exceedingly fat, and their flesh is considered to be a wholesome and palatable food. The hind-quarters, particularly when cut into hams and dried, are held in great esteem.

AARD-WOLF (*Proteles*, Is. Geof.), in Zoology, a genus of digitigrade carnivorous mammals, founded by M. Isidore Geoffroy St. Hilaire, for the purpose of giving a place to a new and singular quadruped brought some years ago from Caffraria by the traveller Delalande. This genus is interesting to the zoologist, as forming the intermediate link which connects the civets with the dogs and hyænas—three genera which have hitherto stood, as it were, insulated from surrounding groups, and widely separated from one another. The dogs and hyænas, indeed, had been united a short time previous, by the discovery of an intermediate species in the same locality which has since produced the *Proteles;* but it is this latter species alone, which, uniting the characters of all these three genera, enables us to trace their natural affinities, and to assign to them their proper position in the scale of existence.

To the external appearance and osteological structure of an hyæna this truly singular animal unites the head and feet of a fox, and the intestines of a civet. Its teeth are remarkable: the permanent canines are tolerably large, but the molars are small, and separated by intervals. It has five toes on the fore feet, and four only on the hind; the innermost toe of the fore foot is placed, as in the dogs, at some distance above the others, and therefore never touches the ground when the animal stands or walks. The legs also are completely digitigrade; that is to say, the heel is elevated, and does not come into contact with the surface, as in man and other similarly formed animals, which walk upon the whole sole of the foot, and are thence said to be plantigrade. It is of great importance to remark the difference between these two modifications of the locomotive organs, because they have a very decided and extraordinary influence upon the habits and economy of animal life. Digitigrade animals, which tread only upon the toes, and carry the heel considerably elevated above the ground, have much longer legs than plantigrade animals, and are, therefore, especially fitted for leaping and running with great ease and rapidity. Accordingly, it will be observed that the horse, the stag, the antelope, the dog, and other animals remarkable for rapidity of course, partake strongly of this formation; and even their degree of swiftness is accurately measured by the comparative elevation of the heel. Inattentive observers sometimes misapprehend the nature of this peculiar conformation of the extremities of digitigrade animals, and are apt to confound the hough with the ankle, and to mistake for the knee what is really the heel of the animal. Thus we have heard it said that, in the hind legs of the horse, the knee was bent in a contrary direction to that of man. This is by no means true: a little attention to the succession of the different joints and articulations, will show that what is called the cannon-bone in the horse, and other digitigrade animals, in reality corresponds to the instep in man; and that what is generally mistaken for the knee really represents the heel.

In the particular case of the *Proteles* the natural effect of the digitigrade formation is, in some degree, lessened by the peculiar structure of the fore legs, which, contrary to the general rule observable in most other animals, are considerably longer than the hind. In this respect, also, the *Proteles* resembles the hyænas; and in both genera this singular disproportion between the anterior and posterior extremities abridges the velocity properly due to their digitigrade conformation. This genus contains but a single species.



Aard-Wolf (*Proteles Lalandii*).

The *Aard-Wolf*, or Earth-Wolf (*Proteles Lalandii*, Is. Geof.; *Viverra cristata*, Sparr.), is so called by the European colonists in the neighbourhood of Algoa Bay, in South Africa, the locality in which M. Delalande procured his specimens of this animal. The size of the aard-wolf is about that of a full-grown fox, which it further resembles in its pointed muzzle; but it stands higher upon its legs, its ears are considerably larger and more naked, and its tail shorter and not so bushy. At first sight it might be easily mistaken for a young striped hyæna, so closely does it resemble that animal in the colours and peculiar markings of its fur, and in the mane of long stiff hair which runs along the neck and back; indeed, it is only to be distinguished by its more pointed head, and by the additional fifth toe of the fore feet. The fur is of a woolly texture on the sides and belly, but a mane of coarse stiff hair, six or seven inches in length, passes along the nape of the neck and back, from the occiput to the origin of the tail, and is capable of being erected or bristled up, like that of the hyæna, when the animal is irritated or provoked. The general colour of the fur is pale cinereous (ash-coloured), with a slight shade of yellowish brown; the muzzle is black and almost naked, or covered only with a few long stiff moustaches. Around the eyes, and on each side of the neck, are dark brown marks; eight or ten bands of the same colour pass over the body in a transverse direction, exactly as in the common striped hyæna; and the arms and thighs are likewise marked with similar transverse stripes. The legs and feet are of an uniform dark brown in front, and gray behind. The long hairs of the mane are gray, with two broad rings of black, the second of which occupies the point; those of the tail are similarly marked, and equally long and stiff; whence it appears as if the mane and tail were clouded with an alternate mixture of black and gray. The ears are gray on the interior surface, and dark brown on the outer.

In its habits and manners the aard-wolf resembles the fox: like that animal, it is nocturnal, and constructs a subterraneous burrow, at the bottom of which it lies concealed during the daytime, and only ventures abroad on the approach of night, to search for food and satisfy the other calls of nature. It is fond of the society of its own species; at least, many individuals have been found residing together in the same burrow; and, as they are of a timid and wary character, they have generally three or four different entrances to their holes; so that, if attacked on one side, they may secure a retreat in an opposite direction. Notwithstanding the disproportionate length of their fore legs, they are said to run very fast; and so strong is their propensity to burrow, that one of M. Delalande's specimens, perceiving itself about to be run down and captured, immediately ceased its flight, and began to scratch up the ground, as if with the intention of making a new earth.

M. Isidore Geoffroy St. Hilaire has bestowed upon this species the name of *Proteles Lalandii*, but Sparrman and Levaillant mentioned the aard-wolf long before the date of M. Delalande's journey; and the former has not only described it with tolerable accuracy, but has even ascertained its true generic characters. (Sparrman's 'Travels,' vol. ii., p. 177.)

In the 'Second Voyage' of Levaillant, vol. ii., p. 360, mention is likewise made of this animal under the appellation of 'Loup de Terre,' which is a simple translation of its colonial name, aard-wolf.

Sparrman mentions having found ants in the stomach of the *Proteles*, and these insects, it may be observed, are also a favourite food of the bear.

ABDOMEN, the *Belly*, from *abdo*, to hide, because it conceals or hides its contents. The last syllable is only a termination. The *Lower Belly*, *Imus Venter*, *Alvus*, *Gaster*, &c. &c., are synonymous.

The human body is divided by anatomists into three portions—the head, the trunk, and the extremities. The head and trunk enclose cavities which contain the organs or the instruments by which the most important functions of the living body are performed. The trunk forms two cavities, the superior of which is termed the Thorax or Chest, and the lower constitutes the Abdomen.

In the artificial skeleton nothing is shown, because nothing remains except the mere framework of the body, or the bones; but in the natural state, when the soft parts remain as well as the bones, there is a complete partition between the cavity of the chest and that of the abdomen (*fig.* I., 1, 2). This partition is effected by means of an organ which is termed the Diaphragm (*fig.* I., 1, 2), a name derived from a Greek word signifying to divide. The diaphragm is composed partly of membrane, but chiefly of muscle (*Fig.* II.) It is placed transversely across the trunk at about its middle portion, dividing it into two pretty nearly equal halves (*Fig.* I.) But the diaphragm is a moveable body; it is, in fact, one of the main organs of respiration: its chief function consists in alternately increasing and diminishing the capacity of the thorax and abdomen, for the purpose of respiration. But since the very partition which separates these two cavities from each other is perpetually changing its relative position—now encroaching upon the one, and now upon the other—it is obvious that their natural capacity must be constantly varying.

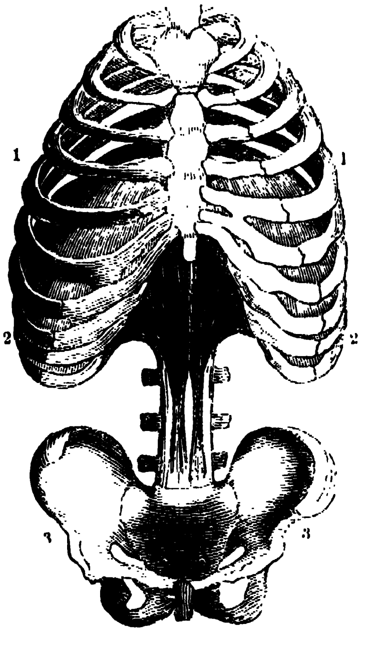


Fig. 1.

The cavity of the abdomen is bounded above by the diaphragm (*Fig.* I., 1, 2), below by the bones of the Pelvis or basin (*Fig.* I., 3, 3), which may be considered as belonging to the bones of the lower extremities, before and at the sides by the abdominal muscles, behind partly by the muscles of the loins, and partly by the bone of the spine. The Spine is composed of a number of separate bones, each of which is termed a Vertebra. The vertebræ are firmly united together, and by their union form what is commonly called the back-bone, termed by anatomists the Spinal Column, or the Vertebral Column.

The cavity of the abdomen is lined throughout by a thin, but dense, firm, and strong membrane, termed the Peritoneum, from a Greek word signifying to extend around.

We have thus spoken of the abdomen as a cavity, but without explanation this mode of expression may occasion misconception. During the state of life there is no cavity. The abdomen is always completely full. It has been stated that the diaphragm alternately enlarges and diminishes the space proper to the abdomen; but the abdominal and lumbar muscles, which form so large a part of the boundaries of the abdomen in front, at the sides and behind, in like manner, alternately contract and relax. The consequence is, that a firm and uniform pressure is at all times maintained upon the whole contents of the abdomen, so that there is always the most exact adaptation of the containing to the contained parts, and of the viscera one to the other, not the slightest space or cavity ever intervening, either between the walls of the abdomen and its viscera, or between one viscus and another. By the cavity of the abdomen, therefore, is not meant what the expression might at first view seem to denote, namely, a void or empty space; but the term is merely employed to mark the extent of the boundary within which the abdominal viscera are enclosed.

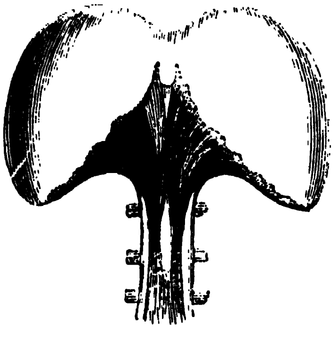

Fig. II.—Diaphragm, removed from its natural situation between the Chest and Abdomen.

The abdomen, for practical purposes, is artificially mapped out into the following regions.

Two imaginary lines are drawn across the abdomen, one of which is supposed to extend from about the seventh rib on one side to the same point on the opposite side (*Fig.* III., 1, 1). The second line is supposed to extend from the fore part of the large bone of the pelvis to the same projecting point on the other side (2, 2). These lines mark out three large and distinct spaces (3, 4, 5). The space above the upper line is termed the Epigastric Region (3). The space below the lower line is termed the Hypogastric Region (5). The space included between the two lines is termed the Umbilical Region (4).

Two lines are next supposed to extend vertically, one on each side, from between the seventh rib to the prominence formed by the large bone of the pelvis (*Fig.* III., 6, 6). By these vertical lines the three first regions are still further subdivided in the following manner:—The right and left parts of the Epigastric Region form two distinct regions (7, 7); these are termed the right and left Hypochondriac Regions (7, 7); while the central part retains the name of the Epigastric Region (3). In like manner the right and left parts of the Umbilical Region form two distinct regions (8, 8), which are termed the Lumbar Regions (8, 8), while the central part retains the name of the Umbilical Region (4). Moreover, the right and left parts of the Hypogastric Region are at the same time each divided into two, which are termed the Iliac Regions (9, 9), while the central part is termed the Region of the Pubis (5).

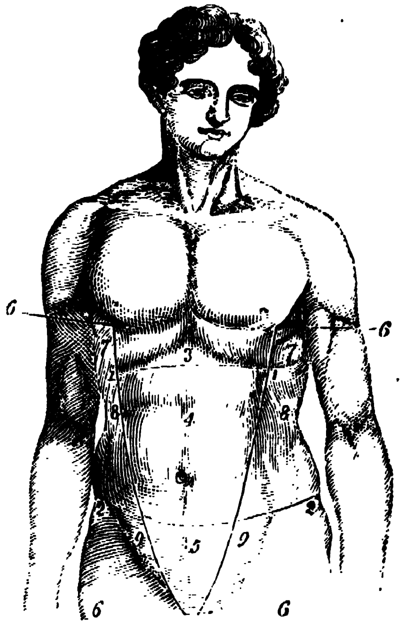

Fig III.

The term *Abdomen*, as applied by entomologists to Insects, has a somewhat different signification from the same term when applied to other animals, being used for the whole portion of the body of an insect behind the corselet (*thorax*), and including the back as well as the belly. It consists, in most cases, of a number of rings without any jointed members for locomotion, and uniformly encloses a portion of the intestines, though sometimes but a very small one. These rings, or very short hollow cylinders, are severally united with each other by a joint, by a membrane, or sometimes by an intimate junction, the exact line of which is not very apparent. The rings in some cases, as in the grub of the chameleon-fly, slide into one another like the tubes of an opera-glass. Each ring is technically termed a segment (*segmentum*), virtually composed of two principal pieces, which, when distinct, are termed arches; the upper the arch of the back, the under the arch of the belly. In some cases these two portions are not distinct, but, when they are so, the two borders usually come into contact. When they do not, but remain free, one usually, more or less overlaps the other, as in bees. In caterpillars, grubs, and wingless insects, such as the flea, where the joining of the corselet with the abdomen is not apparent, the abdomen may always be known by the legs never being jointed with it; and in caterpillars it usually consists of all the body behind the six fore legs, which are always on the corselet.

ABDOMINALES, in Zoology, the name of a group of fishes, to which different naturalists have attached a more or less extensive signification, according to the particular principles of their several systems. The classification of fishes given by Linnæus is founded upon the presence and position of the ventral fins (those of the belly) in relation to the

Salmon, given as a specimen of the family of Abdominales.

pectoral (those of the breast); and these he regards as analogous to the fore and hind members of quadrupeds, and to the wings and feet of birds. Linnæus includes, in his order *Abdominales*, all those species which have the ventral fins placed behind the pectoral, or upon the abdomen, the cartilaginous fishes alone excepted; which, after the example of Ray, Willoughby, and Artedi, he very properly considers as forming an order apart. This arrangement is not now generally adopted, but the term *Abdominales* denotes a family, or subdivision, of malacopterygious (or soft-finned) fishes, only; and, in this restricted sense, includes the greater number of the fresh-water species, as well as those which, like the salmon, periodically migrate from the ocean to deposit their spawn in fresh-water lakes and rivers. M. Cuvier subdivides this family into five subordinate groups, all of which he has defined by appropriate and unequivocal characters. He denominates these sub-families, *Cyprinoïdes*, *Siluroïdes*, *Salmonoïdes*, *Clupeoïdes*, and *Lucioïdes* respectively, from the carps, silures, salmons, herrings, and pikes, the typical genera from which their characters are severally taken.

ABELE TREE, in Botany, the English name of the *Populus alba*. [POPULUS.]

ABELMOSCHUS, in Botany, a genus of the Mallow tribe, usually referred to *Hibiscus*. [HIBISCUS.]

ABERDEVINE (*Carduelis spinus*, Cuvier; *Fringilla ligurina*, Ranzani), sometimes called the Siskin, a well-known song-bird, which has some resemblance to the green variety of the canary-bird, but there is considerable difference in individual birds with respect to the brightness of colouring. The colours of the male in full plumage are as follows: top of the head, black; ear coverts, dusky; a line above the eyes; sides of neck, throat, and chest, lemon yellow; back and shoulders, dark olive green, with obscure dusky dashes; quills, brown, with an oblique yellow bar and another above, produced by the yellow edging of the greater coverts; flanks, dusky, with a few brown dashes; rump, yellow, slightly washed with green; two middle tail feathers, dark brown, the rest yellow, tipped with brown; bill and legs, brown colour. Length, 4¾ inches. Tail, short and forked. The plumage of the female is less bright and decidedly marked.

Aberdevine, or Siskin (*Carduelis spinus*).

Sepp has delineated the nest of the aberdevine in the cleft of an oak, built with dry bent mixed with leaves, and profusely lined with feathers; the base neatly rounded, and the feathers projecting above the rim, and concealing the eggs, which are blueish-white, speckled with purplish red, like those of the goldfinch. Temminck, again, says it builds in the highest branches of the pine.

It breeds in the north of Europe, and only visits Britain, Germany, and France in the autumn and winter. It is represented in some books as very irregular in its migration, particularly to this country; but we suspect that this opinion has arisen from irregular observation, for, since our attention has been directed to the subject, we have remarked its arrival about Lee, in Kent, to be almost as regular as the departure of the swallows, which takes place about the same time. During its winter stay with us, the aberdevine feeds chiefly on the seeds of the birch and alder.

As a cage-bird it is frequently paired with the canary, to produce what are termed mule-birds; but it is, besides, a lively and persevering songster.

ABIES, in Botany (the *Fir*), a genus of trees of the Coniferous tribe, well-known for the valuable timber which is produced by many of the species. It was formerly considered a part of the genus *Pinus*; but modern botanists have made it a distinct genus. The English appellation is the Saxon *furh-wudu*, fir-wood.

Generic Character.

Flowers monœcious.

Males. Catkins simple, solitary, terminal, or axillary. Stamens obtuse, and often callous at the apex, terminated by a jagged membrane.

Females. Catkins somewhat cylindrical; their scales two-flowered, imbricated, and having frequently at their base externally a bractea, which is either very short or lengthened beyond the scales themselves, and terminated by a taper point.

Cones more or less cylindrical; the scales imbricated and woody, but not thickened at the extremity; seeds ending in a membranous wing.

Embryo about the length of the seed, with several closely-packed cotyledons.

Trees of various sizes, usually with a straight, conical, undivided trunk, from which proceed spreading, horizontal, or drooping branches, arranged in a pyramidal manner. Leaves either solitary, or collected in little fascicles, deciduous or evergreen.

From *Pinus* (the Pine-Tree) *Abies* (the Fir-Tree) is obviously distinguished by its more pyramidal form, and by its leaves arising singly from around the stem, not by twos or threes, or a greater number, from out of a membranous shrivelling sheath, as well as by the characters in the fructification above described. Its species form four very natural tribes, of the first of which, the *Silver Fir* may be taken as the representative; of the second, the *Norway Spruce*; of the third, the *Larch*; and of the fourth, the *Cedar of Lebanon*. As most of these are interesting, either for the excellence of their wood or as objects of ornament, we shall briefly notice those that are at present best known. Those who wish for further information should consult Mr. Lambert's 'Monograph of the Genus Pinus,' L. C. Richard's 'Mémoire sur les Conifères,' Michaux's 'Histoire des Arbres Forestiers de l'Amérique Septentrionale,' Loudon's 'Arboretum et Fruticetum Britannicum.'

SECT. I.—SILVER FIRS.

Leaves growing singly round the branches, and all turned towards one side.

Abies Picea, the Silver Fir (*Abies pectinata*, De Candolle; *Pinus Picea*, Linnæus). Leaves arranged like the teeth of a comb, somewhat emarginate, of a whitish colour underneath. Cones erect, with very blunt closely-pressed scales, which are much shorter than the taper-pointed inflexed bracts. It is a native of the mountains of the middle and south of Europe, in stony, dry, exposed situations. Its favourite district seems to be on the Pollino and in the forest of Rubia, in the kingdom of Naples, where it is found in all its grandeur, often growing from 130 to 150 feet in height, and richly meriting the name *pulcherrima* (most beautiful), applied to it by Virgil. This tree is readily known by its leaves having their points all turned towards the sky, and being mealy underneath, as well as by its long, erect, stalkless cones, of a greenish-purple colour, bristling with reflexed taper points of the bracts that subtend the scales. It is the *Sapin*

Silver Fir (*Abies Picea*).

of the French. Planks of indifferent quality, on account of their softness, are sawn from its trunk, which also yields Burgundy pitch and Strasburg turpentine. For its successful cultivation in this country it requires strong land, such as will suit the oak, and a sheltered situation; it will then become a very large tree. From a communication to Mr. Lambert, it appears that trees have been felled which, at 100 years of age, contained six loads, or 240 cubic feet, of timber. It is said by some to grow slowly for the first fifteen years, but afterwards with great rapidity. A plant in Woburn Park is recorded to have grown for 110 years at the rate of one foot in height and nearly three and a half cubic feet per annum. Its trunk sometimes arrives at 150 feet in height, and six feet in diameter.

Antiquarians, not considering that this plant is the real *Abies pulcherrima* of Virgil, and of the Roman authors, have lost themselves in vain attempts to reconcile the declaration of Cæsar ('De Bel. Gal.,' v. 12), that he found in Britain all the trees of Gaul, except the beech and abies, with the well-known fact that fir-wood is abundant in our ancient mosses, and has been met with even beneath the foundations of Roman roads. What Cæsar meant was, no doubt, that he did not meet with the silver fir in Britain. Of the pine he says nothing, and therefore it is to be presumed that he found it.

Abies Sibirica, the Siberian Silver Fir (*Pinus Sibirica* and *Pinus Pichta* of the gardens). Scarcely anything certain has been published of this tree, which, according to Linnæus, Mr. Lambert, and others, is the same as the *Abies picea*. Gmelin describes it as a native of all parts of Siberia as far as 58° N. lat. in mountainous regions, especially in the upper country lying between the Irtish and the Ob, where it forms dense woods.

Abies grandis, Great Californian Fir (*Pinus grandis*, Douglas and Lambert). Leaves long, narrow, very blunt, whitish beneath, all turned one way. Cones oblong, erect, rather curved, with very broad, uneven, downy scales, which are longer than the bracteæ. Found, by Mr. Douglas, in low moist valleys in northern California, where it attains the height of 200 feet. The wood is soft, white, and of inferior quality. Cones from three to four inches long; bracts very short, jagged, two-lobed, with a short intermediate point.

Abies balsamea, the Balm of Gilead Fir (*Abies balsamifera*, Michaux; *Pinus balsamea*, Lambert). Leaves flat, silvery-white beneath, either emarginate or entire at the point, all curved towards the upper side. Cones cylindrical, oblong, erect, purple, with rounded, even, undivided scales. Found, along with *Abies nigra* and *Abies alba*, in the coldest parts of North America, but always in detached individuals, never in large masses. It extends also along the ridge of the Alleghanies as far as the crests of the mountains of North Carolina. It forms a small slender tree, rarely more than 40 feet high, with a diameter of from 12 to 15 inches. The cones are four to five inches long, and about an inch in diameter. Its wood is light, of a pale yellow colour, and but slightly resinous; it is of little value, and is chiefly split up into staves for fish-barrels. The English name has been given in consequence of a resemblance between the clear transparent greenish-yellow turpentine, which is obtained from numerous cysts in its bark, and the Balm of Gilead of the shops. The turpentine is commonly known under the name of Canadian Balsam. In England this is a small tree of very ornamental appearance when young, on the skirts of plantations, but it rarely acquires any considerable size.

Abies nobilis, Large-Bracted Fir (*Pinus nobilis*, Douglas and Lambert). Leaves very numerous, falcate, all turned one way, of nearly the same colour on both sides. Cones oblong, erect, with rounded broad scales concealed by the long wedge-shaped two-lobed jagged scales, which are bent back, and terminate abruptly in a rigid elongated point. It is a majestic tree, forming vast forests upon the mountains of northern California, where it was found by Mr. Douglas. The timber is said to be of excellent quality. The cones are about six inches long.

Abies Frazeri, the Double Balsam Fir (*Pinus Frazeri*, Pursh and Lambert). Leaves linear, emarginate, silvery-white beneath. Cones oblong, squarrose. Bracts somewhat leafy, inversely cordate, mucronate, reflexed. A native of the mountains of Carolina and Pennsylvania.

Abies Webbiana, Webb's Fir (*Pinus Webbiana*, Wallich and Lambert; *Pinus spectabilis*, Lambert). Leaves linear, solitary, flat, all-spreading, and turned one way, silvery-white beneath, with a deep notch at the extremity. Cones oblong, erect, obtuse, with very broad, rounded, even scales. According to the account of Captain Webb, who first discovered it, this remarkable species attains the height of 80 or 90 feet, with a diameter near the ground of 3 or 4 feet. Its wood seems to be valuable. From what has been reported of its general appearance, it is probably one of the most interesting species that has yet been discovered. Inhabiting the colder regions of northern India, and found among plants which are more Siberian in their character than Indian, there can be no reasonable doubt of its being well able to withstand the rigour of the winters of this country.

Abies Canadensis, the Hemlock Spruce Fir (Michaux; *Pinus Canadensis*, Lambert). Leaves flat, arranged irregularly in two rows; when young downy, as well as the young slender branches. Cones very small, ovate, sharp-pointed, with rather acute, even, entire scales: seeds very small.—The most northerly situation in which this tree is found is about Hudson's Bay, in lat. 51°. Near Quebec it forms extensive forests; in Nova Scotia, New Brunswick, Vermont, and the upper part of New Hampshire, it is extremely common; but in the middle and southern states of North America it is confined to the Alleghanies and their dependent ridges, where it inhabits the sides of torrents and the bleakest situations. It is a noble species, rising to the height of 70 or 80 feet, and measuring from 2 to 3 feet in diameter. It appears to be of slow growth, not arriving at its full dimensions in less than 200 years. When from 25 to 30 feet high its form is exceedingly elegant, but when old its huge limbs are apt to be rent and broken by winds and snow; and their naked stumps, sticking out beyond the young and verdant foliage, give the trees an air of decrepitude and decay. The wood is of little value, being neither sound nor durable. The bark is valuable for tanning; mixed with oak-bark, it is said to be much better than oak-bark alone.

Abies Brunoniana, the Deciduous Silver Fir (*Pinus Brunoniana*, Wallich; *P. dumosa*, Lambert). Leaves flat, all turned one way, serrulate towards the points, covered beneath with a milk-white bloom. Cones terminal, erect, ovate, blunt, very small, with lax, ovate, very blunt scales.—Found in the northern parts of India in the provinces of Nepaul, Bootan, and Gossain Than. It is a tree 70 or 80 feet high, with a clear trunk of from 15 to 20 feet, and a spreading very branchy head. The wood is of bad quality, being liable to warp.

Cone of *A. Brunoniana.*

Abies religiosa, the Sacred Mexican Fir (*Pinus religiosa*, Humboldt and Kunth). Young branches quite smooth. Leaves arranged in two rows, sharp-pointed, covered beneath with a glaucous bloom. Found by Humboldt, on the lower hills of Mexico, at an elevation of 4000 feet. Deppe and Schiede found it upon the cold mountains of Orizaba, at the highest limit of arborescent vegetation. It is described as a lofty tree, resembling *Abies picea* and *Abies balsamea*, from which it is distinguished by its sharp-pointed leaves. The flowers are unknown. The branches are used for adorning the churches in Mexico. According to Mr. Lambert, the cones are like those of the cedar of Lebanon, but smaller, and almost black.

Abies hirtella, the Hairy Fir (*Pinus hirtella*, Humboldt and Kunth). Young branches covered with hairs. Leaves arranged in two rows, flat, acute, covered with glaucous bloom beneath. Known only from the incomplete account of Humboldt, who found it on the mountains of Mexico, growing at an elevation of between 8000 and 9000 feet. He describes it as a small tree, three or four times as high as a man.

Abies Smithiana, the Indian Silver Fir (*Pinus Smithiana*, Wallich). Leaves slender, four-cornered, whitish beneath, a little turned towards one side, dark green, from one inch to one and a half long. Cones from four to six inches in length, erect, ovate-oblong, with obovate, rounded, even scales. A native of the slopes of the Himalaya Mountains. It is a tree of enormous size, with nearly opposite branches, covered with short down, and so arranged as to form generally two rows.

Cone of the Indian Silver Fir.

Sect. II. Spruce Firs.

Leaves growing singly round the branches, and all spreading equally.

Abies excelsa, the Norway Spruce Fir (De Candolle; *Pinus abies*, Linnæus). Leaves scattered, somewhat four-cornered, mucronate. Cones cylindrical, pendulous, with blunt, wavy, slightly-toothed scales. It is a native of the mountainous parts of the north of Europe, where it sometimes constitutes, as in Norway, the principal timber. It is found all over Siberia as high as 70° N. lat., in which region it is a certain sign of the presence of springs of fresh water, for it is only seen in moist and springy places. When growing singly in rich soil, separated from other trees, this forms one of the most beautiful objects that can be imagined, with its long drooping branches touching the very ground, and its regularly pyramidal figure: but in other situations, in plantations where the trees are crowded and deprived of their lower branches by want of light and air, it becomes, after nine or ten years, an inelegant plant of little value except to be cut for poles. When in perfection (and occasionally it arrives at its greatest perfection in this country), it acquires a stature of 150 feet. Its wood is of a white colour, of a fine even grain, and very durable: in the market it is known under the name of White Deal or Christiania Deal. In Norway it arrives at maturity in 70 or 80 years. Trees of such an age are what are usually cut down for exportation, and each yields on an average three pieces of timber, eleven or twelve feet long. The Spruce is readily known by its leaves of one uniform dull green colour, spread equally round the branches, and by its long pendant cones.

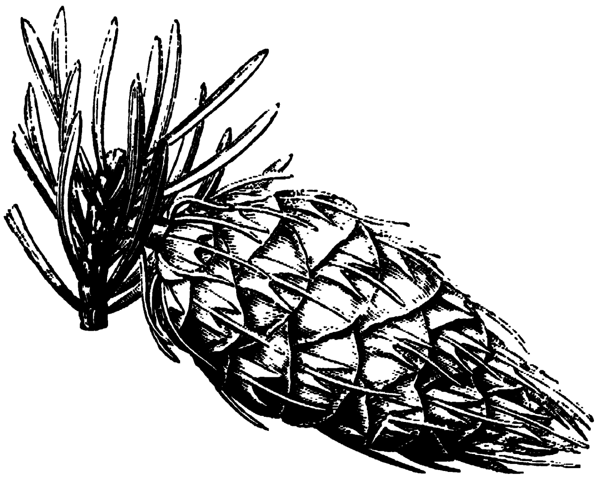
Norway Spruce Fir (*Abies excelsa*).

Abies orientalis, the Oriental Fir (*Pinus orientalis*, Linnæus and Lambert). Leaves very short, uniformly imbricated, quadrangular, with a callous point. Cones ovate, cylindrical, pendulous, their scales somewhat rhomboid. To botanists this is known chiefly by a figure published by Mr. Lambert after a drawing by Aubriet, the draughtsman who accompanied Tournefort in his journey to the Levant. It was found by that traveller in the mountains south-east of Trebisond, above the convent of St. John. It has been subsequently met with by Russian botanists in the woods of Mingrelia, and was seen near Teflis by Sir Gore Ouseley; but little has been added to our knowledge of the species. The young branches are said to be hairy. The leaves are very short and dense. The cones are small and pendulous, of an ovate, tapering figure.

Abies alba, the White Spruce Fir (Michaux; *Pinus alba*, Lambert). Leaves rather glaucous, spreading equally round the branches, four-cornered, somewhat pungent. Cones narrow, oval, tapering towards the point, with even undivided scales. Found along with *Abies nigra* in the colder regions of North America. According to Michaux it does not advance so far to the northward as that species, from which it is known not only by its smaller size, the trunks rarely exceeding 40 or 50 feet in height, but also by the bluish cast which characterises the foliage, and which gives it a much lighter appearance than the sombre *Abies nigra*. Dr. Richardson, however, states that it was the most northerly tree observed in Franklin's first Polar Journey. The timber is of inferior quality. From the fibres of the root, macerated in water, the Canadian Indians prepare the thread with which they sew together the birch-bark that forms their canoes. Its resin is also used to render the seams water-tight. The bark is said to be occasionally used for tanning.

Abies nigra, the Black Spruce Fir (Michaux; *Pinus nigra* and *rubra*, Lambert). Leaves spreading equally round the stem, short, four-cornered. Cones ovate-oblong, obtuse, with ragged rounded scales. It is a native of the most inclement regions of North America, especially in swampy situations and in the valleys between ridges of low hills, where the soil is deep, black, and humid. In such situations are found the finest forests of this species, and there, although the trees are so crowded together as often not to be more than four or five feet apart, the timber arrives at the height of 70 or 80 feet, with a diameter of from 15 to 20 inches. The firs in the landscapes of northern scenery illustrating Franklin's first 'Polar Expedition' are of this species, which, however, Dr. Richardson did not observe higher than 65° N. lat. The trunk is remarkable for the perfect regularity with which it diminishes from the base upwards. The head is of a regularly pyramidal figure, the branches spreading almost horizontally, and not inclining towards the earth, as in the Norway Spruce. The timber is of great value, on account of its strength, lightness, and elasticity. It is employed for the yards of ships; and in America, in districts where the oak is scarce, also for their knees; floors are occasionally laid with it, but it is not well adapted for this usage, as the planks are apt to split. From its young branches is extracted the Essence of Spruce, so well known as a useful antiscorbutic in long voyages. According to Mr. Lambert, the curious Dwarf Spruce, called *Pinus clanbrasiliana*, is probably a variety of *Abies nigra*.

Abies Douglasii, the Douglas Fir (*Pinus taxifolia*, Lambert; *Pinus Douglasii*). Leaves spreading equally, deep green, whitish beneath, obtuse. Cones cernuous, ovate-oblong, with rather uneven cartilaginous scales, much shorter than the bracts, which are three-toothed, the lateral teeth being membranous, with the intermediate ones much longer and more rigid. According to Mr. Douglas, the discoverer of this gigantic species, it is found in immense forests in North-West America from 43° to 52° N. lat. The trunks vary from two to ten feet in diameter, and from 100 to 180 feet in height. Occasionally it arrives at still greater dimensions. It is an evergreen tree, with an erect taper trunk, which when old is covered with a rugged bark from six to nine inches thick, abounding in a clear yellow resin, and making excellent fuel. The young branches have their bark filled with receptacles of resin, as in the Balm of Gilead. The timber is heavy, firm, of as deep a colour as yew, with very few knots, and not in the least liable to warp. The growth is exceedingly rapid.



Cone of Douglas Fir.

A considerable number of plants of this important species are now scattered among the parks and woods of this country, some hundreds having been raised and distributed by the Horticultural Society; it appears to suit this climate perfectly, and to be likely to prove more valuable than even the larch itself, being evergreen, and fully as hardy.

Abies Menziesii, the Menzies Fir (*Pinus Menziesii*, Douglas and Lambert). Leaves very short, rigid, rather sharp-pointed, whitish beneath, spreading regularly round the stem, very deciduous. Cones oblong, composed of very lax, ragged, retuse, ovate, thin scales, much longer than the narrow, serrated, concealed bracteæ. Buds ovate, acute, covered with resin. It is a native of Northern California, where it was found by Mr. Douglas, who describes the wood as being of excellent quality.

SECT. III.—LARCHES.

Leaves growing in clusters; deciduous.

By some botanists this section is considered essentially different from *Abies*; but the want of any clear distinctive characters, either in the mode of growth or the organs of fructification, induces us to concur with Linnæus, Jussieu, and Richard, in considering the Larch as belonging to the same genus as the Spruce. The leaves of the former are clustered or fasciculated, merely in consequence of the universal non-development of lateral branches; so that the leaves themselves make their appearance without a perceptible central axis. This is proved not only in the Cedar of Lebanon, but even in the Larch itself, by numerous cases where the branches being less abortive than usual, lengthen enough to display their real nature.

Abies Larix, Richard; the Common Larch Fir (*Pinus Larix*, Linnæus; *Larix Europæa*, De Candolle). Leaves clustered, deciduous. Cones ovate-oblong, blunt. It is a native of the mountains of the middle of Europe, of Russia, and of Siberia. In the latter country it is the commonest of all trees, delighting in dry elevated situations, where it forms vast forests, sparingly intermixed with pines. Its trunk grows very erect, with graceful drooping branches, gradually diminishing from the base to the apex, and giving it a regularly pyramidal form. In the spring, when its young leaves have just burst into life, it has a peculiar bright yellowish-green tint, which is possessed by no other tree of our forests. The Larch has been now for many years extensively cultivated upon barren exposed land, both in England and Scotland, and it has been found one of the most profitable of all trees to the planter, provided the land be well drained; but it will not succeed in swampy situations. It grows with great rapidity, is subject to very few accidents, transplants with but little risk, and produces timber of great excellence and value, not only for domestic but for naval purposes. In mountainous districts in Scotland the Duke of Athol has planted it in immense quantities; and it appears, from a report of that nobleman to the Horticultural Society, that in situations 1500 to 1600 feet above the level of the sea, he has felled trees, eighty years old, which have each yielded six loads of the finest timber.

The Larch (*Abies Larix*).

From the boiled inner bark, mixed with rye-flour and afterwards buried for a few hours in the snow, the hardy Siberian hunters prepare a sort of leaven, with which they supply the place of common leaven when the latter is destroyed, as it frequently is, by the intense cold to which hunters are exposed in the pursuit of game.

The bark of the Larch is nearly as valuable to the tanner as oak-bark; it also produces the substance called Venice turpentine, which flows in abundance when the lower part of the trunk of old trees is wounded. A sort of manna, called Briançon Manna, is exuded from its leaves in the form of a white flocculent substance, which finally becomes concreted into small lumps.

It is believed that this species was the *πίτυς* of the ancient Greeks. The origin of the more modern word *larix* is uncertain.

Abies microcarpa, the Red Larch Fir (*Pinus microcarpa*, Lambert). Leaves clustered, deciduous. Cones oblong, small; their scales erect, close-pressed, the upper ones much smaller than the lower. This is a graceful tree, with much of the habit of the common Larch, from which its very small cones, of a bright purple in the summer, readily distinguish it. It is a native of North America. This tree is by no means so well adapted to the planter's purposes as the common Larch, growing very much smaller. The wood is so heavy that it will scarcely swim in water.

Abies pendula, the Black Larch Fir (*Pinus pendula*, Lambert). Leaves clustered, deciduous. Cones oblong, with numerous spreading scales, which gradually diminish from the base to the apex of the cones. Branches weak and drooping. It is a native of North America, where it is found growing in a rich clay soil, mixed with sand, in cold mountainous districts. When cultivated in this country it is an elegant tree, having a good deal of resemblance to the common Larch, but being of a brighter green colour, and much more graceful. The leading shoot will often begin to droop at the height of 15 or 20 feet from the ground, and, after gradually acquiring a horizontal direction, will bend towards the earth so as to form a natural arch of great beauty. The wood is less valuable than that of the common Larch.

Sect. IV.—Cedars.

Leaves growing in clusters; evergreen.

Abies Cedrus, the Cedar of Lebanon Fir (*Pinus Cedrus*, Linnæus and Lambert). Leaves clustered, evergreen. Cones oblong, very obtuse, erect, with broad closely-packed scales, which are a little thickened at the margin. Mount Lebanon and the range of Taurus are the native spots of this most stately and magnificent tree, which compensates for its want of height by its huge wide-spreading arms, each of which is almost a tree in itself. According to Labillardière, a French traveller in Syria, the largest of those now remaining on Lebanon is at least nine feet in diameter. The trees are held in great veneration, and a holiday is set apart for the Feast of Cedars. Its growth is far from being so slow as some imagine; on the contrary, the observations of those who have cultivated it with care prove that it will vie in rapidity of growth with almost any forest tree. Cedar-wood has the reputation of being indestructible; instances have been named of its having been taken from buildings uninjured after a lapse of two thousand years. But it appears highly probable, from some interesting observations made at Tangier by Mr. Drummond Hay, that the indestructible cedar-wood was the beautiful, hard, deep-brown timber of *Thuja articulata*, the Sandarac Tree. The wood of *Abies cedrus* produces deal of very indifferent quality.

The Cedar of Lebanon (*Abies Cedrus*).

Abies Deodara, the Sacred Indian Fir (*Pinus Deodara*, Lambert). Leaves evergreen, in clusters, acute, triangular, stiff. Cones growing in pairs, stalked, oval, obtuse, erect: the scales closely packed, very broad, and nearly even at the margin. It is a native of the mountains of Hindustan, near the town of Rohilcund, on the mountains of Nepaul and Tibet, at a height of 10,000 or 12,000 feet, and also in the woods of Almora. It is a large tree, with a trunk about four feet in diameter, resembling the Cedar of Lebanon, from which it differs in having its cones upon stalks, and its leaves longer and more distinctly three-sided, and also in the quality of its timber. The Hindoos are said to call it the Devadara, or God Tree, and hold it in a sort of veneration. Its wood is extremely durable, and so resinous that laths made of it are used for candles. Spars of it have been taken out of Indian temples, known to have been erected from 200 to 400 years, uninjured except in those parts which originally were sap-wood. This tree has been extensively cultivated in England, and seems to be realising the favourable anticipations which were formed on its first introduction.

To the species now enumerated, the following almost unknown kinds have to be added:—

Abies Kæmpferi (*Pinus Kæmpferi*, Lambert). A native of Japan, found wild upon the mountains of Fako.

Abies Thunbergii (*Pinus Thunbergii*, Lambert). A scarce plant in Japan.

Abies Momi (Siebold). Found in Japan, as well as the two following. Its wood is in great estimation for its whiteness and fine grain.

Abies Torano (Siebold).

Abies Araragi (Siebold). Wood brown; used for various domestic purposes.

Cultivation.

The genus of resinous plants called *Abies*, which we have thus described, comprehend many forest trees of great importance; and it will be, therefore, proper to add a few remarks on their cultivation. Some of them, such as the Larch, the Norway Spruce, the Silver Fir, and the Balm of Gilead, are raised in the nurseries annually in the open ground, in large quantities, for the supply of our plantations; others, such as the Cedar of Lebanon and the Douglas Fir, are procured in much less abundance, and are treated with more care, being usually kept in pots until they are finally committed to the earth in the situation they may be subsequently destined to occupy.

All the species are propagated by seeds; they may also be propagated both by inarching and by cuttings; but it is found that plants so obtained are either very shortlived or stunted, unhealthy, and incapable of becoming vigorous trees. In some of the species, such as the Balm of Gilead and the Silver Fir, the scales of the cones readily separate from their axis, so as to render the extraction of the seeds a simple and easy operation; but in others, such as the Larch and the Spruce Fir, the scales will neither separate nor open: in such cases it is necessary to dry the cones as much as possible, then to split them by means of an instrument passed up their axis, and afterwards to thresh the portions so separated till the seeds can be sifted out.

Like other resinous seeds, these are perishable unless sown within a few months after the cones have been gathered; they will, however, keep much longer in the cone than if separated; wherefore, they should always be imported in that state.

It is usual in the nurseries to sow them in the spring in beds of light soil, in which no recent manure has been mixed; they are buried at various depths, according to the force of the vital energy of the species. This has been found by experience, as it is said, to be one inch deep for the Silver Fir; half an inch for the Spruce, Balm of Gilead, and Cedar of Lebanon; a quarter of an inch for the Larch; and less for the American Spruce; it is, however, probable that these depths are of very little importance. In order to protect the surface of the beds from being dried while the young seeds are sprouting, it is generally overspread with a thin layer of long straw, which is removed as soon as the crop begins generally to appear. During the first season the seedlings remain undisturbed; the only attention they receive being to keep them from weeds. In the following spring the young plants are taken up carefully, and their roots, being a little shortened, are imbedded in rows about six inches apart, where they remain for one or two years. After this they are transplanted into quarters, in rows a foot or nine inches apart, the plants being about six inches from each other. Having remained in this situation for a year, they are fit to be transferred to the plantation, or they may stand two years in the nursery quarters, and then be taken up and replaced in a situation of the same kind, if circumstances should render such a proceeding desirable. On no account, however, should they be allowed to remain in the quarters more than two years at a time without being taken out of the ground, because they are apt to form long and strong shoots, which are destroyed in the process of transplantation, so that the life of many must be either materially injured or wholly sacrificed.

None of the firs should be transplanted at a height exceeding three feet, for the reason last mentioned; and the Larch is the only kind that will remove advantageously even at this size. The Spruce and its allied species may be removed more successfully when from a foot and a half to two feet high. To this there is no other exception than that of plants that have been constantly reared in pots, as the Cedar of Lebanon; these may be safely removed at any size, if the transplantation is carefully attended to, because their roots are uninjured in the operation. It should however be remembered, in finally planting out large firs which have been always kept in pots, that it is absolutely necessary that their roots should be spread out among the earth as much as may be practicable without straining or breaking them; because, while in pots, they necessarily acquire a spiral direction, which they will not afterwards lose unless it is destroyed at the period of final transplantation; and, if they do not lose it, they are apt to be blown over by high winds, on account of their roots not having penetrated into the earth far enough in a horizontal direction to form the requisite stay to support the trunk and head.

Where great importance is attached to the raising the seeds of rare species of fir, it has been found a very beneficial practice to place them between two turfs placed root to root, the one upon the other, and to watch them till the seeds begin to sprout; they are then to be sown in the usual way, when every seed will usually succeed.

No trees are more impatient of pruning than these. They exude, when wounded, so large a quantity of their resinous sap as to become weakened even by a few incisions; and, if they have suffered many, they are long before they recover from the effects. So great is their symmetry, and so uniformly will their branches form under favourable circumstances, that it will rarely happen that a necessity for the use of the pruning-knife can arise. The great rule to be observed in their management is to allow them ample room for the extension of their branches; if this is attended to, their beauty is not only ensured, but the rate at which they will form their timber will be a full recompense for the space they may occupy.

ABIETINEÆ. [Coniferæ].

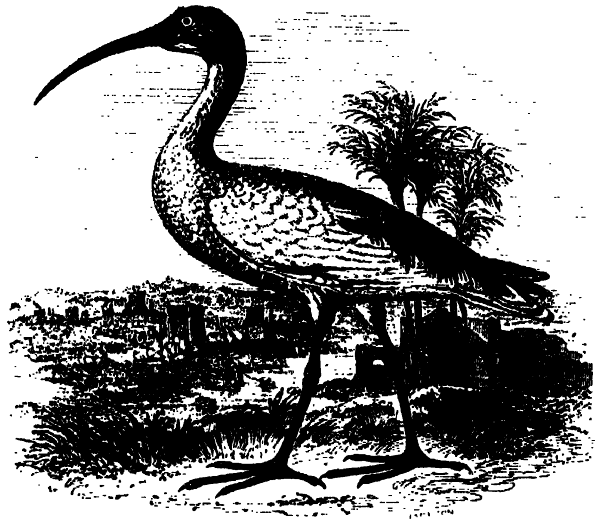
ABOMA, a large species of serpent, which inhabits the fens and morasses of South America, the *Boa cenchria* of Linnæus. [Boa.]

ABORTION, a term used in botany and horticulture. In Botany, abortion is employed to express the absence of an organ in relation to an ideal type. Thus the flowers of *Scrophulariaceæ* and *Lamiaceæ* have their sepals and petals arranged with the number five. According to a very general law the stamense qual in number the petals and sepals, but in this case they do not. In the majority of instances the stamens are but four: hence it is said that one stamen is aborted or there is an abortion of one stamen. The want of harmony between the parts of the flower generally is thus spoken of. In other instances, where the ovules are numerous and the seeds only one, two, or three, the remaining ovules are aborted.

In Horticulture, the premature development of the fruit, or any defect in it, is called abortion.

ABOU-HANNES (*Numenius Ibis*, Cuvier; *Tantalus Æthiopicus*, Latham), an African bird, which has occasioned much discussion among the learned as to its identity with the ancient Ibis. The attention of Bruce was attracted, during his stay in Upper Egypt, by some birds called by the natives Abou-Hannes, whose forms reminded him of the ibis, as represented on Egyptian monuments, and repeated observation confirmed him in the opinion of their identity with the ibis of the ancients. This identity was subsequently corroborated by the distinguished naturalists, Geoffroy and Savigny, who accompanied the French expedition into Egypt, and procured a number of specimens. M. Savigny published his observations in a small work ('L'Histoire Nat. et Mythol. de l'Ibis'), now very scarce, and Baron Cuvier also gave a memoir on the Egyptian ibis in the 'Annales du Muséum' for 1804, in which he has clearly proved, from the comparison of a mummy ibis with a stuffed specimen, that the true ibis is not the *Tantalus Ibis* of Linnæus, that being a much larger bird, but is really a species of curlew. This bird appears to be also a native of regions very remote from Egypt.

Herodotus attributes the veneration of the Egyptians for the ibis, to supposed services rendered them by the bird in freeing their country from winged serpents. That the ibis, however, could not feed upon serpents appears nearly certain from anatomical inspection. The bill, for example, being long, slender, considerably curved, blunt on the edges, and expanded and roundish at the point, could neither divide nor pierce serpents; and indicates rather an aptitude to dabble in marshy and moist grounds.



True White Ibis (*Numenius Ibis*).

On the other hand, Baron Cuvier found, in the mummy of the ibis, remains of the skin and scales of serpents, and hence it has been inferred that the birds might have been serpent-eaters. This inference, however, is at variance with the observations made in Egypt by M. Savigny on a great number of individuals, in the crops of which he uniformly found land and fresh-water shells (*Cyclostomata*, *Ampullariæ*, *Planorbæ*, *&c.*), and these shells were always entire when their inhabitants had not been previously digested.

It does not appear that the ibis breeds in Egypt; but, on the testimony of the inhabitants, it arrives as soon as the waters of the Nile begin to rise, augmenting in numbers as the waters increase, and diminishing as they subside, and disappearing when the inundation terminates. These birds, on their arrival, repair to the low lands, which are first covered with water; but when the waters become deeper and spread wider, the birds betake themselves to the higher lands. They afterwards approach the river, where they establish themselves by the sides of the canals and on the small dykes, with which the greater part of the cultivated grounds are surrounded.

The bird in question sometimes lives solitary, sometimes in small troops of from eight to ten. Its flight is lofty and powerful, and it utters at intervals hoarse cries. When it alights on a fresh piece of land, it remains for hours together occupied in tapping the mud with its bill, in search of worms, &c. It walks leisurely step by step, and has not been observed to run, like our curlew (*Numenius arquata*, Latham), to which it otherwise bears some resemblance.

The Egyptians call the bird *Abou-Menzel*, which literally means

'Father Sickle-Bill,' the bill being curved like a sickle. The Æthiopian name, *Abou-Hannes*, means 'Father-John,' because, as M. Dumont supposes, the birds arrive about St. John's day.

The following is the earliest account that we have of the ibis, from an eye-witness (Herodotus, ii. 76):—"The ibis is all over very black: it has the legs of a crane, and a beak considerably curved: its size is about that of a *crex*. Such is the appearance of the black ibis, which fights against the serpents. But the other ibis, which is more of a domestic bird (for there are two kinds), has the head and all the neck bare of feathers: it is of a white colour, except the head, neck, and the extremities of the wings and tail, all which parts are very black. As to its legs and beak, it resembles the other kind of ibis." The black ibis, according to Herodotus, devoured the winged serpents which yearly attempted to make their entry into Egypt from Arabia. It is needless to add that these winged serpents are a fable. Strabo, who himself was some time in Egypt, gives the following account:—"The ibis is the tamest bird of all: in form and size it is like the stork. But there are two varieties of colour, one of which is that of the stork, and the other is all black. Every street in Alexandria is filled with them, partly to the benefit of the citizens, and partly not. The bird is useful so far as it devours all kinds of vermin, with the garbage of the shambles, and the refuse of the eating-houses, &c." Here Strabo makes no distinction between the two, except in colour, and he describes both species as living on all kinds of garbage. He has probably confounded the real ibis and the stork.

ABOU SCHOM, the Arabic name of a species of fox (*Canis variegatus*.)

ABRAMIS. [Bream.]

ABRAXAS, a genus of nocturnal *Lepidoptera*, to which belongs the common Magpie Moth, *A. grossulariata*. The caterpillar of this moth attacks the leaves of gooseberry and currant bushes at the beginning of the summer. It is of a yellowish white colour, with an orange stripe on each side, and covered with black spots. The chrysalis is black, relieved at its pointed end with orange circles. The expanded fore-wings of the perfect insect measure about one inch and a half across. The wings are of a yellowish white colour, variously spotted with black. The fore-wings have a band of pale orange. The body is orange, spotted with black. The eggs are deposited on currant or gooseberry leaves in July or August, and the caterpillars are hatched in September. To get rid of the attacks of these creatures, they may be picked off, or dusted with the powder of white hellebore, or the leaves of the plants attacked may be burned.

ABRAZITE (*Zeagonite, Gismondine*), a mineral belonging to the group of aluminous hydrated silicates, with alkaline and lime bases. It contains, besides silica and water, about 26 per cent. of alumina, with 14 per cent. of lime and potash.

ABROCOMA. [Habrocoma.]

ABROMA (from *α* and *βρῶμα*, 'not fit for food,' in opposition to *Theobroma*, 'food for gods'), a genus of plants belonging to the natural order *Byttneriaceæ*. The species consist of small trees, with hairy lobed leaves and extra-axillary or terminal few-flowered peduncles at the tops of the branches.

Abroma augusta is a handsome tree, with drooping purple flowers, seated on peduncles opposite the leaves. It is a native of the East Indies. The fibrous tissue of the bark of this plant is manufactured into cordage.

ABRUS (from *αβρός*, soft), a genus of plants belonging to the papilionaceous division of the order *Leguminosæ*. The calyx is bluntly 4-lobed, with the upper lobe broadest. The legume is oblong, compressed, and 4-6-seeded. There is but one species, *A. precatorius*, which is a delicate twining shrub, with abruptly pinnate leaves, bearing many pairs of leaflets. It is a native of the East Indies, but is also found in the tropical parts of Africa and America, where perhaps it has been introduced. The seeds of the commoner variety are red, with a black spot, whilst other varieties produce various coloured seeds. These seeds are in much request as ornaments amongst the inhabitants of the countries where they grow. They are strung as beads, with shells, and other hard seeds. They are brought to Europe from Guinea and the East and West Indies. They are used frequently as beads for rosaries; hence the name *precatorius* given to this species. The leaves and roots of this plant secrete the sweet substance which characterises the liquorice plant (*Glycyrhiza glabra*). In the West Indies it is called Wild Liquorice, and used for the same purposes as the common liquorice. The seeds have been accused of possessing narcotic properties, but this is an error. When swallowed they are very indigestible.

ABSORBENT SYSTEM. The delicate vessels which in the bodies of vertebrate animals are engaged in carrying the food and other matters into the circulation, have this name. It consists of two principal divisions, which may be regarded as two different sets, given off from a common stem. One of these takes its origin in the walls of the alimentary canal, more especially the small intestines, and is called the 'lacteal' system, from the white colour of the liquid it takes up; whilst the other commences in the substance of the body, more especially the skin and neighbouring parts, and is called the 'lymphatic' system, from the colourless fluid, called lymph, which it carries.

The *Lacteals* are the small system of vessels by which the chyle, or nutritive part of the food, is conveyed from the intestines to the left subclavian vein, in which it is mixed with the blood. They have their origin in the villi of the small intestines, which are short hair-like processes, each consisting of a fine net-work of lacteal vessels surrounded by capillary arteries and veins. On the outside the villi are covered with cells, which absorb the chyle before it is conveyed to the loops of the lacteals in the interior of the villus. From the villi the chyle is carried, between the layers of the mesentery, through numberless converging branches, to the thoracic duct, the main trunk of the absorbent system, which, at the part where the chief lacteal branches join it, is dilated into what is called the Receptaculum Chyli. The villi have no visible apertures for the entrance of the chyle, but the walls of the lacteal vessels themselves are extremely thin and permeable, and their canals are furnished with numerous and delicate valves, like those of the veins [Circulation of the Blood], to prevent the fluid which they contain from descending again to their absorbing extremities. In their passage through the mesentery the lacteals traverse numerous mesenteric absorbent glands, where they communicate with veins, and the fluid contained in them is exposed to the influence of the blood, from which it acquires colouring matter and fibrine.

The *Lymphatics* consist of minute branched tubes of extremely delicate membrane, whose extremities are arranged in a more or less dense net-work in every part of the body. From this net-work they gradually converge into a succession of branches of increasing size, and terminate in two main trunks, called the right and left great Lymphatic Veins, through which the lymph is poured with the chyle from the thoracic duct into the right and left subclavian veins. The lymphatics also communicate with the veins at some other parts of their course, chiefly near their minute extremities, and more rarely by larger branches. They have in their interior numerous delicate valves formed of crescentic folds of the lining membrane, like those of the veins and of the lacteals [Circulation of the Blood], and, like them, preventing the retrograde course of the contained fluid. The valves of the lymphatics, however, are much more closely set than those of the veins, so that, when full of fluid, the spaces between them being most distended, they give those vessels a knotted or bearded appearance, by which they are easily distinguished from veins of the same size. In the course of the larger lymphatics there are numerous glands of the same nature as those found in the course of the lacteals. They are called Lymphatic Glands. To each of these there pass two or more lymphatic vessels, which on entering them become extremely tortuous, and after varied convolutions and anastomoses, terminate in nearly the same number of branches, which again pass from the gland, and pursue their course towards the main trunk. These glands attain their fullest development in man and the mammalia. They are far less numerous in birds, and are entirely wanting in the fish and amphibia. The function performed by these glands is somewhat obscure, but it has been recently suggested by Professor Bennett, of Edinburgh, that their function is to prepare or produce the colourless corpuscles of the blood. [Blood.] He arrives at this conclusion from having observed that in cases where these glands or the spleen are inflamed, or in a condition of increased action, that the colourless corpuscles of the blood can be seen under the microscope to be in larger quantity than is normal. (Bennett, *On Leucocythemia*.)

ABSORPTION, one of the first and most essential of the functions of animal and vegetable tissues. Both animals and plants grow and perform other vital functions through the agency of materials derived from without. The passage of all substances from the exterior to the interior of their bodies is effected by the function of absorption. This function is performed in all cases by the aid of animal or vegetable membrane. This membrane is always in the form of the walls of cells or the walls of vessels formed out of cells. Whether the function of absorption be performed in animals or plants, there are certain general conditions of the membrane or cells through which it takes place, that are necessary in all cases. In the first place, as liquids are found to pass through the walls of cells and membranes, it is necessary that they should be permeable. This is found to be the case in all organised bodies, and in proportion to the permeability of the tissue is the activity with which absorption is performed. In certain parts of plants, as well as animals, the cells become almost impermeable, and these are the parts which cease to grow or to perform active functions. Such are the duramen or heart-wood of trees, and the nails, hairs, horns, and teeth of animal bodies.

During the performance of the various functions in which absorption is required, both liquids and gases pass through the cell-membrane or cell-wall. Liquids containing salts in solution pass into the plant and animal in the supply of food for nutrition. Gases, including the vapour of water, are also absorbed by the cells of plants as a nutritive process, and by those of animals during the performance of the respiratory function. This transmission of fluids through organic membranes is sometimes referred to as a peculiar vital property of animal and vegetable tissues; but it seems to depend considerably on the physical properties of the fluids and tissues. Organic membranes, when separated from the living structure, have the power of absorbing fluids, and if two fluids of different densities are separated by a membrane, the flow through the membrane will be greater from the thinner fluid to the thicker than the contrary. This action, which has been called *Endosmosis* [Endosmosis], seems to be a modification of that very general law of attraction by which solids are attracted towards each other, as well as liquids and gases, and which lies at the foundation of those phenomena attributed to capillary attraction. Although it would appear as the result of this law that there must be two currents, the one passing out and the other in, this does not always take place, as the perpetual removal, for the purposes of the system either of the plant or of the animal, of the matter absorbed, prevents the action of the outgoing current, which has been called *Exosmosis*.

The cells and surfaces which carry on absorption in the *Vegetable Kingdom* vary according to the circumstances of the plant. In the simpler plants, such as the lower forms of *Algæ*, which consist of one or only a few cells, the whole of the cells are equally employed in absorbing. But as we ascend to plants where the vegetative and reproductive organs are distinct, there we find absorption performed more abundantly by the former. In the higher forms of phanerogamic plants the active duties of absorption are performed by the roots; the loose tissue at the ends of the fibrils of these organs being remarkably adapted for the performance of this function. The same power is also possessed by the recently formed tissues in the stems of those plants, and thus the food—the sap—is carried from the soil to the branches of the plant, which are covered with leaves. The cells of the leaves are adapted to the exhalation of the fluid which has been absorbed below, and thus a perpetual demand for new supplies is created. Not that the leaves are always exhaling; in moist states of the atmosphere and at night they probably also absorb. This function is also undoubtedly performed by the stems of the leafless *Euphorbiaceæ* and by the *Cactaceæ;* which possess very small roots, and will even grow without them.

Absorption in the *Animal Kingdom,* although performed upon the same general principles, and being adapted to attain the same general ends, presents more various modifications of form and greater complication than in the vegetable kingdom. In the first place, the nature of the fluids taken up differs, more especially in the class of cases where that function is adapted to nutrition. Plants derive their food from the mineral kingdom. Animals obtain their food from plants. Plants live on carbonic acid, ammonia, water, and various salts. Animals live on substances elaborated out of these compounds in the cells of plants. In the next place, animals receive their food into an interior sac or bag called a stomach, whilst plants plunge their absorbent cells into the soil from which they derive their nutriment. In the higher forms of animals, a system of vessels called absorbents [Absorbent System] is made subservient to the ends of the function of absorption—an arrangement which is found nowhere to exist in the vegetable kingdom. In the lower animals, as in the sponges and some of the infusoria, the function of absorption is performed by contiguous cells almost as simply as in plants. In certain parts also of the higher animals, we have absorption carried on in the same way as in the cells of cartilage, and in the contiguous cells of the mucous and cutaneous membranes. In none of the invertebrate animals have we any special absorbent system at all. In the animal kingdom the circulating system has the power of absorption in even a greater degree than the absorbents themselves. From the structure of the walls of the veins, arteries, and capillaries, and the knowledge of the fact that there is constantly passing through them a dense liquid—the blood—we should expect that these organs would offer the necessary conditions for absorption. This has been proved by direct experiment. M.M. Tiedemann and Gmelin found that when such substances as gamboge, madder, camphor, musk, and assafœtida, which are easily detected by their colour and odour, were introduced with the food into the stomach, they were seldom found in the chyle in the time that they had found their way into the blood, and some of them even into the urine. It was also found that if poisonous substances were introduced into the intestines, and secured in one place by two ligatures, and every other part cut away but the artery and vein, they exerted the same influence on the system, and in the same time as usual; whilst if the intestine was treated in the same manner, and all parts cut away but the lacteals, the evidences of absorption were deferred for a much longer period than usual. From these experiments and others it would appear that the lacteals are adapted for receiving only a certain class of compounds, more especially of an oleaginous and albuminous kind.

That part of the absorbent system called Lymphatics were at one time supposed to be engaged in conveying to the blood the used-up matters from all parts of the body preparatory to their final expulsion from the system. The nature, however, of the clear fluid lymph which is contained in them does not support this opinion, and as this lymph has a composition very like to the blood without its red corpuscles; it is inferred that the office of the lymphatics is to assist in the preparation of materials for the blood. These materials being scattered all over those parts of the system on which the lymphatics are distributed, it is to the blood-vessels that the office must be assigned of taking up effete matter, and carrying it into the blood.

That the general cutaneous and mucous surfaces of the body will both exhale and absorb, are well-known facts. The skin, through its perspiriferous glands, which perform their function through the agency of cells, exhales moisture, whilst it is also a powerful absorbent surface. It is proved by direct experiment, that the human hand is capable of imbibing, in a quarter of an hour, an ounce and a half of warm water, which, for the whole body, is at the rate of six or seven pounds per hour. An interesting narrative is on record of a ship's crew who were exposed at sea for several days in an open boat; they had consumed all their water; they had no fluid of any kind which they could drink; they soon began to suffer from thirst; the feeling at length became intolerable, and the drinking of sea-water was found only to increase its intensity. When nearly exhausted, they were exposed, during several hours, to a heavy shower of rain. As soon as their clothes became thoroughly wet their thirst began to abate, and before the rain had ceased their thirst was gone. They did not fail to profit by this experience. From this time each man, as soon as he began to feel thirsty, dipped his shirt in the sea-water and wore it next his skin, which had invariably the effect of removing his thirst, the absorbents taking up the particles of water, but rejecting the saline matter dissolved in it. The mucous surface of the lungs is constantly engaged in throwing off the vapour of water and carbonic acid, and absorbing oxygen gas. It is also through the pulmonary surface that poisons are introduced into the blood, which result in the production of disease, as small-pox, measles, scarlet fever, and others. The different relations of absorbing surfaces to poisonous substances is an interesting subject. Thus, poisons which may be introduced with impunity into the stomach will destroy life when applied to the minutest wound in the skin, as in the case of the poison of venomous serpents, and the Woorara poison. This has been proved not to depend on any decomposition taking place upon the surface of particular membranes, as the Woorara has been introduced into the stomach and bladder, and when rejected has been found to retain its primitive destructive power.

ABUTILON (αβυτιλον, the Greek for mulberry-tree, which the species of this genus resemble), a genus of handsome plants, belonging to the natural order *Malvaceæ.* The species of this genus, amounting to about 80, have been removed from *Sida.* They have a naked five-cleft calyx, with a multifid style, capsular one-celled carpels, 5-30 in a whorl. Several of the species are cultivated in this country. *A. striatum* blossoms freely nearly all the year round, when turned out under a wall in Hampshire. *A. vitifolium, A. venosum, A. rufinerve,* and *A. pæoniflorum,* are also tolerably hardy species. The plant known as Bencao de Deos, in the province of Rio Janeiro, in Brazil, is the *A. esculentum.* It has large purple solitary axillary flowers, which are dressed and eaten with their viands by the inhabitants of Rio. In cultivation the species require a light rich loam and peat-soil, and should be propagated by striking cuttings in sand in a close frame or under a glass in summer.

ACA'CIA, the name of a plant belonging to the order *Leguminosæ,* mentioned by Dioscorides, as a useful astringent thorn, yielding a white transparent gum. The account given by this Greek author, meagre as it is, accords so well with the gum-arabic trees of modern Egypt, that we can scarcely doubt their identity. Accordingly it is to these, and to others closely related to them, that the classical name is still applied.

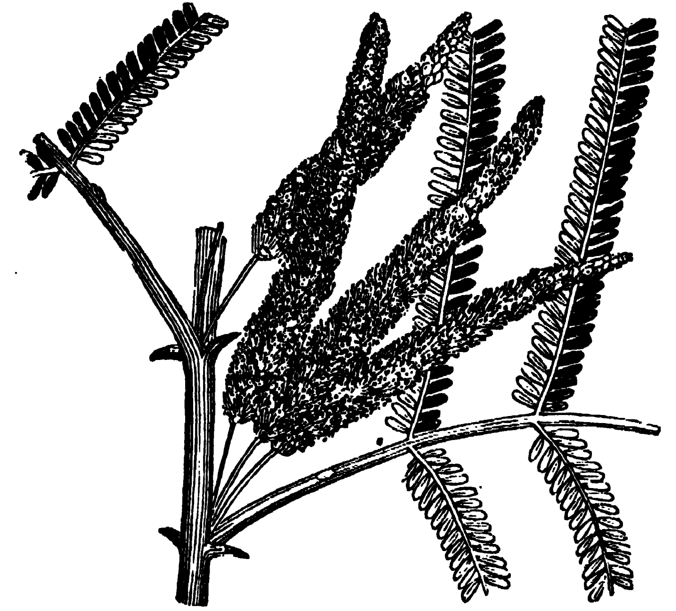
Amongst modern botanists the Acacia is a very extensive genus of trees or shrubby plants, inhabiting the tropical parts of both the Old and New World, and, in a very few instances only, extending into temperate latitudes; although over the whole of Australia, and its dependent islands, the species are spread in much abundance. There are nearly 300 species.

Generic Character.—Flowers polygamous. Calyx, with either four or five teeth. Petals, either four or five; sometimes distinct from each other, sometimes adhering in a monopetalous corolla. Stamens varying in number from 10 to 200. Pod not separating into many joints; juiceless, two valved. The species are extremely variable in the structure of their leaves and flowers. Some of them have true leaves that are twice or thrice pinnate, with a multitude of minute, shining, or at least even, leaflets; others have in a perfect state no leaves properly so called, but in their stead the leaf-stalks enlarge, and assume the appearance, and no doubt also the functions, of true leaves: species of the latter description are known by their spurious leaves being expanded vertically, instead of horizontally as in leaves of the ordinary construction. By these very remarkable points of difference in structure the species may be conveniently separated into two great subdivisions.

I. *Leaves pinnated in various degrees.* About 200 species known.

Acacia Catechu (Wildenow), the Catechu Acacia (*Mimosa catechu,* Linnæus). Spines growing in the place of the stipules; when young, straight, but afterwards becoming hooked. Leaves in ten divisions; leaflets in from 40 to 50 couples, linear, downy; with one depressed gland at the base of the leaf-stalk, and from two to three between the upper divisions. Flowers arranged in cylindrical spikes, which grow two or three together. It is a tree with a tolerably high and stout stem; and is found in mountainous places in the East Indies, especially in Bengal and Coromandel. It is most common in Canara and Bahar. Its unripe pods and wood yield, by decoction, one of the sorts of catechu, or terra-japonica. [Catechu.]

Acacia Arabica (Roxburgh), the Gum-Arabic Tree. Spines growing in pairs. Branches and leaf-stalks downy. Leaves in from four to six divisions; leaflets in from ten to twenty couples, oblong-linear, with a gland between the lowest, and often between the outermost divisions. Heads of flowers growing in threes upon stalks. Pod necklace-shaped. It is an inhabitant of the East Indies, Arabia, and Abyssinia, where it forms a tree 13 or 14 feet high, of inelegant appearance; easily recognised by its long curved pods, which are divided into a number of round compressed joints, by means of contractions between the seeds. This is one of the plants that yield the useful substance called Gum-Arabic, which is procured by wounding the bark; after which the sap runs out, and hardens into transparent lumps, of various figures, very similar to the concretions found upon the bark of the cherry-tree in this country. Gum-Arabic is also produced abundantly by some of the species nearly related to this, such as *A. Nilotica*, or *vera*, found in Egypt; *A. Ehrenbergii*, a native of Dongola; *A. tortilis*, a common plant in the west of Nubia, Kordofan, and Arabia, especially upon Mount Sinai; and *A. Seyal*, an inhabitant of Upper Egypt, Nubia, and western Arabia. It is supposed that Gum-Arabic is collected indifferently from all these, and that the gums of Jidda and Bassorah, Gum-Thur, and East India Gum, are only picked samples. Gum-Senegal is the produce of a distinct species, called *A. Senegal*, found in Arabia and the interior of Africa.



Acacia Catechu.

Acacia Arabica.

Acacia discolor (De Candolle), the Purple-Stemmed Acacia (***Mimosa discolor***, 'Bot. Repository'), has no spines; the leaves have five pairs of pinnæ. It is a middle-sized tree, found in the southern parts of Australia and in Van Diemen's Land, where it, in common with many others of the same genus, is called Wattle. It appears better adapted than most other Australian species to support our winters. Near London it succeeds perfectly well, all winter long, in the open air, if wrapped round with mats, and it is to be presumed that there is no obstacle to its being almost naturalised in Devonshire and Cornwall and the west of Ireland. It is readily known by its bluish stems and leaves, which are slightly stained with dull purple, and form a strong contrast with its long erect bunches of yellow blossoms.

Acacia pubescens ('Hortus Kewensis'), Downy Acacia. No spines. Leaves with from three to ten pairs of pinnæ. It is a native of the east coast of Australia. In this country it is one of the most beautiful of green-house plants. If allowed to grow freely in the border of a good conservatory, it attains the height of 10 or 12 feet; and in January and February produces a vast abundance of yellow blossoms, which weigh down the slender graceful branches, and perfume the air with a weak but pleasant odour.

Acacia Julibrissin (Willdenow), Silk-Tassel Acacia (*Mimosa Julibrissin*, Scopoli). No spines. Leaves with from eight to twelve pairs of pinnæ. It is a native of Persia and of the Levant. Its specific name is Latinised from two Persian words—*gul*, a rose; and *ebruschim*, silk. In the countries where it grows wild it becomes a small tree, remarkable for its light airy foliage, and for the great beauty of the clusters of lilac flowers, the long and slender stamens of which stream in the wind and glitter in the sun, like a number of silken tassels artificially fastened to the boughs. This species is now commonly cultivated in the warmer parts of Europe.

Acacia acanthocarpa (Willdenow), Prickly-Fruited Acacia. Spines, from the place of the stipulæ, growing in pairs, and hooked. Leaves in from six to eight principal divisions. It is a native of Mexico, where it forms a small tree, with flesh-coloured flowers.

The Black Wood of Van Diemen's Land is the timber of *Acacia melanoxylon*; and the astringent Jurema Bark of Brazil is the produce of *Acacia jurema.*

II. *Leaves pinnated in the young plant; in the old, consisting of nothing but the vertically distended leaf-stalks, called Phyllodia.* About 100 species.

Acacia decipiens ('Hortus Kewensis'), Paradoxical Acacia. Stipules spiny, deciduous. Phyllodia either triangular or trapezoidal; their midrib nearest the lowest side, and lengthened into a spine; a single glandular tooth on the upper edge. Flowers in nearly solitary compound heads. This species is remarkable for the blunders to which it has given rise. When botany was only a science of names, its flowerless branches were taken for the leaves of a kind of fern; and, at a later period, when botanical geography was as yet unheard of, it was believed to be a native of the north-west coast of North America. It is an inhabitant of the south-west coast of Australia, where it forms a bush of singular aspect. In this country it is cultivated in the green-house, and it flowers in March, April, and May.

Acacia Sophoræ ('Hortus Kewensis'), Fragrant Acacia. Phyllodia narrow. Heads of flowers in dense slender racemes. Pods long, curved, taper-pointed, a little contracted between the seeds. It is a native of the south side of Australia and of Van Diemen's Land. In this country it is a very ornamental greenhouse plant, which, if planted in the open border, will grow as high as eight feet. Few plants are more worthy of a permanent station in a good conservatory.

Acacia longifolia (Willdenow), Long-Leaved Acacia. Phyllodia of a narrow lanceolate form, tapering to each end. Spikes of flowers axillary, growing in pairs, on short stalks. It is found very commonly on the eastern coast of Australia, especially in the neighbourhood of Port Jackson, whence it was introduced into Great Britain, among the first of the natural productions of that remarkable country.

Cultivation.—The species of this genus are increased artificially in two different ways. Most of them may be multiplied by cuttings struck in silver sand, placed under a bell-glass, and kept in a warm place, to which no direct solar light has access. Such of them, however, as do not increase with sufficient certainty by this method, *A. Julibrissin* for instance, have the power of producing shoots from pieces of their root placed in earth in a hot-bed; and by these the nurserymen generally propagate them. Their seeds also are very often received, and from these they can, of course, be multiplied in all cases.

Fragrant Acacia.

ACACIA, FALSE, or *Locust Tree.* [ROBINIA.]

ACADIOLITE, one of a group of minerals of doubtful identity, composed of nearly 50 per cent. of silica, with alumina, lime, soda, potash, and water.

ACALEPHÆ (from ἀκαλήφη, a nettle), *Sea-Nettles*, a class of marine invertebrate animals, belonging to the sub-kingdom *Radiata*. It is now made to include a large number of animals, of which the genus *Medusa* of Linnæus may be taken as a type.

The genus *Medusa* was placed by Linnæus in the second section of his *Vermes*, viz. *Mollusca*. The *Mollusca* were divided into six sections in the 'Systema Naturæ;' and in the last of those, consisting of those molluscous forms which had a central mouth below, *Medusa* stood as the first genus, followed by *Asterias* and *Echinus*. The third section of *Vermes* (*Testacea*), with *Chiton* at its head, immediately followed. In this arrangement *Medusa* came between *Nereis* and *Asterias*; but in the body of the work it stands between *Sepia* and *Asterias*.

The following is the Linnæan definition of the genus *Medusa* :—

Body gelatinous, orbiculate, depressed. Mouth beneath, central.

The genus contained 12 species, and these consisted not only of true *Medusæ*, but of such genera as *Porpita* and *Velella*.

The *Acalephæ* of Cuvier (his third class of *Zoophytes*) comprehend, to use his own terms, Zoophytes which swim in the sea, and in whose organization may be perceived vessels, which in truth are most frequently nothing but productions of the intestines, hollowed in the parenchyma of the body.

Cuvier's first order of *Acalephæ*, or *Sea-Nettles*, consists of the *Simple Acalephæ*, which he characterises as floating and swimming in the sea by means of the contractions and dilatations of their body, their substance being gelatinous, without apparent fibres. The sort of vessels which are seen in some are hollowed in the gelatinous substance; they often visibly come from the stomach, and do not give place to a true circulation.

The genera contained in this order are the great genus *Medusa*, Linn., with its subgenera *Porpita* and *Velella*.

The great genus *Medusa* is characterised as having a disk more or less convex above, similar to that of a mushroom, and called the *umbrella*. Its contractions and dilatations concur to the motivity of the animal. The edges of this umbrella, as well as the mouth, or the suckers, more or less prolonged into pedicles, which take its place, in the middle of the lower surface, are furnished with tentacles of very different form and size. These different degrees of complication have given rise to very numerous divisions.

The *Arachnodermata* form the second class of M. de Blainville's *Actinozoaria*. He observes that this class corresponds exactly to the genus *Medusa* of Linnæus.

The following is M. de Blainville's definition of this genus :—

Body free, regularly oval or circular, subgelatinous, covered with an extremely fine skin, which is but little or not at all distinct, sustained or not by a solid subcartilaginous part, and provided with very diversiform radiated appendages.

Intestinal canal limited to the stomach, and provided with a single orifice.

Ovaries multiplied, radiated, and opening in the interior of the stomach.

M. de Blainville goes on to state that their form, which is regular, is nearly always circular (the *Velellæ* alone being oval), sometimes discoid or spheroidal, but most frequently hemispherical, which causes them to resemble our umbrellas, and has given rise to the distinction of their body by that name. This body is sometimes furnished in addition, in its circumference, with more or less long cirrhi, to which the name of tentacles, or better, of tentaculiform cirrhi, has been given.

The lower surface of the umbrella, he observes, is sometimes entirely naked, but in other cases is provided with numerous and dispersed tentaculiform suckers, as in the *Porpitæ* and *Velellæ*, or else with very diversiform appendages, capillaceous at least at their extremity, which zoologists have termed arms, whence the denomination of *Brachideous* which they have given to some species. These appendages or arms are sometimes free from their base, but in other cases are united, which unity produces a sort of peduncle, which has originated the designation of *Pedunculated* for those species that are so provided. In the middle of the lower surface of the umbrella of these *Medusæ* is sometimes a species of peduncle formed by a proboscidiform prolongation of the buccal orifice, and they are then called *Proboscideous*; but in the greater number of cases, the middle of the lower part of the umbrella is occupied by a more or less considerable mass, attaching itself to the body by four roots, in the form of a cross, so as to divide the buccal orifice into four semilunar parts. This peduncle, terminated by more or less numerous capillaceous divisions, has caused the name of *Pedunculated*, or *Polystomatous*, to be applied to those *Medusæ* which are provided with it.

The first subdivisions of the *Arachnodermata* established by M. de Blainville depends on the existence or absence of a solid piece for the support of the umbrella or body of the animal, and consists of the *Cirrhigrada*, which are provided with that support, and of the *Pulmograda*, which are without any such support. These orders, observes M. de Blainville, are further distinguished by the very different nature of the appendages with which the umbrella is furnished on the buccal surface.

The difficulty of examining the *Acalephæ* is, from the very nature of their texture, considerable, and that of preserving them in spirit great. It is not, then, to be wondered at that a great portion of their organization remained for a long time in obscurity, and that much relating to it still remains to be cleared up. To observe them with anything like a satisfactory result, they must be studied on the spot, and while they are alive; and thus it is that several points relative to their organization and habits, and their generation especially, have only lately been cleared up. The possibility of fairly preserving them in spirit is shown in the museum of the Royal College of Surgeons in London, where, in the department comprehending the first division of the Preparations of Nat. Hist., in spirit, several of the Acalephans, (No. 64 to 73 A, both inclusive) are to be seen so preserved. In the following remarks the structure of the typical *Medusæ* will be more especially referred to.

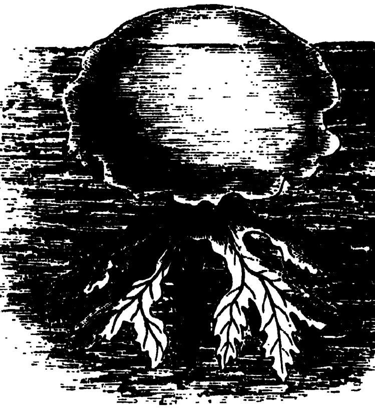
The disk presents a uniform cellular appearance internally, and the cellular substance is very soft. In its mass no fibre has hitherto, we believe, been traced, and indeed the quantity of solid matter in the whole animal must be very small. Those who have taken *Medusæ* out of the sea, and laid them upon a dry board or dry stone, must have observed how soon they sink into a sort of deliquescence. Spallanzani came to the conclusion that the sea-water penetrating the organic texture constitutes the greater part of the volume in the *Medusæ*, some of which when newly taken out of the sea weighed 50 ounces, though their dried remains gave a weight of little more than 5 or 6 grains. A fine muscular membrane appearing, when examined with a magnifying glass, to be composed of numerous fleshy fibres disposed in small bundles, radiating as regards the axis of the *Medusa*, and adhering closely to the gelatinous substance of the disk, may be seen in some species stretching over a given extent of the lower surface of the umbrella, a little within its outer margin. Portions of the disk, or umbrella, have been cut from these animals whilst they were alive: those portions which had no part of this muscular membrane attached to them exhibited no signs of motion; in those, on the other hand, whose connection with the muscular membrane was preserved, the reciprocal contraction and dilatation were continued for some time. Those *Pulmograda* which have cilia around their margins have also circular vessels running along their bases, and most of the projectile and extensile tentacles and filaments have sacs and canals with contained fluids at their roots. If these cilia may be regarded, and they doubtless may be, as one of the causes, and a principal one, of locomotion, the pensile tentacles of the *Medusæ* may be viewed as ancillary at least to that faculty, though they probably are principally employed as nutrient organs. They are hollow and simple, and appear to increase in their extensibility in proportion to their connexion with the appendages of the digestive cavities, or when furnished with a vesicle at their base. Suckers are found at the extremities and along the sides of these tentacles in several of the genera, so as to enable them more securely to catch the floating destined prey, or to assist in anchoring the *Medusa* when it would rest, as we have reason to believe it occasionally does.

Nervous System and Senses.—We are not aware of any quite satisfactory demonstration of a nervous system in the Acalephans. Dr. Grant indeed ('Zool. Trans.,' vol. i.) notices a structure in *Cydippe* which in his opinion can only belong to that system; but Eschscholtz, whose labours in investigating the organization of this class were not small, failed to discover nerves in the largest which he examined. That they enjoy sight has been a question. Ehrenberg has endeavoured to show that *Medusa aurita* possesses eyes in the form of small red points visible on the surface of the eight brown masses which are round the circumference of the umbrella; and he has compared these so-called eyes to those of certain *Rotifera* and *Entomostraca*. He considers the glandular body at the base of the pedicle to be an optic ganglion, and notices its connection with two filaments that decussate about the middle of their course; and he views these as constituting part of a nervous circle, situated, for the greater part of its extent, directly along the bases of the row of tentacles surrounding the umbrella, and so forming a sort of outer wall of the circular vessel or appendage of the intestinal cavity which runs round the margin of the umbrella. He also describes another nervous circle, formed of four ganglion-like masses. These he states to be disposed round the mouth, and to be each connected with a corresponding group of tentacles.

But the general opinion seems to be that touch is the only sense possessed by the Acalephans, as far as proof has hitherto gone. That they are sensible to light, though the evidence in favour of their possessing sight properly so called may not be deemed conclusive, will be generally admitted. It is said that some of the smaller tribes have been known to shun a bright light, and to sink into deep water to avoid it.

The chief seat of the touch appears to be in the tentacula and cirrhi with which the majority of Acalephans are furnished. Many of them, as we have ourselves observed, make no sign when wounded extensively in the umbrella or disk.

Muscular System.—In most of the species of *Pulmograde Medusæ* distinct muscular fibres exist, which present the peculiar markings observed on the fibres of voluntary muscles. Where these cannot be seen, tissue consisting of a granular substance exists which possesses the peculiar power of contraction. Professor E. Forbes says, that he has "paralysed one side of a *Rhizostoma Aldroandi*, whose disk measured more than a foot across, by removing with a scalpel the bands of that half, whilst the other side contracted and expanded as usual though with more rapidity, as if the animal were alarmed or suffering." The tentacles of most species are capable of wonderful extension and retraction, movements which must be effected by means of muscular tissue.



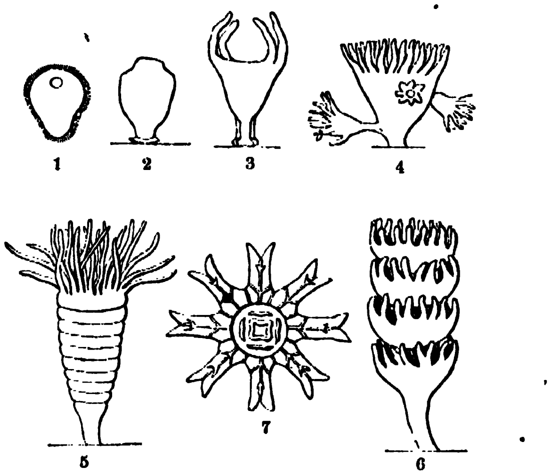
Rhizostoma cerulea (Cuvier).

Food and Digestion.—The food, small fishes and marine animals, both living and dead, is probably conveyed to the mouth not only by the tentacles and cirrhi with which the greater part of the *Medusæ* are furnished, but also by contractions in the umbrella or disk itself. Fishes of some size have been found dead and entangled in the tentacles of *Medusæ*, killed most probably by that benumbing or stinging quality which has obtained for them the name of Sea-Nettles. Professor E. Forbes, speaking of the habits of *Sarsia tubulosa*, says, "being kept in a jar of salt water with small crustacea they devoured these animals, so much more highly organised than themselves, voraciously, apparently enjoying the destruction of the unfortunate members of the upper classes with a truly democratic relish. One of them even attacked and commenced the swallowing of a *Lizzia octopunctata*, quite as good a Medusa as itself. An animal which can pout out its mouth twice the length of its body, and stretch its stomach to corresponding dimensions, must indeed be 'a triton among the minnows,' and a very terrific one too."

By the investigations of M. Milne-Edwards principally, we now know that all the *Pulmograda* have gastric cavities, but all have not mouths in the ordinary acceptation of the word. In *Rhizostoma*, for instance, the only communication between the stomach and the outer surface is carried on through numerous branching canals in the pensile arms. In most cases a system of vessels is observed proceeding directly from the stomach, partly nutritive and partly respiratory, but there does not appear to be any distinct blood-vessels. From the recent researches of Frey, Leuckhart, and E. Forbes, it does not appear that any special blood-fluid exists amongst the species they have examined.

Reproductive System and Development.—The majority of the Acalephæ have very distinct reproductive glands. In the *Pulmograda* they are placed either on the surface of the sub-umbrella, or on the inner and upper part of the cavity of the peduncle. In most cases these animals appear to be bisexual, though the two sexes are often united in the same individual; but Milne-Edwards, Wagner, and Will have observed individuals with sperm-cells only, and with germ-cells only. Although probably in all cases reproduction takes place by conjunction of those cells, the *Medusæ*, like some other lower animals, have the power of producing their offspring by germination. This fact was first made known by Sars in 1836. Professor E. Forbes, in his great work on the British Naked-Eyed Medusæ, says, "I have observed four modes of propagation by germination among the Medusæ. 1. Germination from the ovaries, as observed by Sars. 2. Germination from the peduncular stomach. 3. Germination from the walls of a tubular proboscis. 4. Germination from the bases or tubercles of the four marginal tentacles in *Sarsia prolifera*." In order to suggest the nature of this mode of reproduction, Forbes has the following passage:—"What strange and wondrous changes! Fancy an elephant with a number of little elephants sprouting from his shoulders and thighs, bunches of tusked monsters hanging epaulette-fashion from his flanks in every stage of advancement. Here a young pachyderm almost amorphous, there one more advanced, but all ears and eyes; on the right shoulder a youthful Chuny, with head, trunk, toes, no legs, and a shapeless body; on the left, an infant better grown, and struggling to get away, but his tail not sufficiently organised as yet to permit of liberty and free action! The comparison seems grotesque and absurd, but it really expresses what we have been describing as actually occurring among our Naked-Eyed Medusæ!"

The history of the development of the ova is not less interesting. When first produced they are retained in the interior of the creature until they are covered with cilia, when they pass out, and are found in the water resembling *fig.* 1. In the course of a little time it attaches itself to some fixed object, and then puts out four arms. In the first stage we have an infusorial animalcule; in the next, *fig.* 2, we have a rotifer or hydroid polype. Not only have we the resemblance to, but some of these forms have been shewn by Steenstrup ('Alternation of Generations') to have been mistaken for permanent states of other animals. The first four arms are succeeded by four more, *fig.* 3: at this stage germs or buds frequently grow from its side, *fig.* 4: the polypiform body then lengthens, and at last becomes wrinkled, *fig.* 5: depressions appear, and the elongated body is cut up into a series of horizontal slices, from the edges of which tentacles grow, *fig.* 6: each layer escapes, and presents itself in the form of a young Medusa, *fig.* 7. Such is the history given by Steenstrup, in one of the common forms of Pulmograde Medusæ, and such with modifications appear to be the changes which each ovum of the Medusa passes through before it becomes a fully developed animal.



Power of Stinging.—The name *Acalephæ*, Sea-Nettles, suggests this property. It is not, however, improbable that this function is possessed only by a few species. Some possess this property in a remarkable degree, as the *Cyanea capillata*, which is a terror to bathers in our seas. At most two or three others possess it in relation to the human skin. It is probable they exert greater power over their prey or their enemies amongst the lower classes. The stinging power is supposed to reside in small capsular hairs, which are found in the tissues of the *Acalephæ* as well as in *Actiniæ* and other polypes.

Phosphorescence.—On whatever property this phenomenon depends, there is no doubt that it is possessed in a high degree by almost every species of *Medusæ*. The circumstances, however, on which it depends seem to be little known. On some occasions the *Acalephæ* with other marine creatures will give out abundance of light, whilst at other times not a glimmer can be observed.

The *Acalephæ* have been divided into four families: the *Pulmograda*, the *Ciliograda*, the *Cirrhigrada*, and the *Physograda*. The following is the arrangement of the *Pulmograda* given by M. de Blainville, who, by intercalating the genera of Péron and Lesueur, and of Eschscholtz, the existence of which he is far from guaranteeing, gives us the following synoptic table:—

PULMOGRADA, OR MEDUSARIA.

SECT. I.—*Simple.*

Genera: *Eudora, Ephyra, Phorcynia, Eulymene, Charybdæa.*

SECT. II.—*Tentaculated.*

Genera: *Berenice, Æquorea, Mesonema, Polixena, Ægina, Cunina, Foveolia, Eurybia, Pegasia, Obelia.*

SECT. III.—*Sub-Proboscidean.*

Genera: *Oceania, Aglaura, Melicerte, Cytacis, Thaumantias, Tima, Campanella.*

SECT. IV.—*Proboscidean.*

Genera: *Orithyia, Geryonia, Saphenia, Dianæa, Linuche, Favonia, Lymnorea, Sthenonia.*

SECT. V.—*Brachideous* and *Pedunculated.*

Genera: *Ocyröe, Cassiopea, Aurelia, Melitæa, Eragora, Cephæa, Rhizostoma, Chrysaora, Pelagia.*

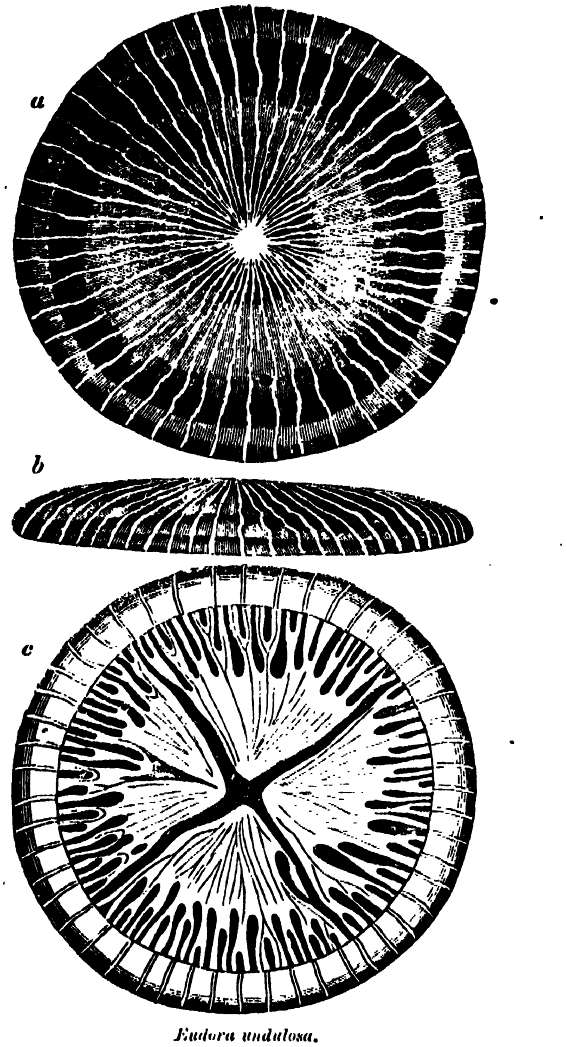
We now proceed to lay before the reader examples of these several sections.

Section I.

Eudora.

Generic Character.—Body very much depressed, discoïd, simple, without tentacular cirrhi, without either peduncles or appendages, and offering within only ramified canals opening (s'abouchant) by four large trunks, in the form of a cross, into a small central cavity without external aperture.

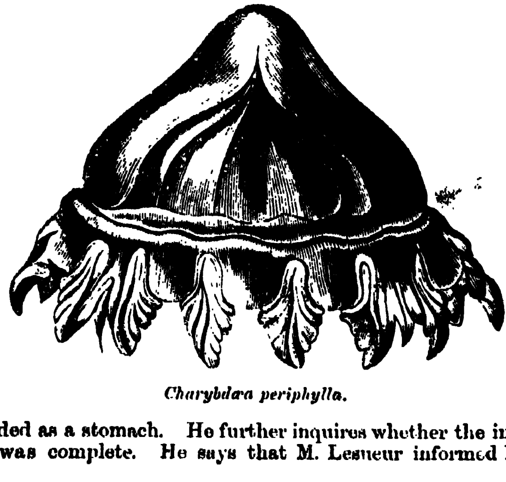
Example, *Eudora undulosa* (Péron and Lesueur).



Eudora undulosa.

a, view of the upper side; *b*, in profile, or with the edge of its disk towards the spectator; *c*, view of the lower side.

M. de Blainville remarks that he only knows this genus from the characteristic and short description given by Péron and Lesueur. He doubts whether this Medusa has not a mouth; for he thinks that the centre of the reunion of the four large trunks of the canals ought to be regarded as a stomach. He further inquires whether the individual figured was complete. He says that M. Lesueur informed him that there was a membrane on the lower surface, and he inquires whether this was not perhaps some remains of the stomachal cavity.



Charybdæa periphylla.

Cuvier united this genus with the *Geryoniæ*. Eschscholtz places it in his family *Berenicidæ*, and unites *Euryale* with it.

Charybdæa.

Generic Character.—Body hemispherical, sub-conical, or even semi-elliptical, furnished on its circumference with foliaceous subtentacular lobes, hollowed below by a great stomachal excavation with an aperture as large as itself.

Example, *Charybdæa periphylla* (Pér. and Les.).

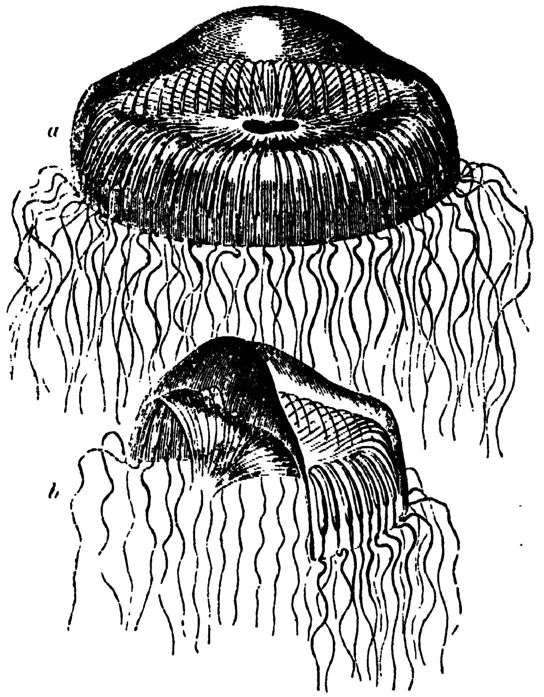
Section II.

Æquorea.

Generic Character.—Body slightly diversiform, furnished at its circumference with a circle of filamentous tentacular cirrhi, often very long, and more or less numerous, a good deal excavated below, with a median orifice often at the extremity of a sort of circular lip, which is more or less projecting or provided with tentacular fringes. Stomachal appendages linear, numerous, or sacciform and not numerous.

Example, *Æquorea cyanea* (Pér. and Les.).

Habitat.—South Seas.



Æquorea cyanea.

a, the animal complete; *b*, a portion thereof.

M. de Blainville divides this genus into the following sections:—

*

Marginal cirrhi very numerous; stomachal appendages equally numerous and linear.

A. Lip simple.
Genus *Æquorea.*
B. Lip fringed.
Genus *Mesonema.* (Esch.)

* *

Marginal cirrhi as well as the stomachal appendages sufficiently numerous, or not numerous.

C. Cirrhi sufficiently numerous, originating opposite to the triangular stomachal appendages.
Genus *Polyxena.* (Esch.)
D. Cirrhi and sacciform stomachal appendages few.
Genus *Ægina.* (Esch.)

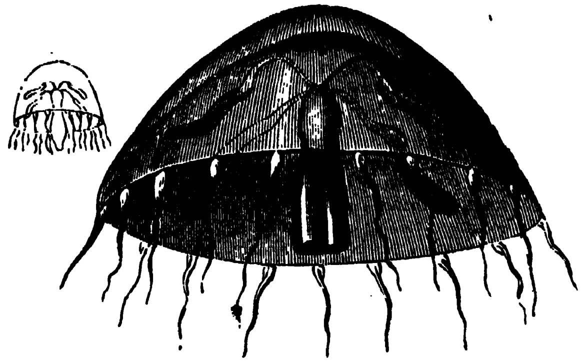
We have selected a genus of the first subdivision for illustration.

Section III.

Thaumantias.

Generic Character.—Body hemispherical, provided at its circumference with tentaculiform cirrhi which are bulbous at the root; very much excavated beneath, and having in its middle a free pedunculiform stomachal cavity dividing itself into claviform canals, and terminated by a simple buccal orifice.

Example, *Thaumantias cymbaloïdea.* (*Med. cym.* Slabber.; *Dianæa, cymb.*, Lam.)

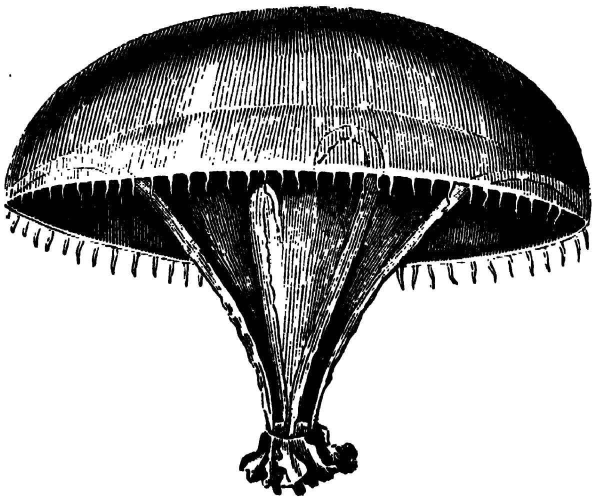


Thaumantias cymbaloïdea.

Placed by Péron among his *Oceaniæ.*
Habitat.—Coasts of Europe; Holland.

Tima.

Generic Character.—Body hemispherical, depressed, furnished on its circumference with a circle of tentaculiform cirrhi, which are short and numerous; not much excavated beneath, and prolonged into a very thick conic peduncle, which is entirely exserted, and terminated by a plicated enlargement; buccal orifice at the centre of four labial appendages; stomachal cavity in the enlargement of the peduncle, and giving origin to four ascending canals, and communicating with a marginal canal.



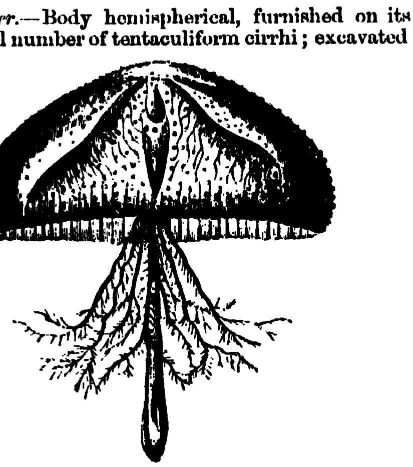
Tima flavilabris.

Example, *Tima flavilabris.*
Habitat.—The Azores.

SECTION IV.

Dianæa (Quoy and Gaim.)

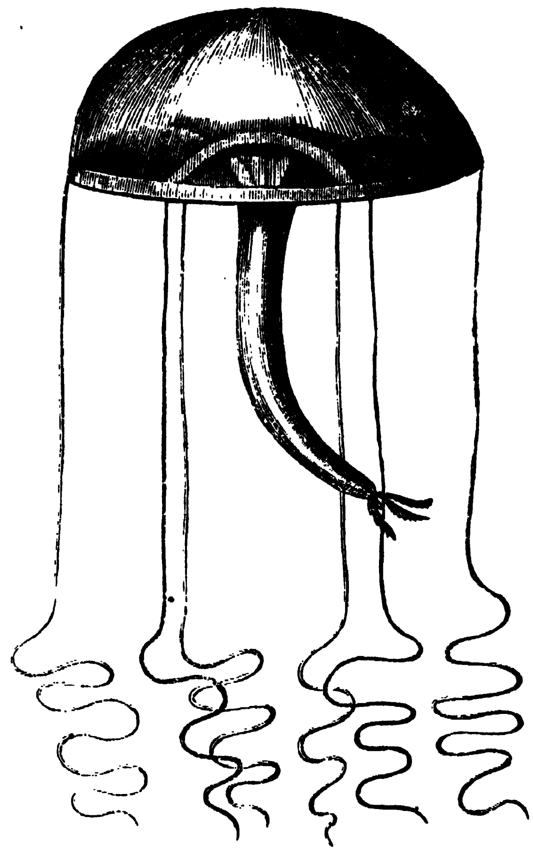
Generic Character.—Body hemispherical, furnished on its circumference with a small number of tentaculiform cirrhi; excavated beneath, and provided at its middle with a strong exserted proboscidiform appendage, with four brachideous appendages at its extremity.



Favonia octonema.

Favonia.

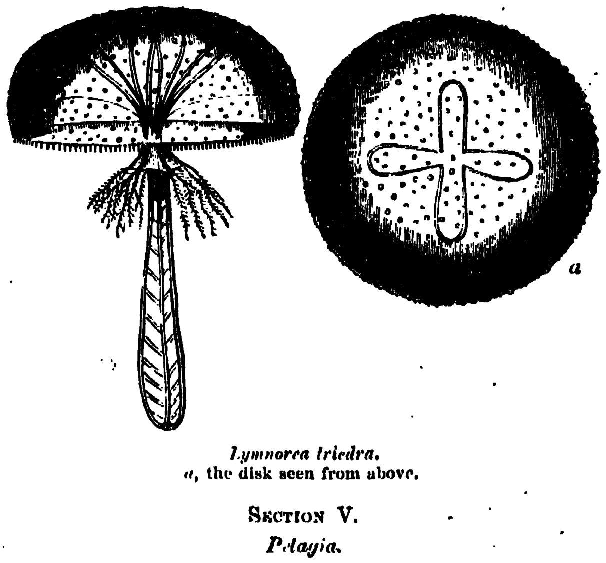
Generic Character.—Body subhemispherical, with neither cirrhi nor tentaculiform marginal cilia; rather deeply excavated beneath, with a long, median, proboscidiform prolongation, having at its root six or eight brachideous appendages, furnished with radiciform suckers. Four ovaries.
Example, *Favonia Octonema.* (*Orithyia Octonema,* Lam.)
Habitat.—South Seas.



Dianæa.

Lymnorea.

Generic Character.—Body subhemispherical, furnished on its circumference with very fine, short, and numerous tentacular cilia; rather deeply excavated beneath, and provided with a long proboscidiform prolongation, having at its base eight bifid and finely divided appendages. Four ovaries, in the form of a cross.
Example, *Lymnorea triedra.* (*Dianæa triedra,* Lam.)
Habitat.—South Seas.



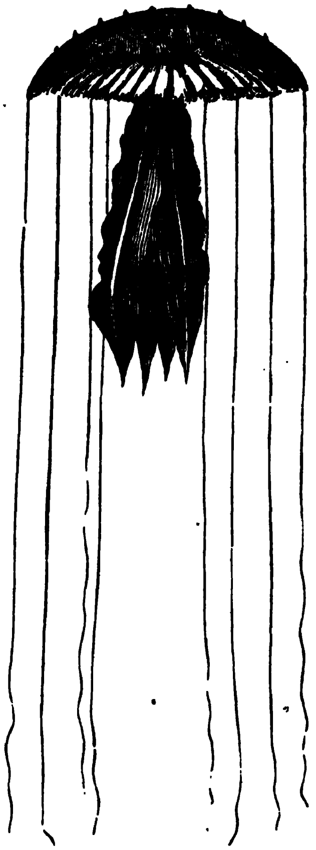
Lymnorea triedra.
a, the disk seen from above.

SECTION V.

Pelagia.

Generic Character.—Body subhemispherical, lobated, auriculated, furnished on its circumference with a few tentaculiform cirrhi; eight inferior apertures at the extremity of a fistulous peduncle provided with four very strong and foliaceous arms. Four ovaries. Stomach with cæciform appendages.

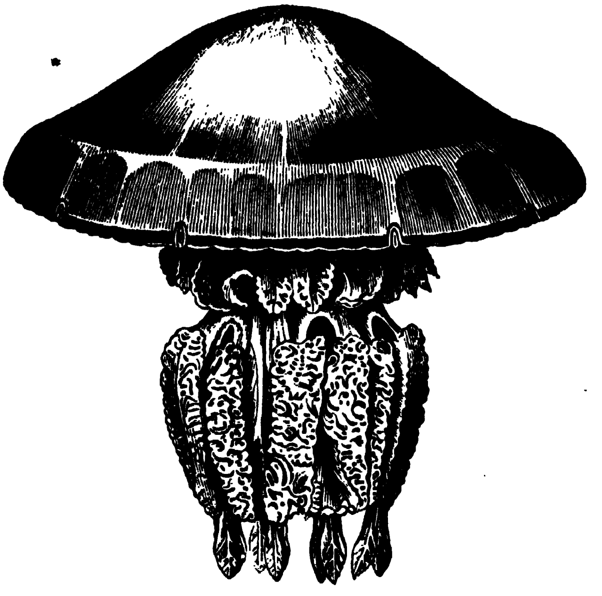
Example, *Pelagia Labiche*, Esch. (*Cyanea Labiche*, Quoy and Gaim.)



Pelagia Labiche.

Rhizostoma.

Generic Character.—Body circular, hemispherical, provided on its circumference with lobes or festoons intermingled with auricles, largely excavated below, with four semilunar orifices, produced by four roots of insertion of a considerable pedunculated mass, afterwards divided into eight very complex brachideous appendages furnished with fibrillary suckers, without a median prolongation. Four ovaries, in the shape of a cross. Stomachal cavity very large and vascular at its circumference.



Rhizostoma Cuvieri.

Example, *Rhizostoma Cuvieri.*

Habitat.—European Seas.

M. de Blainville separates the genus into two divisions.

A.

Species having a peduncle of insertion for the root, with radical appendages, besides those of the arms.

B.

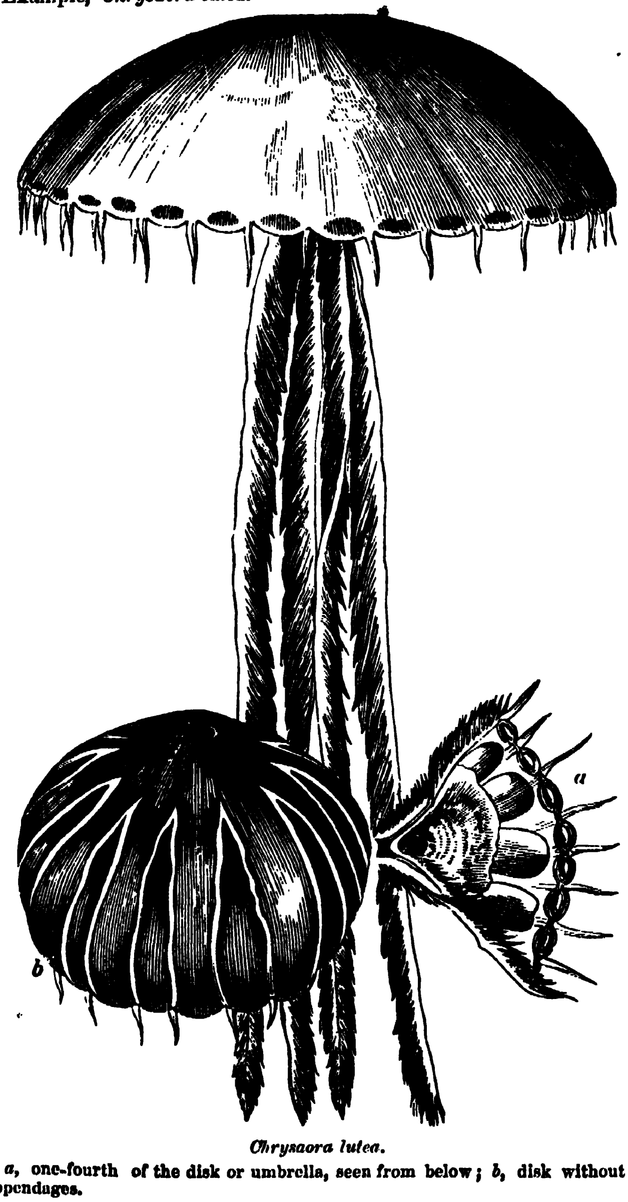
Species having a very short peduncle of insertion, without radical appendages, besides the four bifid arms. (*Evagora*, Pér.)

We have given an illustration of the first. The species grows to a very large size.

Chrysaora.

Generic Character.—Body circular, hemispherical, festooned, and provided with at least twenty-four tentaculiform cirrhi on its circumference; excavated internally into a considerable cavity with sacciform appendages; communicating externally by a single orifice, pierced in the centre of a median peduncle, provided with distinct brachideous appendages. Four ovaries.

Example, *Chrysaora lutea.*



Chrysaora lutea.

a, one-fourth of the disk or umbrella, seen from below; *b*, disk without its appendages.

The Pulmograde Medusæ have been recently studied with great care by Professor E. Forbes, and he proposes to divide them into two groups according as their eyes or ocelli are covered or destitute of this protection. When any of the more common forms of *Medusæ* are examined, as the species of *Rhizostoma* or *Pelagia*, it will be found that the margins of the ocelli are protected by more or less complicated membranes, hoods, or lobed coverings. This character accompanies another of great importance, that is, the possession of a complicated anastomosis and ramification of the vessels. In the case of *Thaumantias* and other genera it will be found that the ocelli are either absent or entirely naked, and this condition is accompanied with a very simple vascular system. Hence Professor Forbes proposes the following classification.

I. Steganopthalmata (*στεγανός, covered*).

Genera. *Aurelia*, Péron; *Medusa*, Eschscholtz; *Pelagia*, Péron and

Lesueur; *Chrysaora*, Péron; *Rhizostoma*, Cuvier; *Cassiopea*, Péron; *Cyanea*, Péron.

II. GYMNOPHTHALMATA (γυμνός, *naked*).

1. Vessels branched (*Willsiadæ*).
Genus. *Willsia*, Forbes.

2. Vessels simple. Ovaries convoluted, and lining the pedunculated stomach (*Oceanidæ*).
Genera. *Turris*, Lesson; *Saphenia*, Eschscholtz; *Oceania*, Péron.

3. Vessels simple, eight or more. Ovaries linear, in the course of the vessels on the sub-umbrella (*Æquoreadæ*).
Genera. *Stomobrachium*, Brandt; *Polyxenia*, Eschscholtz.

4. Vessels simple, eight. Ovaries as many as the vessels, small, in the course of the sub-umbrella (*Circeadæ*).
Genus. *Circe*, Mertens.

5. Vessels simple, four. Ovaries four, in the course of the vessels on the sub-umbrella (*Geryoniadæ*).
Genera. *Geryonia*, Péron; *Tima*, Eschscholtz; *Geryonopsis*, Forbes; *Thaumantias*, Eschscholtz; *Slabberia*, Forbes.

6. Vessels simple, four. Ovaries in the substance of the peduncle (*Sarsiadæ*).
Genera. *Sarsia*, Lesson; *Bougainvillea*, Lesson; *Lizzia*, Forbes; *Modeeria*, Forbes; *Euphysa*, Forbes; *Steenstrupia*, Forbes.

This arrangement applies to the British genera only, the species of which, with figures, are described in Professor Forbes's 'Monograph of the British Naked-Eyed Medusæ,' published by the Ray Society.

The second order of the *Acalephæ* are the CILIOGRADA, of which De Blainville gives the following definition:—

Body gelatinous, very contractile, free, diversiform, evidently binary or bilateral, sometimes appearing subradiated, provided with a kind of straight ambulacra, formed by the approximation of two series of vibratory cilia.

Intestinal canal complete, or provided with two orifices, a mouth and a vent.

The term *Ciliograde* has been given to these *Medusæ* on account of the minute organs called Vibratile Cilia, with which they are covered.

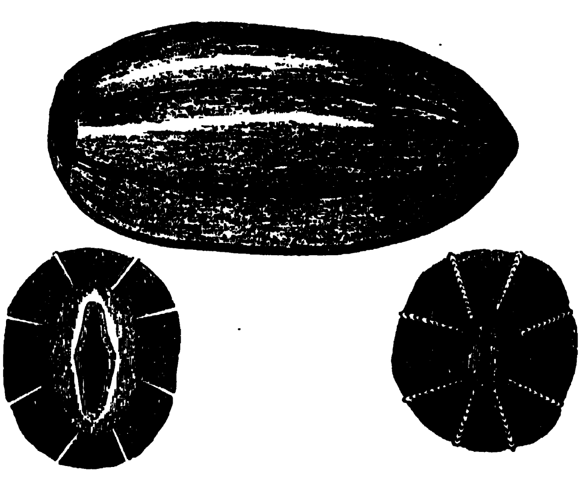
Arrangement.

De Blainville, whose amended arrangement we take, observes that systematists have hitherto agreed to imitate Gmelin more or less on the subject of the place of the *Ciliograda* in the animal series, that is to say, in making them a genus approximating to the *Medusæ*; and he instances Lamarck, Cuvier, Latreille, and Oken, as not having expressed any doubts on the subject.

Genera.

1. *Beröe.*

a. Species whose cilia are smaller than the interstices which separate them. (Genus, *Beröe* of Eschscholtz.)



Beröe ovata.

Example, *Beröe ovata.* Those found by Browne seldom exceeded three inches and a half in length, or two and a half in the largest transverse diameter. "This beautiful creature," says Browne, 'Jamaica,' p. 384, "is of an oval form, obtusely octangular, hollow, open at the larger extremity, transparent, and of a firm gelatinous consistence; it contracts and widens with great facility, but is always open and expanded when it swims or moves. The longitudinal radii are strongest at the crown or smaller extremity, where they rise from a very beautiful oblong star, and diminish gradually from thence to the margin: but each of them is furnished with a single series of short, delicate, slender appendices or limbs (the cilia) that move with great celerity either the one way or the other, as the creature pleases to direct its flexions, and in a regular accelerated succession from the top to the margin. It is impossible to express the liveliness of the motions of those delicate organs, or the beautiful variety of colours that rise from them while they play to and fro in the rays of the sun; nor is it more easy to express the speed and regularity with which the motions succeed each other from the one end of the rays to the other." Dr. Browne frequently met with these animals to the north of the western islands (West Indies).

β. Species whose cilia are twice as long as the interstices. (Genus, *Medea*, Eschscholtz.)

Example, *Beröe rufescens.*

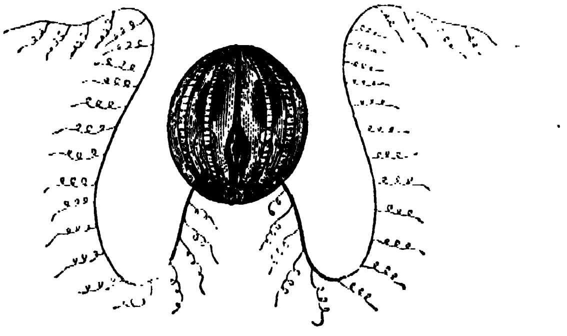
γ. Species whose cilia are situated in two ambulacral ridges. (Genus, *Pandora*, Eschscholtz.)

Example, *Beröe Flemingii.*

2. *Cydippe.*

Body regular, free, gelatinous, divided into eight sections, more or less distinct, by as many double longitudinal rows of vibratory cilia. An internal cavity, with a large buccal (?) aperture, whence issue, and are prolonged more or less below, a pair of long appendages, which are retractile, and also furnished with vibratory cilia.

Example, *Cydippe pileus; Medusa pileus*, Gmelin; *Beröe pileus*, Lamarck; *Pleurobrachia*, Fleming; *Eucharis*, Péron, who really established the genus; but Eschscholtz having transferred the last name to a genus of Ciliobranchians, De Blainville prefers following him, to avoid greater confusion. [BERÖE.]



Beröe (*Cydippe*) *pileus.*

3. *Callianira.* [CALLIANIRA.]

4. *Mnemia.*

Body smooth, oval, elongated vertically, very much compressed on one side, and as if lobated on the other. Buccal opening between the prolongation of the sides; conical appendages, on which the rows of vibratory cilia are ranged.

Example, *Mnemia heteroptera, Callianyra heteroptera* of Chamisso, thus described by Chamisso and Eisenhardt:—Body hyaline, cylindrico-tubular, dilated at one extremity, with a transverse mouth, into which it was impossible to penetrate. A large cestoid wing on each side, with vibratory cilia on its edges; six intermediate smaller wings, of which the four inferior (buccal) are lanceolated, ciliated on the edges, and attached to the base of the body; two superior cestoid wings uniting themselves to the two large lateral ones, which Péron, according to the describers, erroneously regarded as branchiæ.

5. *Calymma.* [CALYMMA.]

6. *Axiotima.*

Body a little elevated, a little compressed, or subcircular, prolonged to the right and left into a sort of appendages, bearing the series of cilia towards their terminal half only, and up to their end. Mouth small, entirely deprived of labial appendages.

Example, *Axiotima Gaïdis*, Eschscholtz. Locality, South Seas, near the equator.

7. *Eucharis* (Eschscholtz).

Body oval, sufficiently elevated, slightly compressed, or subcircular, covered with papillæ, with the ambulacra of natatory cilia extended from the summit to the base. Mouth small, provided with two rather long pairs of appendages.

Example, *Eucharis Tiedmanni*, Eschscholtz. Locality, seas of Japan. This name had been employed, as we have seen, by Péron, to distinguish another genus of Ciliograda, and should not have been transferred: for in all such cases confusion must be the consequence. The student must now remember that the *Eucharis* of Péron and that of Eschscholtz represent two different generic forms.

8. *Ocyröe.*

Body gelatinous, transparent, vertical, cylindrical, provided above with two lateral musculo-membranous, bifid, thick, wide lobes, and with two fleshy ciliated rib-like elevations, with two other ciliated ribs upon the edges between the lobes: aperture provided with four ciliated arms.

Example, *Ocyröe crystallina*, Rang, who founded the genus. De

Blainville thinks that it bears much resemblance to the last species of *Callianira*—*Callianira hexagona* ?

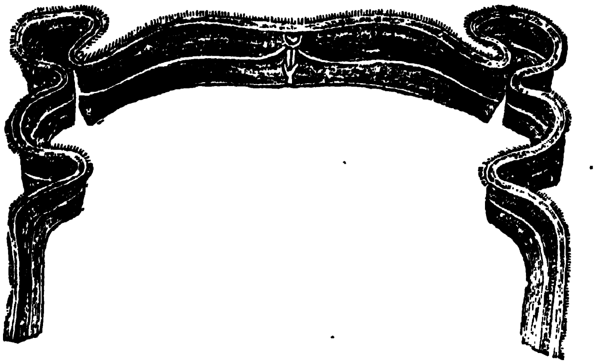
9. *Alcynöe.*

Body gelatinous, transparent, vertical, cylindrical, with eight ciliated ribs, hidden in part under the vertical natatory lobes. Aperture provided with four ciliated appendages.

Example. *Alcynöe vermiculata*, Rang, who established the genus. Locality, coasts of Brazil.

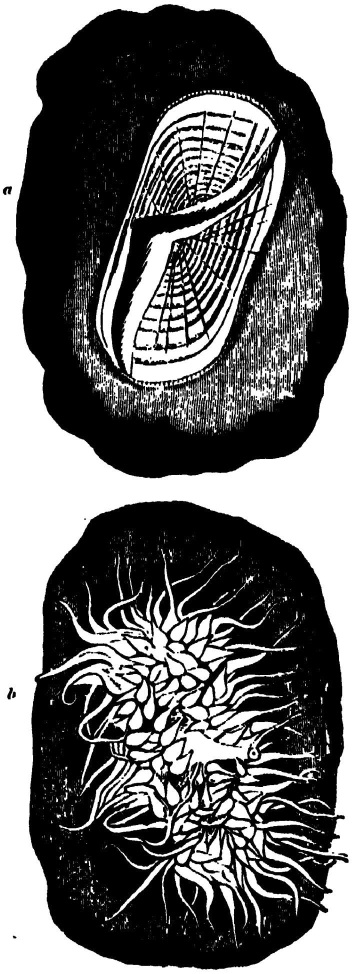
10. *Cestum.*

Body gelatinous, free, regular, very short, but extended or prolonged on each side into a long riband-like appendage, bordered on each angle with a series of vibratory cilia, thus forming four ambulacra, two on each side. Mouth inferior and mesial, accompanied by a pair of long, ciliferous, retractile and simple appendages.



Cestum Veneris.

Example, *Cestum Veneris*, Lesueur.



Velella lata.

a, upper side; *b*, lower side.

Although there is not much resemblance between this singular genus and the typical forms of Ciliograda, yet they are connected by a succession of intermediate links. If we refer to the genus *Callianira*, we shall find that its globular body is so extended laterally as to have a wing-like appendage on either side. In other genera these lateral appendages are still more extended, until the globular body in the centre is entirely lost. The alimentary canal of *Cestum* runs across the middle of its length, and from it extends, as from the stomach of the *Medusæ*, a series of gastric canals which carry the nutriment to all parts of the body.

The third order is the CIRRHIGRADA. They are thus called from the cirrhi which are attached to the disk upon which their organs are disposed. These cirrhi are, some of them, tubular, and are furnished with suckers. The cæcal appendages are attached to their base, in which are produced the ova, which pass out at the mouth of the cirrhi. The following is De Blainville's definition of the order :—

Body, oval or circular, gelatinous, sustained in the interior of the dorsal disk by a solid subcartilaginous part, and provided on the lower surface of the disk with tentaculiform cirrhi, which are very extensible.

Genera.

1. *Velella.*

Body membranous, oval, very much depressed, convex, swollen, sustained above by a transparent oval subcartilaginous piece, marked with concentric striæ, and surmounted by a vertical and oblique crest, concave below, with a sort of mesial nucleus, offering a central mouth at the extremity of a proboscidiform prolongation, surrounded by tentacular cirrhi of two kinds, the external being much longer than the internal ones.

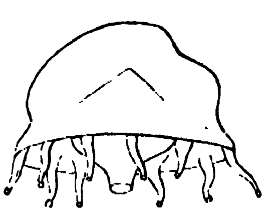
De Blainville observes that Imperato and Columna would appear to be the authors who first noticed the animals which constitute this genus, established, at first, under the name of *Phyllidoce*, by Patrick Browne, and figured by him in his 'History of Jamaica,' tab. 48, *fig.* 1. Forskahl, who gave a very good description of it, arranged it under his genus *Holothuria*. Lœfling made it a *Medusa*, denominating the species known to him *Medusa Velella*, a name adopted by Linnæus in the 'Systema Naturæ.' Dana ('Soc. Roy. de Turin,' 1766) proposed the name of *Armenistarus* for it; and Lamarck published it under the generic appellation of *Velella*, by which it is now generally known to naturalists.

This form is widely diffused, and has been found in the seas of Europe, America, Asia, and Australasia. One of the species, *V. limbosa*, is often taken on the southern coasts of England. The animals are met with far at sea, and often huddled together, young and old, in considerable masses. Sailors are said to fry and eat them.

The *Phyllidoce labris cæruleis*, the *Sally-Man* of Browne, appears to be the *Velella cyanea*, of Lesson and Garnot, and one at least of the species which gave rise to the *Medusa Velella* of Linnæus and Gmelin (Lamarck quotes the last name as well as Browne's *Phyllidoce*, as synonyms of his *Velella mutica*).

2. *Rataria.*

Body oval or circular, sustained by a subcartilaginous, compressed, elevated piece, with a muscular, moveable, longitudinal crest above, concave below, and provided in the middle with a free proboscidiform stomach, and with a single row of marginal tentaculiform suckers.

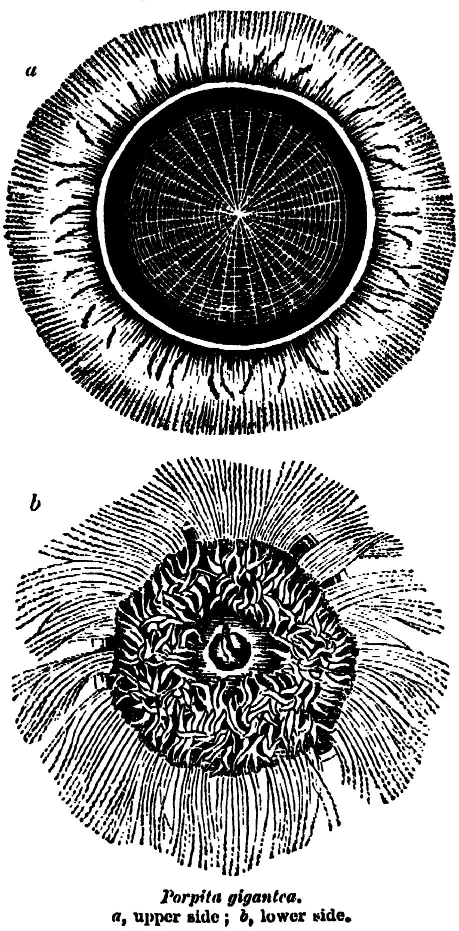


Rataria mitrata, highly magnified.

Eschscholtz established this genus for some very small cirrhigrade animals, whose back is sustained by a subcartilaginous piece, not elevating itself in the dorsal cavity, and which only offer marginal cirrhi on the central surface. De Blainville, after observing that Forskahl has figured with his *Holothuria spirans* (*Velella limbosa* of Lamarck) some very small animals, which M. Eschscholtz himself regards as closely approximating to his *Rataria cordata*, says that it seems possible that the *Rataria* may be only degrees of development of *Velella*. Example, *Rataria mitrata*.

3. *Porpita.*

Body membranous, regular, circular, depressed, slightly convex above; internal cartilaginous support circular, with its surface marked by concentric striæ crossing radiated striæ, covered on its upper surface by a delicate membrane merely. The body is concave below, and the inferior surface is furnished with a great number of tentacula, of which the exterior ones are the longest, and furnished with small cilia, each terminated by a globule: they sometimes contain air; and the internal ones are the shortest, the most simple, and the most fleshy. In the centre of these tentacula is the mouth, in form of a small proboscis, which leads to a simple stomach, surrounded by a somewhat glandular substance.

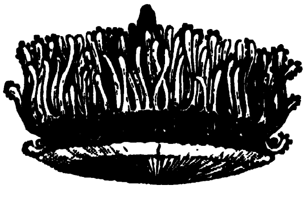


Porpita gigantea.

a, upper side; *b*, lower side.

Cuvier, from whom a great portion of the above description is taken, says, in the last edition of the 'Règne Animal,' that there is but one species (*Porpita gigantea*) of a beautiful blue colour, from the Mediterranean, and other warmer seas. Lamarck, who established the genus for an animal which had been placed among the *Medusæ* by Linnæus, gives four species;

but De Blainville and MM. Chamisso and Eisenhardt coincide with Cuvier in believing that they are all referable to one, though the former admits that the fact is still somewhat doubtful. He observes that Bosc's species, *Holothuria appendiculata*, (*Porpita appendiculata*, Lam.) was evidently established on an impaired animal. Eschscholtz, under the name of *Porpita Mediterranea*, conjoins three of Lamarck's species, and describes three new ones, taking for his character the proportion of the cartilaginous disk, and especially that of the marginal cirrhi.



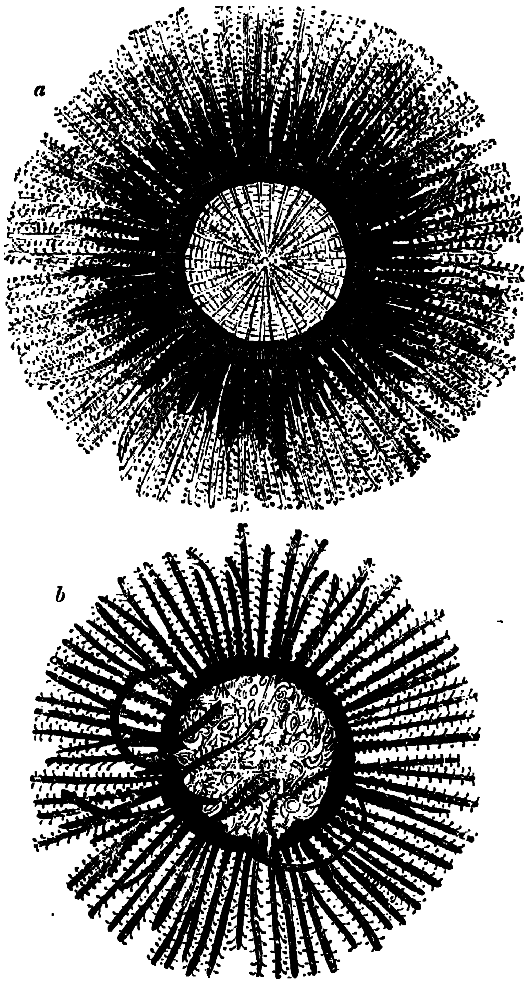
Profile of *Porpita glandifera*.

Geographical Distribution.—Like that of *Velella*, very wide. Bosc, who met with them at sea, says the animal has the appearance of a 24-sous piece borne along by the waves. Examples, *Porpita gigantea*, and *P. glandifera*.

4. *Polybrachionia*. (Guilding).

Dorsal support (sustentaculum) cartilaginous, naked, flattened, rounded, radiated, concentrically striated; mantle (pallium) narrow, free, surrounding the support; arms numerous, parallel, of various lengths, elongated, affixed beneath, with a power of taking a declining position for the purpose of taking prey. Mouth below, central, purse-shaped, extensile. Tentacula many, varying in form, suctorial, covering the whole ventral surface. Eggs, very small, innumerable, nestled among the tentacula. Example, *Polybrachionia Linnæana*.

This genus has been established by Mr. Guilding, who describes the support as broad and vitreous, the body as cerulean, the tentacula as pallid, and the arms, which are in a triple series, glandulous, the glandules being pedunculated. The diameter of the mantle, exclusive of the arms, is stated to be eleven and a half lines. Mr. Guilding states that the animal is wonderfully beautiful, swimming, or rather floating on the serene surface of the Caribean Sea in calm weather, and embracing its prey by the sudden downward application of some or all of its arms, which are easily broken by attrition.



Polybrachionia Linnæana, enlarged. *a*, upper side; *b*, lower side.

We think there is hardly enough to warrant a generic separation in this case; the species bears a strong resemblance to the *Porpita cærulea* of Eschscholtz. Mr. Guilding observes that the *Medusa porpita* of the 'Amœnitates Academicæ' seems nothing more than the central disk of some species deprived of all the organs of the body.

The fourth order is the PHYSOGRADA. The structure of the creatures belonging to this order were but little known till the publication of Mr. Huxley's researches, in 'Philosophical Transactions' for 1849. They are allied to the preceding order both in the conformation of the gastric organs and in their means of locomotion. The principal difference between this and the preceding families is, that we here lose the radiate form, and observe in the creatures which belong to it a lateral symmetry. This order is now made to include the genus *Physalia* and its allies, which are possessed of an air-bag, by means of which they float through the ocean, and also the various forms of *Diphydæ*. These two forms were included by Cuvier in his division of *Hydrostatic Acalephæ*. Before referring to their arrangement, we shall give the principal results of Mr. Huxley's researches into the anatomy of these creatures, as given by him in the 'Report of the Twenty-First Meeting of the British Association for the Advancement of Science.' We shall speak first of the *Diphydæ*. If one of these creatures is examined, it will be found to consist of two transparent crystalline pieces, which look, when taken out of the water, like morsels of cut-glass. One or both of these pieces contains a wide cavity, lined with a muscular membrane, by the contraction of which the animal is propelled through the water. The attachment of the posterior piece to the anterior is very slight, and when detached it will swim about independently for hours together. It was this circumstance which led Cuvier to suppose that the two pieces were two independent animals, and in this he has been followed by the majority of zoologists. He describes the two individuals as always together, one including itself in a hollow of the other (l'un s'emboîtant dans un creux de l'autre), an arrangement which nevertheless permits their separation without the destruction of life. They are, he observes, gelatinous, transparent, and move very nearly like the *Medusæ*. The including individual (l'emboîtant) produces from the bottom of its hollow a chaplet (chapelet) which traverses a demi-canal of the included individual (l'emboîté), and would seem to be composed of ovaries and of tentacula and suckers like those of the preceding genera. Cuvier then goes on to state the divisions established by MM. Quoy and Gaimard, according to the relative forms and proportions of the two individuals. Thus in the *Diphyes*, properly so called, the two individuals are nearly alike, pyramidal, and with some points round their opening, which is at the base of the pyramid. In the *Calpes*; the included individual has still the pyramidal form, but the including individual is very small and square. In the *Abyles*, the included individual is oblong or oval, and the including rather smaller and bell-shaped. In the *Cuboïdes*, it is the included individual which is small and bell-shaped; the including individual is much larger and square. In the *Navicules*, the included individual is bell-shaped; the including individual large also, but slipper-shaped (en forme de sabot). Cuvier concludes by remarking that there are many other combinations. There are two prominent forms of *Diphydæ*, the *Monogastric* and the *Polygastric*. In the former a single polype is developed in a special cavity of the anterior piece. In the polygastric a long chain of such polypes, each enveloped in a little transparent bract, occupies a similar position. These polypes have no oral tentacles; but a long thread-like tentacle, bearing lateral branches, which are terminated by small sacs, is developed from the base of every polype. The small prehensile sac has a peculiar form, but is only a dilatation of its pedicle. It is much thickened on one side, and contains a great number of the stinging hairs to which we have before alluded. The reproductive organs are medusiform bodies, which are developed by gemmation from the pedicle of the polype.

In the *Polygastric Diphydæ* new polypes are continually being produced by gemmation at the attached extremity of the polype-chain, and in all the species the same gemmation is continually going on among the prehensile and reproductive organs.

The structure of the other forms of *Physograda* are modifications of a common type, in the main identical with that of the *Diphydæ*. The great difference is in the absence of the air-organ, or float. The same continual multiplication of parts by germination goes on among the *Physsophoridæ* as among the *Diphydæ*, and the structure and mode of development of the young organs are the same. Great variety is presented by the reproductive organs, from the form of mere sacs to that of free-swimming bodies precisely resembling *Medusæ*, and developing the generative elements only subsequently to their liberation. In *Physalia* the female organs are free-swimming medusiform bodies, while the male organs are simply pyriform sacs.

As a general conclusion it may be stated that the *Physograda* are essentially composed of two membranes, an outer and an inner, which are called by Mr. Huxley 'foundation membranes,' since every organ is formed by the modelling into shape of one or other or both of these; commencing as a simple process, or diverticulum, and assuming its perfect form by a gradual change of development. The stomach has no walls distinct from those of the general varieties. The reproductive organs are always developed externally. The stinging hairs, or thread-cells, are found in all the species in the greatest abundance.

The following is the arrangement of these creatures according to M. de Blainville:—

PHYSOGRADA.

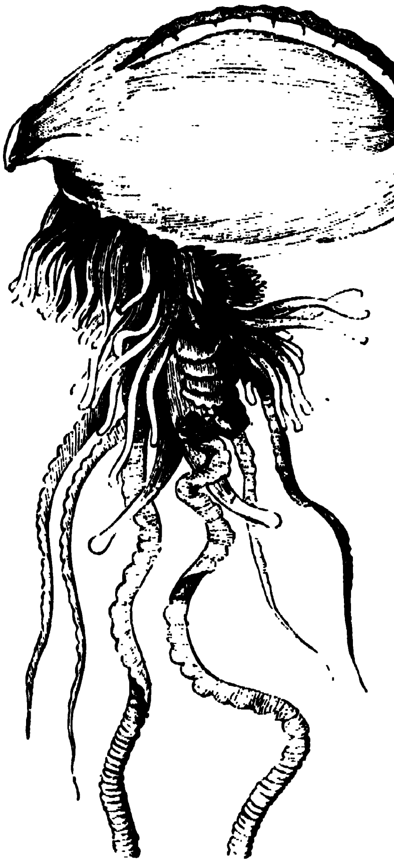
Natatory organ simple and lamellar.

1. *Physalia*.

Generic Character.—Body oval, rather elongated, more narrow and proboscidiform anteriorly, hydatiform in the middle, attenuated and obtuse posteriorly; mouth star-shaped and terminal; anus lateral; a foot in form of a crest or oblique lamina, directed from before backwards; branchiæ very anomalous, and composed of a great number of diversiform cirrhous productions; organs of generation terminating at the anterior third of the right side by two closely approximated orifices.

Example, *Physalia Arethusa.*

This is the *Arethusa* of Browne; *Medusa Caravella* of Müller and Eschscholtz; *Physalus Pelagicus* of Lamarck; the Portuguese Man-of-War of English voyagers. This *Physalus* is an inhabitant of the warm seas, but a shoal of them are sometimes driven into our bays, particularly on the south-west coast.



Physalus Pelagicus · the crest not expanded.

* *

Locomotive organs complex and vesicular.

2. *Physsophora.*

Generic Character.—Body more or less elongated, cylindroid, hydatiform in its anterior part, provided below with two series of vesicular diversiform bodies, with a regular aperture, and behind with a variable number of very diverse cirrhiform productions, two of which are longer and more complex than others; mouth at the extremity of the hydatiform part; anus terminal.

Example, *Physsophora Muzonema.*

M. de Blainville states that the *Physsophoræ* differ from the *Physaliæ* in swimming or floating in a vertical position, the air-bag being above and the cirrhiferous productions below. The distinction of the species appears to him to depend especially on the number and form of the natatory organs.

3. *Diphysa.*

Generic Character.—Body cylindrical, elongated, contractile, muscular, composed of three parts, the anterior part vesicular, the middle part bearing on its lower part two hollow natatory organs, placed one before the other, and the third part (which is the longest) provided above with a fibrillo-capillaceous plate, and below with cirrhiform productions; mouth terminal.

Example, *Diphysa singularis* (Quoy and Gaimard; 'Astrolabe, Zoologie').

4. *Rhizophysa.*

Generic Character.—Body free, transparent, very contractile, very much elongated, swollen at one extremity into a sort of aëriferous bladder with a terminal orifice, provided throughout its length with scattered tentaculiform productions mingled with cirrhiform filaments.

This genus is divided by M. de Blainville into two sections.

α.

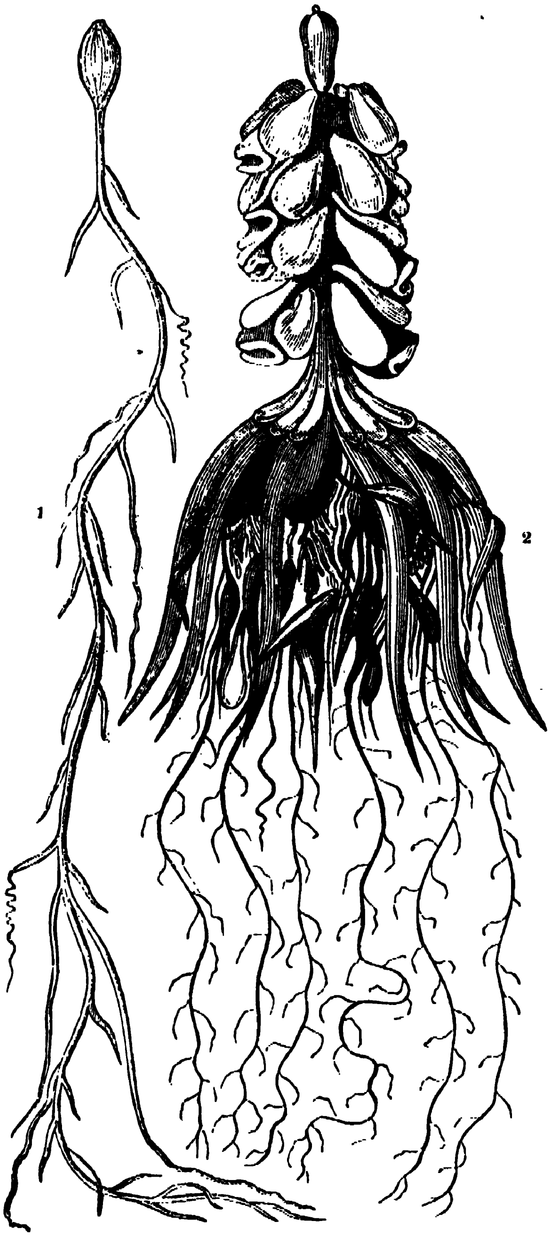
Species with simple tentaculiform productions. Natatory organs hollow. (Genus *Rhizophysa.*)

Example, *Rhizophysa planostoma*, Péron. (*Rhizophysa Péronii*, Esch., 'Acaleph.,' p. 148, No. ii., t. 13, *fig.* 3.)

β.

Species whose tentaculiform productions are covered with cirrhiform filaments. Natatory organs unknown. (Genus *Epibulia*, Esch.)

Example, *Rhizophysa filiformis.* (*Physsophora filiformis*, Forsk.)



1. *Rhizophysa filiformis;* 2. *Physsophora Muzonema.*

* * *

Species provided with two sorts of locomotive organs, the anterior ones hollow, the posterior solid.

5. *Apolemia.*

Generic Character.—Body very much elongated, cylindrical, vermiform, provided anteriorly with many hollow natatory organs in two rows, and behind with solid squamous organs, between which come forth tentaculiform cirrhi, furnished with vermiform suckers.

Example, *Apolemia Urania.*

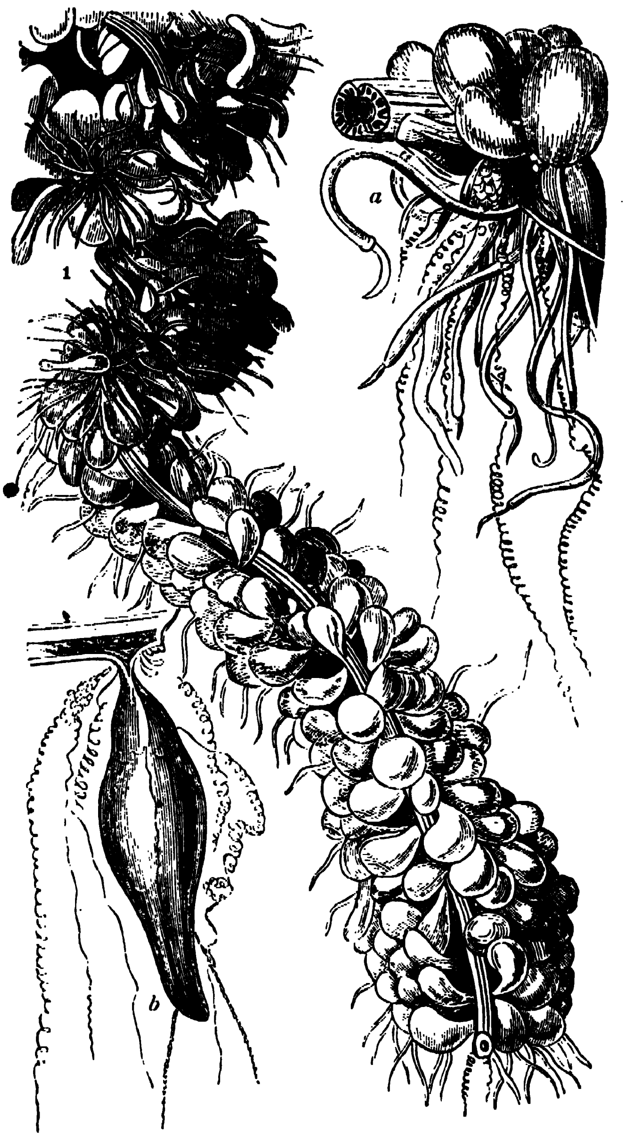
6. *Stephanomia.*

Generic Character.—Body in general very much elongated, cylindrical, vermiform, covered throughout its extent, except in the lower median line, with squamous natatory organs, full and dispersed in transverse bands, between which come forth, and especially inferiorly, long, very much diversified cirrhiform productions, mingled with the ovaries. Orifices of the intestinal canal terminal.

Example, *Stephanomia Amphitrides*, Péron et Lesueur ('Voyage aux Terres Austr.,' p. 45, pl. 29, *fig.* 5).

7. *Protomedea.*

Generic Character.—Body free, floating, cylindrical, fistulous, very long, provided above with an imbricated assemblage of gelatinous bodies (on two alternate rows) which are full and hippopodiform, and throughout the rest of its length with filamentous, cirrhous, diversiform productions. Mouth proboscidiform, at the extremity of a sort of vesicular stomach.

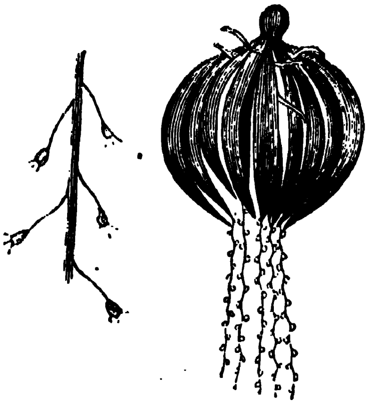


1, a portion of *Apolemia Urania.*
a, a part still more highly magnified; *b*, a single sucker.

Example, *Protomedea lutea.*

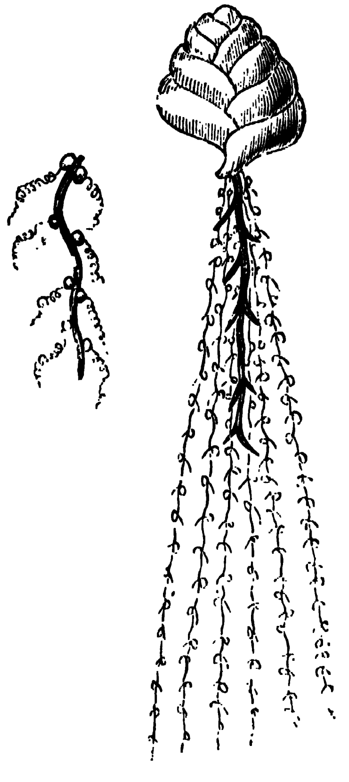
8. *Rhodophysa.*

Generic Character.—Body short, cylindrical, fleshy, swollen above into an aëriferous bladder, and provided below with a variable number of gelatinous bodies, which are full, costiform, forming a single transverse series, and with a variable number of filamentous diversiform productions. Mouth and anus terminal.



Rhodophysa Helianthus.

Example, *Rhodophysa Helianthus.*



Protomedea lutea.

DIPHYDÆ.

a.

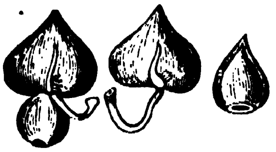
Diphydæ whose anterior part has but a single cavity (Monogastric).

Genera.

1. *Cucubalus.*

Body provided with a large proboscidiform exsertile sucker, with a bunch (grappe) of ovaries at its base, lodged in a large single excavation of a natatory anterior cordiform organ, receiving also the posterior, which is also cordiform and hollowed into a cavity with a posterior and sub-oval orifice.

Example, *Cucubalus cordiformis*, the only species cited of the genus established by MM. Quoy and Gaimard. Length, two lines. Differs from the other *Diphydæ*, first, in having the nucleus much less hidden and sunk in the anterior natatory body, which has moreover only one large cavity in which it is plunged; secondly, in having the oviferous production very short; and, lastly, in the mode of locomotion, for the animal always swims vertically.

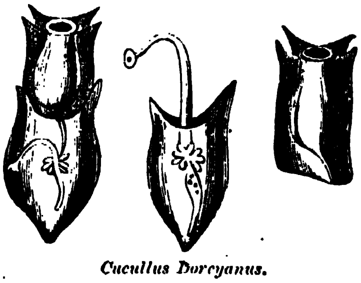


Cucubalus cordiformis.

2. *Cucullus.*

Body furnished with a great exsertile proboscidiform sucker, with a bunch of ovaries at its base, lodged in a deep excavation, the only one in the anterior natatory organ, in form of a hood, in which the posterior is inserted (s'emboîte); the latter is tetragonal, and pierced behind with a rounded terminal orifice.

Example, *Cucullus Doreyanus* (Quoy and Gaimard). Locality, New Guinea.

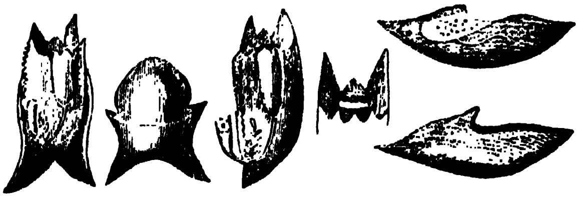


Cucullus Doreyanus.

3. *Cymba* (*Nacelle*).

Body furnished with a large exsertile and proboscidiform sucker, having at its base a mass of ovariform organs, lodged in the single and rather deep cavity of a naviform natatory organ, receiving and partially hiding the posterior natatory organ, which is sagittiform, pierced behind with a rounded orifice crowned with points, and hollowed on its free border by a longitudinal gutter.

Example, *Cymba sagittata* (Quoy and Gaimard); *Nacelle sagittata* (De Blainville). Locality, Straits of Gibraltar.

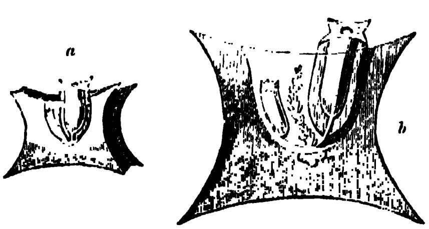


Cymba sagittata.

M. de Blainville remarks that he ought to observe that M. Eschscholtz says that this genus, to which he unites the two following genera, possesses an anterior natatory organ with two cavities, and of these the natatory cavity projects in the form of a tube. M. de Blainville further observes that this genus does not differ from the *Cuculli*, except in the form of the natatory organs; in fact, the disposition of the nucleus in the bottom of the single cavity into which the anterior organ is hollowed, and the penetration of the posterior organ into this same cavity are absolutely the same as in the two preceding genera, as M. de Blainville has been able to satisfy himself from the examination of many individuals preserved in spirit.

4. *Cuboïdes.*

Body nucleiform, provided with a large proboscidiform sucker, surrounded by an hepatic mass, having at its base an ovary, whence proceeds a filiform ovigerous production, contained in a large, single, hemispherical excavation of an anterior, cuboïd, natatory organ, much larger than the posterior one, which is tetragonal, and nearly entirely hidden in the first.



Cuboïdes vitreus.

a, natural size; *b*, magnified.

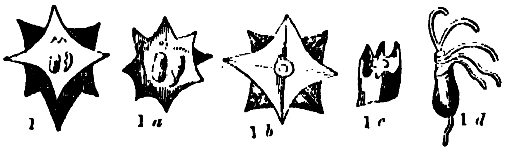
Example, *Cuboïdes vitreus* (Quoy and Gaimard). Locality, Straits of Gibraltar.

This again, according to M. de Blainville, is a genus scarcely distinguishable from the preceding genera, and only by the form and proportion of the natatory organs.

5. *Enneagona.*

Body nucleiform, provided with a large exsertile sucker, having at its base an assemblage of ovaries, whence proceeds an oviferous production. Anterior natatory organ enneagonal, containing with the nucleus in a single (?) excavation the posterior organ, which is much smaller, with five points, and canaliculated below.

Example, *Enneagona hyalina* (Quoy and Gaimard).



Enneagona hyalina.

1, 1 *a*, 1 *b*, *Enneagona hyalina* under different aspects; 1 *c*, visceral part; 1 *d*, nucleus.

6. *Amphiroa.*

Body nucleiform, of considerable volume, furnished with a proboscidiform stomach, having at its base a bunch of ovaries, prolonged into a long filament, contained in an anterior, polygonal, short, natatory organ, cut squarely, with a single cavity in which the posterior organ, which is equally short, polygonal, and truncated, is inserted.

Example, *Amphiroa alata* (Lesueur). Locality, Seas of Bahama.

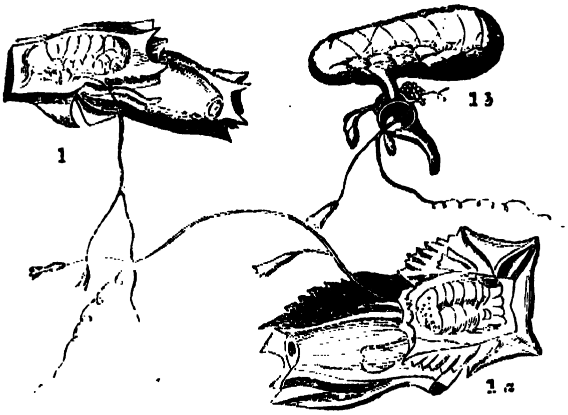
β.

Diphydæ whose anterior part is furnished with two distinct cavities.

1. *Calpe.*

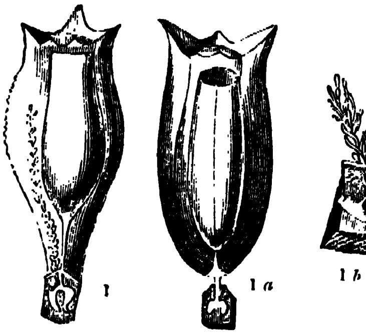
Body nucleiform, without an exsertile proboscis, having a sort of aëriferous vesicle, and at its base an ovary (?) prolonged into a long cirrhigerous and oviferous production. Anterior natatory organ short, cuboïd, having a distinct locomotive cavity; posterior natatory organ very long, truncated at the two extremities, not penetrating into the anterior organ, and provided with a round terminal aperture.

Example, *Calpe pentagona* (Quoy and Gaimard). Locality, Straits of Gibraltar?



Amphiroa alata.

1, 1 *a*, *Amphiroa alata*; 1 *b*, its nucleus extracted.



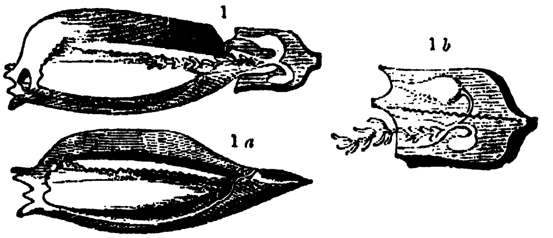
Calpe pentagona.

1, *Calpe pentagona* (profile); 1 *a* (under side); 1 *b*, nucleus.

2. *Abyla.*

Body nucleiform, inconsiderable, with a very long cirrhigerous and oviferous production. Anterior natatory body much shorter than the other, subcuboïd, with a distinct cavity for the reception of the anterior extremity of the posterior natatory body, which is polygonal and very long.

Example, *Abyla trigona* (Quoy and Gaimard). Locality, Straits of Gibraltar.



Abyla trigona.

1, *Abyla trigona*; 1 *a*, posterior part; 1 *b*, anterior or visceral part.

3. *Diphyes.*

Body nucleiform, indistinct, situated in the bottom of a deep cavity, whence proceeds a long tubular production, furnished throughout its extent with proboscidiform suckers, having at their root granular corpuscles and a cirrhiferous filament. Natatory bodies nearly equal and similar; the anterior with two distinct cavities, the posterior with a single one, with a round aperture provided with teeth.

Example, *Diphyes Bory* (Quoy and Gaimard); *Diphyes campanulifera* (Eschscholtz).

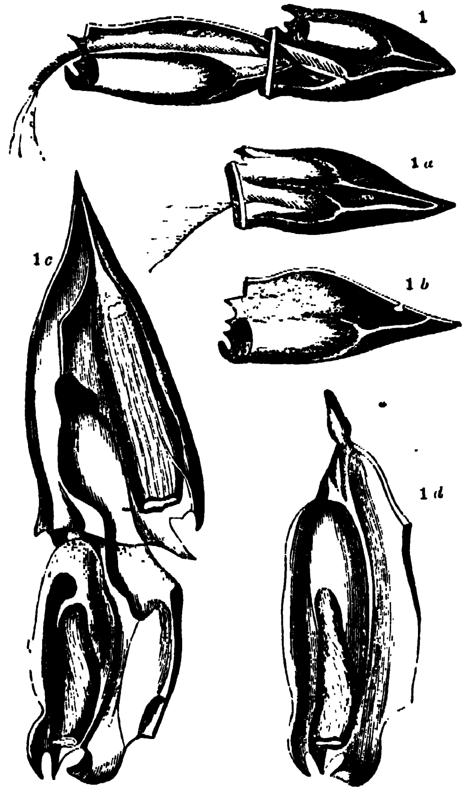
γ.

Doubtful species, or those with one part only.

1. *Pyramis.*

Body free, gelatinous, crystalline, rather solid, pyramidal, tetragonal, with four unequal angles, pointed at the summit, truncated at its base,

with a single rounded aperture communicating with a single deep cavity, towards the end of which is a granular corpuscle.
Example, *Pyramis tetragona* (Otto).



Diphyes Bory.

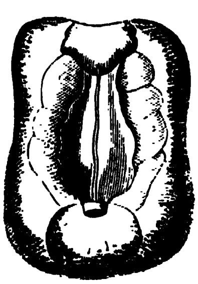
1, the entire animal (profile); 1 *a*, anterior part of the same; 1 *b*, posterior part; 1 *c*, animal magnified; 1 *d*, posterior part of the same.

M. Eschscholtz makes this organised body a species of his genus *Eudoxia*, which comprehends *Cucubalus* and *Cucullus* of Quoy and Gaimard, admitting that the two natatory organs are intimately united so as to form, apparently, but one.

Pyramis tetragona.

2. *Praia.*

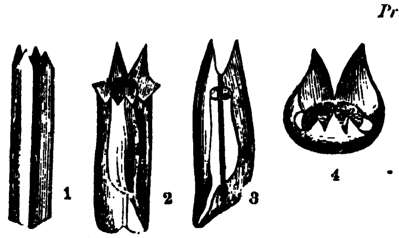
Body subgelatinous, rather soft, transparent, binary, depressed, obtuse, and truncated obliquely at the two extremities, hollowed into a cavity of little depth, with a round aperture nearly as large as the cavity, and provided with a large canal or furrow above.
Example, *Praia dubia* (Quoy and Gaimard).



Praia dubia.

3. *Tetragona.*

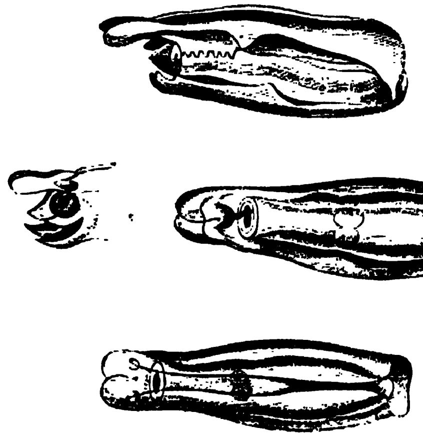
Body gelatinous, transparent, rather solid, binary, of an elongated, parallelopiped, tetragonal form canaliculated below, truncated obliquely anteriorly, pierced behind by a gaping orifice furnished with symmetrical points, and leading into a long blind cavity.
Example, *Tetragona hispidum* (Quoy and Gaimard).



Tetragona hispidum.
1, *Tetragona hispidum*; 2, 3, 4, details of the same.

4. *Sulculeolaria.*

Body subcartilaginous, transparent, elongated, cylindroïd, traversed throughout its length by a very large furrow, bordered with two membranes, truncated at the two extremities, with a posterior aperture, with appendicular lobes on its circumference, and leading into a very long and blind cavity.
Example, *Sulculeolaria quadrivalvis* (Lesueur). Locality, Mediterranean (Nice).

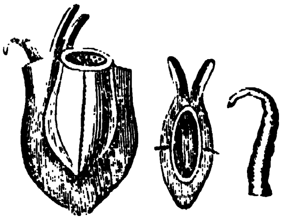


Sulculeolaria quadrivalvis.

A genus characterised by De Blainville, who found it established in the figures of Lesueur, from those figures; but the former is strongly inclined to believe that the genus is founded on the part of an animal, and not on an entire one.

5. *Galeolaria.*

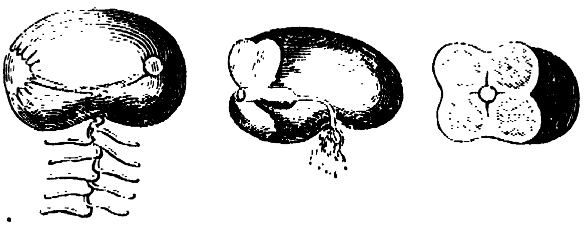
Body gelatinous, rather firm, perfectly regular, symmetrical, subpolygonal or oval, compressed on the sides and furnished with two lateral rows of extremely fine cirrhi. A large posterior aperture pierced in a sort of diaphragm with appendicular lobes, binary above, leading into a large cavity with muscular walls. An ovary at the anterior superior surface, coming out by a mesial and bilabiated orifice.
Example, *Galeolaria australis*, *Beroïdes australis* (Quoy and Gaimard).



Galèolaria australis.

6. *Rosacea.*

Body free, gelatinous, very soft, transparent, suborbicular, with a single terminal aperture at one of the poles leading into an oval cavity which communicates with a depression, whence proceeds a cirrhigerous and oviferous production.
Example, *Rosacea Ceutensis* (Quoy and Gaimard).

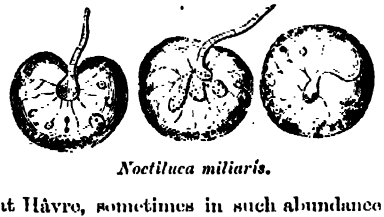


Rosacea Ceutensis.

7. *Noctiluca.*

Body free, gelatinous, transparent, spheroïdal, reniform, with a sort of infundibuliform cavity, whence proceeds a proboscidiform contractile production.
Example, *Noctiluca miliaris* (Lamarck).

M. Surriray, a doctor of medicine, while investigating the cause of the phosphorescence of the sea-water at Hâvre, appears to have been the first who observed and called attention to the genus *Noctiluca*, which he described and figured in the memoir that he communicated to the class of sciences of the French Institute. Its size hardly equals that of a small pin's head, and it is as transparent as crystal; he found it very common in the basins at Hâvre, sometimes in such abundance as to form a considerably thick crust (croûte assez épaisse) on the



Noctiluca miliaris.

surface of the water. It has also been observed in England as the cause of phosphorescence in the ocean.

8. *Doliolum.*

Body gelatinous, hyaline, cylindrical, truncated, and equally attenuated at the two extremities, which are largely opened and without apparent organs.

Example, ***Doliolum Mediterraneum*** (Otto).

M. Otto describes the organism on which he has established this genus as swimming by ejecting and absorbing the water by means of the alternate dilatation and contraction of its two orifices. M. Delle Chiaje ('Mem.,' tom. iii.) seems inclined to believe that the *Doliolum* of Otto is merely a fragment of a species of *Holothuria,* which he names *Holothuria inhærens.* De Blainville observes that if Otto's description of the motion, &c., above stated, be correct, it is probable that the animal is a true *Biphore.*

"Among the genera," says De Blainville, "*incertæ sedis,* which, wrong or right, have been connected with *Physsophora* or *Diphyes,* without even being very certain that they are animals, we shall cite the following genera intentionally omitted in our work."

Cupulites (Quoy and Gaimard), placed among the *Physsophoræ,* whose capsules are disposed on each side of a very long axis, established on an organised body, figured pl. 87, fig. 4—16 in the zoological part of the 'Voyage of the Uranie.' Not having met with this animal in their second voyage, MM. Quoy and Gaimard doubt ('Astrolabe, Zoolog.,' t. iv. p. 53 n.) whether it is an incomplete *Physsophora* or a *Stéphomonise* (*Stephanomia ?*) with hollow natatory organs. Cuvier places the genus between *Hippopus* and *Racemis.*

Polytoma (Quoy and Gaimard, 'Zool. of the Uranie,' pl. 87, fig. 12, 13), which may be defined to be an oval mass of globular trivalvular corpuscles (corpuscules globuleux comme trivalves), and which MM. Quoy and Gaimard conceive to be rather a *Biphore* than a *Physograde.*

Tetragona (p. 10), (Quoy and Gaimard, 'Zool. of the Uranie,' pl. 86, fig. 11). This the authors themselves ('Astrolabe,' iv. p. 103) have recognised as being nothing more than the posterior point of *Diphyes hispida.*

Racemis (Delle Chiaje, Cuvier), figured by Delle Chiaje, 'Mem.' tab. 50, f. 11, 12, and described as a globose vesicle endowed with a very quick motion, and disposed towards an ovate shape; but, observes De Blainville, the figures and description are too incomplete to afford a supposition of what it is; in fact, Delle Chiaje confines himself to stating that his *Racemis ovata* executes all the rotatory and rapid motions at the surface of the water, and that those of each vesicle are so lively that it has been absolutely impossible to perceive the aperture with which, according to Delle Chiaje, they are provided. Cuvier only adds to the description of Delle Chiaje, who also places *Racemis* near the *Physsophoræ,* a small membrane with which each vesicle is furnished. M. De Blainville concludes by observing that he had seen a drawing, by M. Laurillard, which had been taken at Nice from one of these organised bodies while alive, and that he supposed that it might well be a mass of eggs of *Mollusca.*

Relations of the Acalephæ to the other Invertebrata.—Mr. Huxley, in his memoir before referred to, proposes to consider the *Acalephæ* in some new relations. The presence of stinging hairs in these animals, in common with the *Hydroïd, Sertularian,* and *Anthozoic Polypes,* he regards as a fact of primary importance. He endeavours to show that this fact, combined with the radiate polype form, and the composition of the body of two distinct membranes, forms a very good positive character for a group embracing the *Hydroïd* and *Anthozoic Polypes,* and the *Acalephæ.* He proposes to give the name of *Nematophora* ('thread-bearers') to this group, in allusion to the characteristic presence of the 'thread-cell.' Frey and Leuckart had, however, applied the term *Cælenterata* to the same group. It will admit of subdivision into two equivalent subclasses: one including the *Hydroïd Polypes,* the *Diphydæ, Physsophoridæ,* and *Medusidæ,* in which the stomach is not distinct from the common parietes, and the reproductive organs are external; the other, embracing the *Anthozoic Polypes* and *Beroïdæ* in which the stomach is distinct from the common parietes, and the reproductive organs are internal. The author proposes the terms *Anæcioa* and *Æcioa* for these two divisions. These groups mutually represent each other as ollows:—

ANÆCIOA.	ÆCIOA.
Hydroïdæ.	*Actinidæ.*
Corynidæ.	*Zoanthidæ.*
Pennatulidæ.	*Physsophoridæ.*
Beroïdæ.	*Medusidæ.*

On these grounds Mr. Huxley proposes to break up the class *Radiata* of Cuvier into four groups. Supposing the *Cælenterata* to form a sort of central group, we have, on the one hand, the ***Ascidians*** and the ***Bryozoa*** leading to the *Mollusca;* on the other, the ***Echinoderms*** and the ***Entozoa*** leading to the *Annulosa;* whilst the *Polygastria, Sponges,* and *Gregarinadæ* conduct us towards the lowest plants. These relations may be thus represented:—

MOLLUSCA. ANNULOSA.

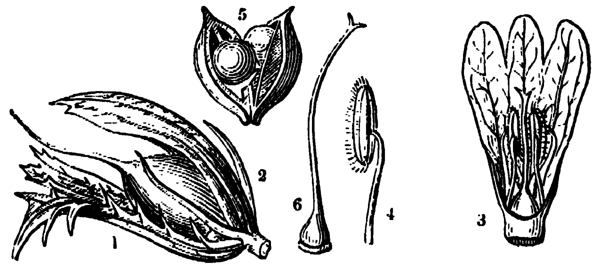
Ascidians. Bryozoa. Echinodermata. Entozoa.
RADIATA.
CÆLENTERATA.
Anæcioa. Æcioa.
PROTOZOA.
Polygastrica. Spongiadæ. Gregarinadæ.

FOSSIL IMPRESSIONS OF MEDUSÆ?

Mr. Babbage, in his paper 'On Impressions in Sandstone resembling those of Horses' Feet,' December, 1836, in which he noticed those in the channel of a stream on the extensive moor called Pwll-y-Duon, about seven miles from Merthyr Tydvil, to which his attention was drawn by Mr. Guest of Dowlais, and the analogous casts in the old red-sandstone of Forfarshire, there called Kelpies' Feet, described some observations made by Sir C. Lyell, on impressions left by *Medusæ* on the rippled sand near Dundee. On removing the gelatinous body of the animal, a circular space was exposed, not rippled, but having around half the border a depression of a horse-shoe form. These marks, however, were not considered by Sir C. Lyell as identical with those called Kelpies' Feet, but merely so far analogous as to invite further observations, and to make it desirable to possess drawings of the impressions which different species of *Medusæ* leave when thrown by the tide upon a beach of soft mud or sand. ('Geol. Proc.,' vol. ii.)

ACANTHA'CEÆ, an order of plants belonging to the Monopetalous division of *Dicotyledons.* Its type is the genus *Acanthus.* The species are herbaceous or shrubby; they are extremely common in every tropical country. Many of the species are mere weeds; others bear handsome flowers with gaudy colours, but seldom with any odour; a very small number have been occasionally employed medicinally as emollients or diuretics.

The roots of *Acanthaceæ* are either annual or perennial. The stems are usually four-cornered when young, but afterwards become nearly round; their inside is occupied by a large proportion of pith, which is enclosed in a thin layer of imperfectly formed wood; and at each joint there is a slight tumour with an articulation, by which they are readily known from both *Scrophulariaceæ* and *Verbenaceæ.* Their flowers are often enclosed within large, leafy, imbricated bracts (1). The calyx (2) is usually composed of either four or five parts, which overlap each other, and occasionally grow together at the base. The corolla (3) is monopetalous and irregular. The stamens (4) are either two or four, but in the latter case are of unequal lengths. The pistillum (6) is superior and turcilled. The seed-vessel (5) contains two cells, which burst when ripe, often with elasticity, and expose a few roundish seeds hanging to the cells by curious-hooked processes.



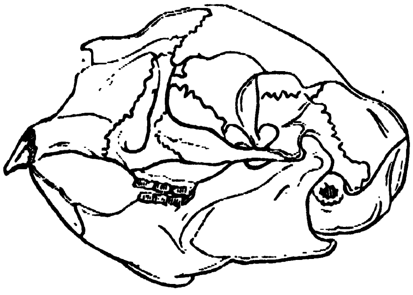
Analysis of *Acanthaceæ.*

The stems of all the species emit roots very readily from their tumid articulations; on which account gardeners universally increase them by cuttings of the full-grown branches. They are always easy to cultivate, provided they are not kept in too cold or too dry a situation. The annual kinds freely produce seeds, by which they are readily multiplied.

The most common genera are ***Justicia, Acanthus, Ruellia, Thunbergia, Barleria, Eranthemum, Lankesteria,*** and ***Henfreya.***

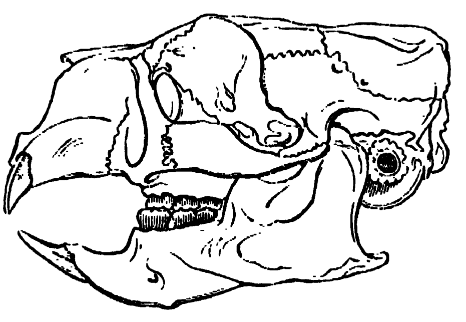
(Brown's ***Prodromus Floræ Novæ Hollandiæ;*** Bartling's ***Ordines, Naturales;*** Lindley's ***Introduction to the Natural System;*** and Nees von Esenbeck's ***Exposition,*** in the third volume of Dr. Wallich's ***Plantæ Asiaticæ Rariores.***)

ACA'NTHION, in Zoology, a genus of *Rodentia,* established by M. F. Cuvier, and embracing two species, which are only known, at present, by their osteology. In the number and form of their teeth,



Skull of Acanthion.

these animals agree in all respects with the common porcupine, from which, indeed, they only differ in the general form or outline of the cranium, and the comparative development of the bones of the face and skull; characters which have no very assignable influence upon the habits and economy of animal life. There has been some difference among zoologists as to the use of this term. Thus, *Acanthion* of F. Cuvier is *Acantherium* of J. E. Gray, whilst the *Acanthion* of Gray includes both the genera *Hystrix* (Porcupine) and *Acanthion* of F. Cuvier. (Waterhouse, *Rodentia.*)

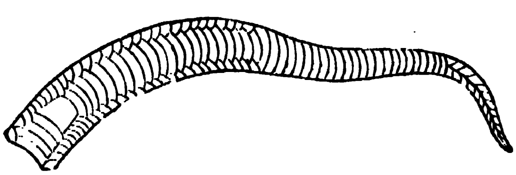


Skull of Porcupine.

ACANTHODE'RMA, a fossil genus of fishes, from Glaris. (Agassiz).

ACANTHO'DES, a genus of fossil Ganoid fishes, established by M. Agassiz. The species occur in the carboniferous strata near Edinburgh. (Agassiz.)

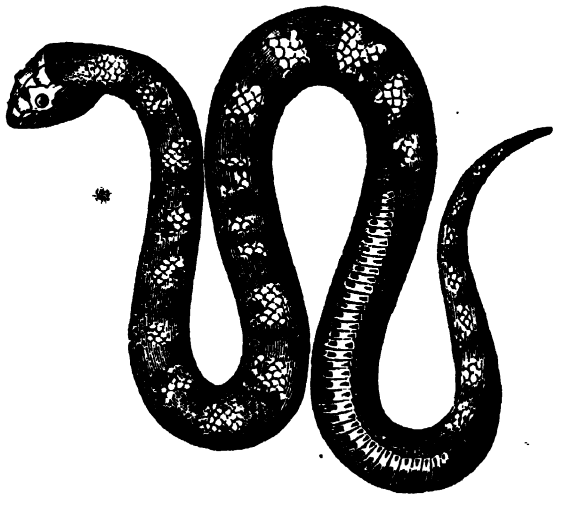
ACA'NTHOPHIS (from ἄκανθα, a thorn, and ὄφις, a snake), in Zoology, a genus of venomous serpents, allied to the vipers, but distinguished by having a single series of plates beneath the tail, except towards the very extremity, where they are, in some cases, separated into two small rows. The bodies and tails of these animals are elongated and cylindrical; their heads round, obtuse, rather prominent over the eyes, and covered in front with nine or ten polygonal plates. The back and upper surface of the tail are covered with reticulated scales of a rhomboidal form; the breast and belly are covered with single transverse plates, as is likewise the tail, excepting towards the very extremity, which is sometimes furnished with a double row of plates, as in the common viper. The tail is terminated by a little spur, or horny excrescence, which has suggested the name of *Acanthophis* (that is 'thorn-snake') for this genus. It springs out of the very end of the tail, and does not appear to be of the same utility as the two horny spurs which grow upon each side of the anus in the Pythons and Boas, and which, being retractile, or capable of being erected and depressed at will, execute important functions in the economy of these animals.



Tail of *Acanthophis*.

The head of the *Acanthophis* is broad and compressed, the mouth capable of great distension, and furnished on each side, besides the retractile poison-fangs common to all the family of truly venomous serpents, with a double row of sharp curved teeth. The species of this genus are of small size, reside on the surface of the dry land, and feed upon frogs, lizards, and small mammals. They are viviparous, and secrete themselves in rat-holes, or beneath the roots of trees. They never strangle or crush their prey by coiling themselves round its body, but expect a more speedy and certain victory from the deadly effects of their poison. The species best known are—

The *Acanthophis cerastinus*, first described by Merrem, and so named from the general similarity which it bears, at first sight, to the *Cerastes*, or Horned Viper, in its short body, large flat head, and eyes surmounted by prominent scales. The length of this species is about fifteen inches, of which the tail measures rather more than a fifth part; the body is thick in proportion to its length, having a circumference of two inches and a half in the middle, from whence it gradually tapers towards either extremity. The native country of this species is unknown.



Acanthophis cerastinus.

The *Acanthophis Brownii* is briefly described by Dr. Leach, and figured in the first volume of the 'Naturalist's Miscellany.' The specific name is given out of compliment to Mr. Robert Brown, the celebrated botanist, from whose manuscripts the brief description of Dr. Leach was taken. The body is said to be of a uniform dark brown, the under lip whitish, the upper with a transverse groove in front, the tail small and rather abruptly contracted at its junction with the body, and the apex compressed laterally. This is probably the Death Adder, or Tammem, referred to by Mr. G. Bennett, in his 'Wanderings in New South Wales.' It is a hideous and exceedingly venomous reptile.

ACANTHOPTERY'GII (from ἄκανθα, a thorn, and πτέρυξ, a wing), in Zoology, one of the three primary divisions, or natural orders, of fishes. The fishes are divided into three orders—the *Chondropterygii* (from χόνδρος, cartilage, and πτέρυξ, a wing or fin), or cartilaginous fishes, without a solid bony skeleton; *Acanthopterygii*, fishes having bony skeletons with prickly spinous processes in the dorsal fins; and *Malacopterygii* (μαλακός, soft, and πτέρυξ, a wing), fishes with bony skeletons indeed, but with soft articulated radii in the dorsal fins. These divisions were first employed by Willughby and Ray. Cuvier divides the Acanthopterygious Fishes into fifteen natural families, which he calls after the names of their typical or most common genera.

1. *Percidæ*, including the common Perch, the Sea-Perch, the Barber of the Mediterranean, the Weevers, the Stargazers, and the Sea-Pike.

2. *Triglidæ*, which include the Gurnards, the Flying-Fishes, the Bull-Heads, the Miller's-Thumb, and the Sticklebacks.

3. *Sciænidæ*, which include the Maigres, the Stone-Perch, the Drumheads, the Red-Throats, and a number of other fishes less known.

4. *Sparidæ*, including the Sea-Breams, the Spanish Bream, the Gilt-Head, and Black Bream.

5. *Menidæ*, a small family whose species are not much known.

6. *Squamipennes*, including the Chætodons and other curious fishes, as the Coachmen, the Horsemen, and others.

7. *Scomberidæ* include the Mackerel, the Tunnies, the Sword-Fishes, the Pilot-Fishes, the John-Dory, and the King-Fish.

8. *Tænidæ*, including the Scabbard-Fish, the Hair-Tail, Red-Band-Fish, and others.

9. *Theutyes*, including the Lancet-Fishes, and some other genera remarkable for their powerful cutting spines.

10. *Anabadæ* include the Climbing Perch and other allied fresh-water fishes.

11. *Mugilidæ* include the Gray Mullet, the Ramando of Nice, and some others.

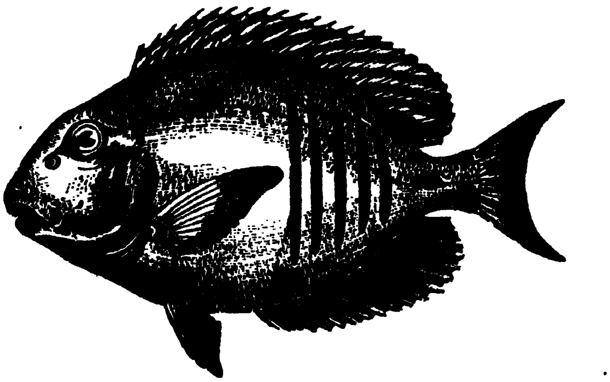
12. *Gobiodæ* include the Blennies, the Gobies, or Sea-Gudgeons, and the Dragonet.

13. *Lophiadæ* include the Anglers, the Fishing-Frog, or Sea-Devil, and the Frog-Fishes.

14. *Labridæ* include the Wrasses, or Rock-Fishes, the 'Old Wives of the Sea,' the Captains, and the Scarus.

15. *Fistularidæ*, include the Pipe-Mouths, the Snipe-Fish, the Sea-Trumpet, or Bellows-Fish.

ACANTHU'RUS (from ἄκανθα, a thorn, and οὐρά, a tail), a genus of Acanthopterygious Fishes. It contains a great number of species, many of which are remarkable for the beauty of their external forms, and the variety of their colours. They are distinguished from proximate genera by the form of the body and tail, which are exceedingly compressed; by their trenchant teeth, denticulated like a very fine comb; but above all by the moveable spines, edged and sharp like a lancet, with which they are armed on each side of the tail, and with which they inflict dangerous wounds upon the hands of those who touch them incautiously. It is this circumstance that has acquired for the *Acanthuri* the name of Doctors and Lancet-Fishes, by which they are well known to the English sailors and colonists. These animals have the mouth small, and the muzzle rather advanced. They are among the small number of fishes which live entirely upon vegetable substances, feeding only upon *Fuci*, and other marine plants; their intestinal canal is consequently longer and more complicated than in other species, and their flesh has a peculiar flavour, very different from that of fishes in general. The dangerous weapons with which nature has provided these otherwise harmless fishes are well calculated to defend them from the attacks of their enemies. They abound in all the tropical seas, both of the East and West Indies, and are never known to advance beyond the tropics; consequently they are unknown in the more temperate latitudes.



Chætodon Chirurgicus. (Bloch.)

ACAN'THUS. Under this classical name have been described, by ancient authors, at least three totally different plants. Firstly, a prickly tree with smooth evergreen leaves, and small round saffron-coloured berries, frequently alluded to by Virgil; this is conjectured to have been the Holly. Secondly, a prickly Egyptian tree, described by Theophrastus as having pods like those of a bean; it is probable that this was the *Acacia Arabica*. Thirdly, a herb, mentioned by Dioscorides, with broad prickly leaves, which perish at the approach of winter, and again sprout forth with the return of spring. It is said that the idea of the Corinthian capital of Greek columns was taken from some of the leaves of this *Acanthus*. To this latter plant the name is now applied. The word, in all cases, alludes to the prickly nature of the leaves or stems.

In modern botany *Acanthus* is a genus of herbaceous plants found in the south of Europe, Asia Minor, and India, belonging to the natural order *Acanthaceæ*.

Acanthus spinosus.

The commonest species is *Acanthus mollis*, or Brankursine, a native of many parts of the South of Europe, growing in shady moist places, among bushes. Its stem is about two feet high, and is covered from the middle to the top with fine large white flowers, slightly tinged with yellow. The leaves are large, soft, deeply cut, hairy, and shining, and surround the lower part only of the stem. Both the leaves and the roots, which are perennial, abound in mucilage, which has caused them to be substituted in domestic medicine for the marsh-mallow. It is this species which is usually supposed to have given rise to the notion of the Grecian capital. But it appears, from the investigation of Dr. Sibthorp, that it is nowhere to be found, either in the Greek islands, or in any part of the Peloponnesus; and that the plant which Dioscorides must have meant was the *Acanthus spinosus*, still called **ἄκανθα**, which is found, as he describes it, on the borders of cultivated grounds, or of gardens, and is frequent in rocky moist situations. This species differs from *A. mollis* in having a dwarfer stem, flowers tinged with pink instead of yellow, and spiny leaves, much more deeply cut. Both the one and the other are half-hardy perennials, increased by division of the summit of the root. They have been long cultivated in the gardens of Great Britain, but perish if not protected from severe frost.

A'CANUS, a fossil genus of fishes, from Glaris. (Agassiz.)

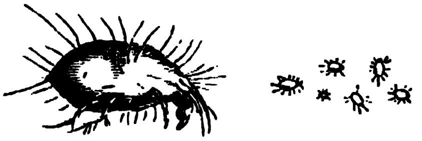
ACA'RIDÆ, a division of *Arachnida* [Arachnida], which comprehends the small spider-like animals popularly termed Mites (*Acari*), as well as Water-Mites and Ticks. Some of these are wanderers on land or in water; others are fixed upon various animals, whose blood or humours they suck, and even insinuate themselves beneath the skin, and often multiply prodigiously.

These minute animals are not considered by modern naturalists to rank among insects, on account of their structure being very different, and from their having, in most cases, like spiders, eight feet, while no insect has more than six feet. Their mouths, in some, are furnished with jaws (*mandibulæ*), either having pincers or claws, but concealed in a projection of the breast-plate (*sternum*) in form of a lip; in others it is in the form of a syphon or sucker; and in others it presents a simple cavity. M. Latreille makes four divisions of the *Acaridæ*:—1, Mites (*Trombidites*); 2, Ticks (*Ricinites*); 3, Water-Mites (*Hydrachnellæ*); and 4, Flesh-Worms (*Microphthira*).

All the creatures now embraced in this family were included by Linnæus under his genus *Acarus*, and the whole of the species are popularly called Mites, or *Acari*. They are all very minute, some being almost microscopical. They are very generally distributed. Some are parasitic, whilst others are free. The itch is now well known to owe its existence to a creature of this tribe. Others live naturally in the human skin, whilst beetles and other insects are very liable to be attacked by them. They are found on the leaves, fruit, flowers, and bark of plants; and on all kinds of provisions, as flour, dried meat, dried cheese, and putrid animal matters.

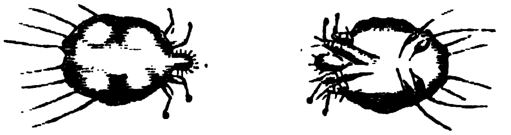
Amongst the true Mites (*Trombidites*, Latreille), the following common forms are placed:—

The Domestic Mite (*Acarus domesticus*, De Geer), is very commonly found in collections of insects and stuffed birds, and is exceedingly destructive to cabinets. Camphor has some effect in destroying this pest, but is not powerful enough to prevent it altogether. Moistening the specimens with a weak solution of corrosive sublimate, is said to prove an effectual preventative. The species found in flour and on food is called *A. Farinæ*.



Domestic Mite (*Acarus domesticus.*)

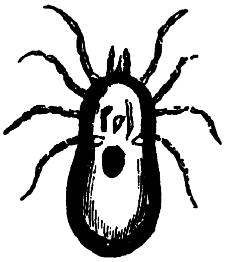
The Itch Mite (*Acarus Scabiei*, Fabricius, *Sarcoptes Galei*, L.) is a microscopic animal, found under the human skin in the pustules of a well-known cutaneous disease. It has a remarkable suctorial apparatus, by means of which it secures its hold under the epidermis of the skin, into which it has the power of penetrating. This animal is most effectually destroyed by sulphur; and indeed this is a specific for the disease which the *Acarus* produces.



Itch Mite (*Acarus Scabiei.*)

The Sugar Mite (*Acarus saccharinum*) is found in the brown sugar of commerce. Thirty-five out of thirty-six specimens examined by the analytical commissioners of 'The Lancet,' bought in the shops of London, in 1850, were found to contain these creatures.

The Red Spider of the hot-houses is the *Acarus tellarius*. It is the pest of hot-houses and green-houses. Though so small as scarcely to be seen by the naked eye, its effects on plants are very obvious. These creatures live upon the juices of the plant which they attack, and also prevent the function of the leaves from being properly performed. They are best destroyed by sulphur. The mode of applying it is to sprinkle the sulphur on the hot pipes or on plates; afterwards, the plants should be syringed. Other species, as *A. hortensis*, *A. holosericeus*, *A. geniculatus*, attack various plants, and the best way of treating them is the same as the above.



Sparrow Mite.

The Sparrow Mite (*Acarus passerinus*, Fabricius) is distinguished by the remarkable size of its third pair of legs. Geoffroy called it the Bat Tick, and Latreille formerly placed it in his genus *Sarcoptes*.

A very interesting form of these creatures is that first described by Dr. Simon, of Berlin, as inhabiting the sebaceous sacs and hair-follicles of the human skin. He called it an *Acarus*, but Professor Owen regards it as a lower form of one of the higher divisions of *Arachnida*. He names it *Demodex Folliculorum*. It has also been described in this country by Mr. Erasmus Wilson, under the name of *Entozoon Folliculorum*. It has an elongated body, with eight short legs, and is found very commonly in the sebaceous follicles of the nose. In its parasitical habit it resembles some of the lower forms of the *Crustacea*, as the *Cymothoe* and *Bopyrus;* and, perhaps, through the *Tardigrada*, it has a relation with the *Rotifera*.

The Ticks (*Ricinites*, Latreille) are, some of them free, some parasitic. The latter have no eyes. They embrace the genus *Ixodes*, which are well known from attacking cows, horses, dogs, and even tortoises. They bury their suckers so deeply in the skin, that they frequently cannot be taken away without tearing the flesh. They deposit a prodigious quantity of eggs, which are discharged from the mouth. The genus *Argas* is found on pigeons and other birds. The *A. Persicus* is the venomous bug of Miana.

The Water Mites (*Hydrachnellæ*) live only in the water. They are often parasitic or aquatic insects. Dugès has recently made some important observations on the development of these mites, in which he shows that in their earlier stages of growth they have but six legs. If this be correct, it will probably lead to the rejection of Latreille's fourth division, the *Microphthira*, which are characterised by possessing six legs, as they are probably only earlier stages of some of the higher forms.

ACARUS. [ACARIDÆ.]

ACCIPENSER. [STURIONIDÆ.]

ACEPHALOCYST, one of the simplest forms of *Entozoa*, also called *Hydatid*. [ENTOZOA.]

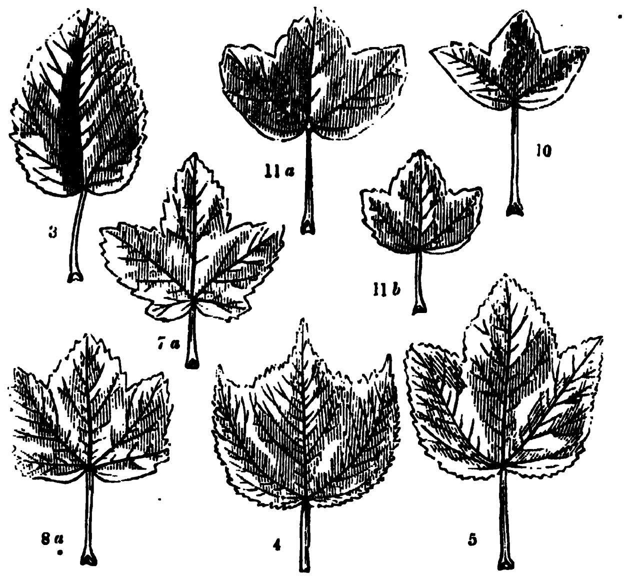
ACER, a name given by the Romans to a tree called *Maple* by the English. It is now applied to a genus of arborescent or shrubby plants, many of which are extremely valuable for the sake either of their timber or of their ornamental appearance. It is the type of the natural order *Aceraceæ*. It has the following characters:—Flowers green and inconspicuous, either containing stamens only, or pistils only, or both united, upon the same individual. Calyx divided into five lobes, of uncertain length. Stamens occasionally five; more frequently varying from seven to nine. Leaves in all cases simple. Fruit double; each division containing one single-seeded cavity, and extended at the back into a kind of wing, called *Key* in English, or *Samara* by botanists.

1. *Acer oblongum*, Oval-Leafed Maple, an evergreen tree, of rapid growth, native of the northern parts of India, both in Nepaul and Kumaon. It is probably confined to the hot valleys of those regions, for it has been found incapable of supporting the climate of England.

2. *Acer lævigatum* (Wallich), the Polished Maple. Leaves oblong, taper-pointed, slightly serrated, shining, green beneath. Flowers white, in branched erect thyrses. Keys broad, short, smooth. It is found in the woods of the higher mountains of Nepaul, and also in the Alps of Sirmoor, where it acquires a trunk thirty or forty feet high, and from three to four feet thick. Its growth is slow; its timber is said by Dr. Wallich to be used by the inhabitants of Nepaul for rafters, beams, and similar building purposes.

3. *Acer Tataricum* (Linnæus), the Tartarian Maple. Leaves heart-shaped, oblong, unequally serrated, usually undivided. It forms an ornamental tree, or rather large bush, from fifteen to twenty feet high, often met with in gardens and plantations. Its native countries are the southern provinces of Russia in Asia, whence it extends as far as Hungary, there finding its most western limit. From its keys, deprived of their wings, the Calmucs form, by the aid of boiling water, an astringent beverage, which, mixed with an abundance of milk and butter, forms a favourite article of their diet. The wood is hard and white, mixed with brownish veins.

4. *Acer striatum*, the Striped-Bark Maple (*A. Pennsylvanicum*, Linnæus). Leaves roundish, finely serrated, divided at the upper end into three nearly equal tapering lobes; when young, covered with a mealiness, which is gradually thrown off as they increase in size. It is a native of North America, from Canada to the high lands in Georgia. In those countries it forms a considerable part of the undergrowth of the woods, among sugar-maples, beeches, birches, and hemlock-spruce firs. It rarely exceeds eight or ten feet in height, except in a very few favourable situations, when it will occasionally grow double that height. Its wood is very white, and is used by the North Americans for inlaying cabinet-work; its shoots afford food to various animals, especially to the moose-deer, in winter and spring, whence it has acquired the name of Moose-Wood. In Europe it is occasionally seen in plantations, where it is remarkable for the bright rosy tint of its young leaves in spring. When cultivated, it frequently grows to thrice its native size, in consequence of being grafted upon the Sycamore Maple.



Forms of the leaves of Species of Maple.

3. *A. Tataricum.* 11 *a* and *b*. *A. Creticum.*
10. *A. monspessulanum.* 7 *a*. *A. opulus.* 8 *a*. *A. obtusatum.*
4. *A. striatum.* 5. *A. barbatum.*

5. *Acer barbatum* (Michaux), the Bearded Maple. Leaves heart-shaped, three-lobed, nearly equally serrated; the lobes of nearly equal size, or the lateral ones much the smallest; nearly smooth beneath. It is a native of deep pine and cedar swamps in Jersey and Carolina, where it forms a small tree.

6. *Acer spicatum*, the Spike-Flowered Maple (*A. montanum*, Aiton). Leaves heart-shaped, smooth above, downy and glaucous beneath, of an oblong figure, with about five unequal, tapering, coarsely and unequally serrated divisions. It is a native of the United States and Canada. The red colour of its keys in the autumn forms its principal beauty.

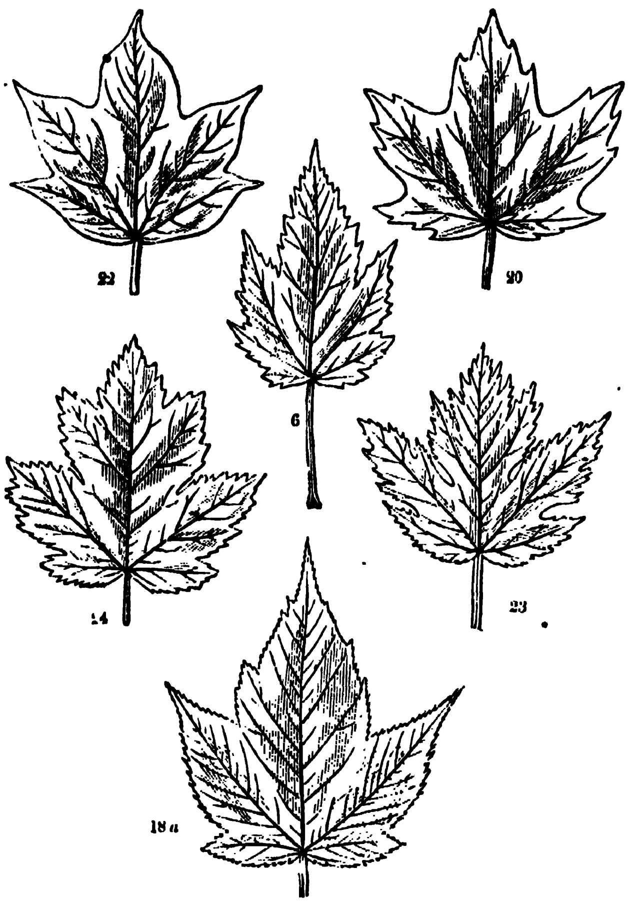
7. *Acer opulus* (Aiton), the Gueldres-Rose-Leaved Maple. Leaves more or less heart-shaped, roundish, five-lobed, smooth beneath. It is a small tree, ten or twelve feet high, found in France, especially in Dauphiny.

8. *Acer obtusatum* (Willdenow), the Neapolitan Maple. Leaves heart-shaped, roundish, five-lobed, woolly beneath; the lobes either obtuse or pointed, and coarsely serrated. Flowers in drooping corymbs. Hungary, Croatia, and many parts of Italy, produce this beautiful species. On all the hills and lower mountains of the kingdom of Naples, in Camaldoni, Castellamare, and the Abruzzi, it is found abundantly, growing usually to the height of forty feet; it is extremely striking, with its reddish-purple branches, in the wood of Lucania, between Rotonda and Rubia; and in the Basilicata and Calabria it is said, by Tenore, to acquire colossal dimensions. It is certainly very singular that so fine a tree as this, occupying so large a tract of country, frequently visited by English tourists, should be almost unknown in this country; and yet, although it is perfectly hardy, and very easily multiplied, it is scarcely ever met with in any but botanical collections. There are two forms of the leaf—one with blunt, and the other with pointed lobes.

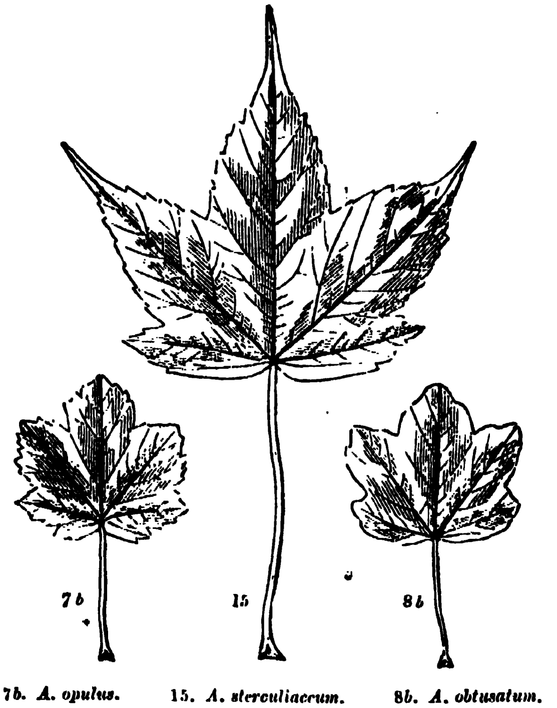
9. *Acer campestre* (Linnæus), the Common Maple. Leaves heart-shaped, with three or five deep segments which are not serrated, but generally two-lobed or three-lobed, and narrow at their base; downy beneath—at least, when young. Branches covered, when old, with a corky bark. Flowers in erect, branched, downy corymbs. Keys short, smooth, with nearly parallel edges, diverging at right angles. Found in every hedge-row in England, and spread over the greater part of Europe. It is said not to be indigenous in Scotland, and on the continent it does not approach the north nearer than the southern provinces of Sweden. It advances as far to the eastward as the range of the Caucasus, where it disappears. In England this is either a bush or a small tree, of inelegant appearance, and its wood is of little value, except for the use of the turner, who makes it into cups, bowls, &c. The Common Maple is sometimes planted by farmers upon bad land, for the purpose of fencing; for which, however, it is ill adapted.

10. *Acer Monspessulanum* (Linnæus), the Montpellier Maple. Leaves deciduous, very slightly cordate, and downy at the base, with three perfectly entire, nearly equal, diverging lobes, slightly hairy beneath.

It is found in dry stony situations in Languedoc, Dauphiny, Provence, and Piedmont; it even occurs as far north as the departments of the Rhine.



22. *A. Lobelii.* 20. *A. saccharinum.* 24. *A. rubrum.*
23. *A. eriocarpon.* 18a. *A. caudatum.* 6. *A. spicatum.*



7b. *A. opulus.* 15. *A. sterculiaceum.* 8b. *A. obtusatum.*

11. *Acer Creticum* (Linnæus), the Candian Maple. Leaves evergreen, variable in form, wedge-shaped at the base, leathery, glossy, smooth, with three entire or serrated lobes, of which the side ones are the shortest, sometimes undivided. It is a native of the mountains of Candia and the Grecian Archipelago; it is frequently cultivated in the South of Europe.

12. *Acer heterophyllum* (Willdenow), the Variable Maple. Leaves evergreen, ovate, unequally-serrated, entire or occasionally three-lobed, very glossy. This is the plant sold in the English nurseries under the name of *A. Creticum.* It is rather delicate, and is a native of the Levant.

13. *Acer pseudo-platanus* (Linnæus), the Sycamore Maple. Leaves heart-shaped, coarsely and unequally serrated, glaucous and downy on the veins beneath; with five lobes, of which the lower ones are generally the smallest. This noble tree is scarcely met with in a truly wild state beyond the limits of middle and southern Europe: it is occasionally seen on the lower ridges of the Caucasus, and does not appear to extend much farther eastward. In Italy it is said to arrive at its greatest degree of perfection, acquiring the height of 50 and 60 feet. Its English name has originated in an erroneous notion that this is the sycamore of Scripture—a totally different tree, the *Ficus Sycamorus.* It flourishes in many parts of England: many varieties are known to gardeners.

14. *Acer macrophyllum* (Pursh), the Broad-Leaved Maple. Leaves deeply heart-shaped, not serrated, divided into five deep, spreading, slightly-lobed segments, the middle one of which is often narrow at its base, and the lower ones generally smaller than the others; when young slightly downy, when old shining and perfectly smooth: is a native of the north-west coast of North America, where its timber is used.

15. *Acer sterculiaceum* (Wallich), the Shady Maple, is a large tree, with a trunk often three feet in diameter; found in Nepaul.

16. *Acer villosum* (Wallich), the Shaggy Maple, is a very large tree, found on the Himalaya Mountains, approaching the limits of perpetual snow in Sirmoor and Kumaon.

17. *Acer cultratum* (Wallich), the Curve-Keyed Maple, is a large tree, native of the regions towards the Himalayas, in Kumaon and Srinaghur.

18. *Acer caudatum* (Wallich), the Long-Pointed Maple. It is a native of the highest regions of Nepaul, of Sirmoor, Kumaon, and Srinaghur.

19. *Acer Platanoïdes* (Linnæus), the Norway Maple. Leaves heart-shaped, very smooth, except at the axils of the veins; five-lobed, the lobes taper-pointed and diverging, with a few taper-pointed diverging teeth. This is a fine tree, with very handsome glossy deep-green leaves, for the sake of which it is a great deal cultivated. The northern and midland parts of Europe, and the north of Asia, as far as the Ural Mountains, produce this species. In the Russian Empire it passes from the state of a shrub, in the northern provinces, to that of a handsome tree with a trunk two feet thick, in the more southern districts. Its wood is valued for turners' work. From its ascending sap a kind of coarse sugar has been procured, in the same way as from the *A. saccharinum,* in America. Two varieties are known to gardeners; one, the Silver-Striped, in which the leaves are slightly stained with white; and the other, the Cut-Leaved, in which the leaves are deeply and irregularly jagged. When the foot-stalks of the leaves are broken they exude a milky fluid.

20. *Acer saccharinum* (Linnæus), the Sugar Maple. Leaves heart-shaped, glaucous beneath, very smooth, except at the axils of the veins; five-lobed, the lobes taper-pointed, and very coarsely toothed. Flowers in nodding corymbs. Keys not much diverging. From a little to the north of the Saint John, in Canada, to the woods of Upper Virginia, and probably still farther south, this species prevails; and it forms a large portion of the vegetation of New Brunswick, Nova Scotia, Vermont, and New Hampshire, sometimes becoming as much as 80 feet high. In the autumn the woods of those countries are dyed of a crimson hue by the changing leaves of the Sugar Maple. The wood is hard, and has a satiny lustre, but it is readily attacked by insects, and is not of much value, except when its grain is accidentally waved, and then it is in request for the cabinet-makers. The younger Michaux states, that it may be at all times known from that of the Red Maple by a very simple test. If you pour a drop or two of solution of sulphate of iron upon the wood of the Sugar Maple, in a minute it becomes of a greenish cast, while that of the Red Maple becomes deep blue. The saccharine matter contained in its ascending sap is the principal cause of this species being in so much request. From this, obtained by tapping the trunk in the spring during the space of six weeks, a very considerable quantity of a fine brown sugar is procured; as much, it is said, as 33 lbs. per tree. The Sugar Maple does not generally succeed very well in England, where it is rarely seen; and even when in health does not attain a height of more than fifteen or sixteen feet.

21. *Acer nigrum* (Michaux), the Black Sugar Maple. This plant is a native of similar situations with the last, of which perhaps it is only a variety.

22. *Acer Lobelii* (Tenore), Lobel's Maple, is found among the mountains in the north of the kingdom of Naples.

23. *Acer eriocarpon* (Michaux; *A. dasycarpum,* Willdenow), Sir Charles Wager's Maple is found in most parts of North America on the eastern side, where it is commonly called White Maple. It grows with great rapidity, and is extremely common in the plantations of all Europe, where it is remarkable for the deep crimson hue of its leaves in autumn. Its wood is light, and of little or no value except to the

turner. It is said to make excellent charcoal for gunpowder. The nurserymen usually call this species the Cut-Leaved Scarlet Maple.

24. *Acer rubrum* (Linnæus), the Red or Scarlet Maple. The deep-red colour of the flowers in the spring, and of the keys and leaves in autumn, have given rise to the name of this species, which is found, from Canada to Florida, growing in swamps along with alders. Its wood is used by the Americans for articles of furniture, and is also in request for the stocks of rifles—for which, when it is what they call 'curled,' its toughness renders it well adapted. Two varieties of this species are cultivated in this country, under the names of *A. coccineum* and *A. intermedium.*

25. *Acer circinatum* (Pursh), the Curled Maple, grows on the north-west coast of North America, and is a small, scrubby, worthless tree.

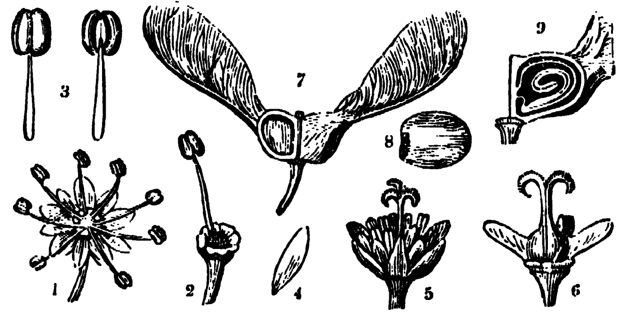
Cultivation.—The hardy maples, which are the only kinds of any importance in this country, are all increased either by seeds or layers. The European species readily yield their keys, which should be gathered when fully ripe, and immediately buried in heaps of river sand, where they may remain till the following February; they may then be sown in beds, rather thinly, and, when one year old, should be transplanted, and treated like other forest trees. They ought never to be headed back, as oaks and Spanish chestnuts are. From layers they all make excellent plants very rapidly. They are occasionally budded upon the common sycamore, but this mode is little practised in England.

ACERAS, a genus of Orchidaceous plants, of which one species, the *A. anthropophora,* is found growing in Great Britain. It is a small plant, from 8 to 12 inches in height. It has a long lax spike of greenish yellow flowers, the parts of which are so arranged as to give them the appearance of the small figure of a man: hence this plant has been called the Man-Orchis.

ACERATHE'RIUM. Some Fossil *Rhinocerata* have been thus named by Kaup.

ACERDESE, in mineralogy, a hydrous sesquioxide of Manganese, called also *Manganite.* Varieties of it have been called *Newkirkite* and *Varoacite.*

ACERACEÆ, an order of Polypetalous Dicotyledons. Their flowers are unsymmetrical, their stamens hypogynous, their fruit is winged, and their petals have no appendages upon them. The species are all trees or shrubs, with opposite stalked exstipulate leaves, and are found exclusively in the north of Europe, Asia, America, and India. A sweet mucilaginous sap is common in these plants, from which sugar can be manufactured.



1. Unisexual Flower. 2. Stamen on Disk. 3. Stamens separate. 4. Petal. 5. Bisexual Flower. 6. Pistil. 7. Fruit. 8. Seed. 9. Embryo.

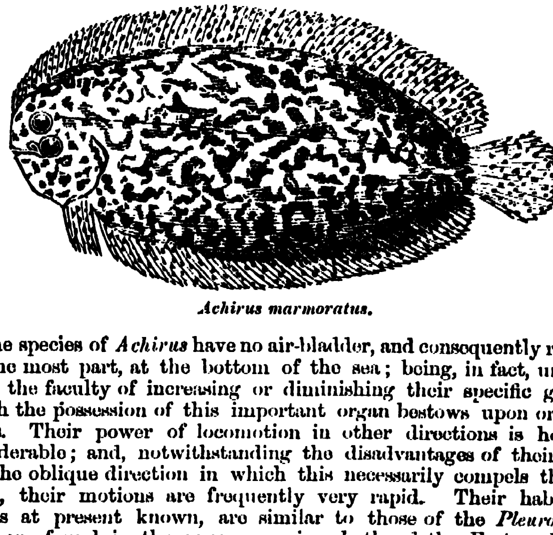
ACERVULA'RIA, a genus of Fossil *Madrephylliœa.*

ACHILLEA, a genus of plants belonging to the natural order *Compositæ,* consisting of 60 or 70 species, found exclusively in the colder climates of the northern hemisphere. This genus is found in the suborder *Corymbiferæ,* and is distinguished by the florets of the disk being hermaphrodite and tubular, and the tube being plane, compressed, and two-winged. The fruit is compressed, and has no pappus. There are five British species. *A. Ptarmica* is an abundant plant, and on account of its strong odour is called Sneezewort. *A. millefolium* has got its specific name from the segmented character of its leaves. It is called in English Millefoil and Yarrow. This plant has the tonic and stimulant properties of the sub-order to which it belongs in a slight degree, and on that account has been employed as a remedy in some diseases, but its medical properties are very feeble.

ACHILLE'UM, a genus of Fossil *Spongiadæ,* of which two species occur in the cretaceous strata of England. (Goldfuss.)

ACHIME'NES (from *α*, prefix, and *χεῖμα*, winter), a genus of plants belonging to the order *Gesneraceæ.* The species of this genus are very numerous, and, although not useful, they are many of them extensively cultivated, on account of the beauty of their flowers. In consequence of their general culture, a great many varieties of the species are becoming known. After flowering, the stems die down; and the tubers should be dug up, and kept free from frost and wet till January, when, by planting them in succession, flowers may be obtained till the summer. They may be planted in a mixture of loam and leaf-mould, with a little silver sand. They can be placed out in the summer, but require shading on hot days.

ACHI'RUS, a genus of flat-fish, belonging to the sub-branchiate division of *Ma'acopterygii.* In external form these fishes resemble the common sole. Like the *Pleuronectes* in general, they have the body and tail very much compressed, and the eyes both on the same side of the head; but they are easily distinguished from all other genera of flat-fish by the total want of pectoral fins.



Achirus marmoratus.

The species of *Achirus* have no air-bladder, and consequently remain, for the most part, at the bottom of the sea; being, in fact, ungifted with the faculty of increasing or diminishing their specific gravity, which the possession of this important organ bestows upon ordinary fishes. Their power of locomotion in other directions is however considerable; and, notwithstanding the disadvantages of their form, and the oblique direction in which this necessarily compels them to move, their motions are frequently very rapid. Their habits, as far as at present known, are similar to those of the *Pleuronectes.* They are found in the warmer regions both of the East and West Indies, but not in deep water, or in situations far removed from land; they abound along the shores, and furnish a plentiful and wholesome food to the inhabitants.

Various species of *Achirus* have been enumerated by zoologists, the most remarkable of which appears to be the *Achirus marmoratus* of Lacépède. The flesh is of a delicate flavour, and highly esteemed: it inhabits the coasts of the Isle of France. The *Achirus pavonicus* is distinguished by the beauty of the spots, which, like the eyes on the peacock's tail, cover its body; and the *A. fasciculatus* and *A. bilineatus* are easily recognised by the characters from which they respectively derive their names. The former is found on all the coasts of America and the West Indies: the latter inhabits the shores of China, and feeds upon small crustacea and mollusca.

ACHLYA, a genus of Cryptogamous plants, belonging to the order *Conferraceæ.* It is composed of a single tubiform cell, which expands at the end into a large cell, which is cut off from the lower portion of the tube by the formation of a partition. In this enlarged cell a circulation of granular particles has been observed. In the course of time cells are formed in this enlarged cavity, and fill it up. The parent cell eventually bursts at some spot, and allows of the escape of the enclosed cells; but before this takes place the cells in the interior move about, and, after their escape, exhibit for a considerable time an active movement. They are good examples of the *Zoospore.* They soon attach themselves to some fitting object, and grow into little plants, like their parent. A similar process goes on in most of the *Algæ,* but is not so easily observed as in this case.

The only species of *Achlya* which has been described is the *A. prolifera,* which is found parasitic upon fish and other aquatic animals. This plant is more especially developed on fish and aquatic reptiles kept in confinement. It was first observed on gold fish, but several writers have described it as existing on other animals, as the Stickleback, Water Salamander, Frog, and Newt.

(*Reports on Botany,* Ray Society, 1845; Lindley's *Vegetable Kingdom.*)

ACHMITE. [EUCHYSIDERITE.]

ACHRAS, a genus of tropical plants belonging to the natural order *Sapotaceæ.* It has a calyx divided into six parts; a corolla monopetalous, divided into six lobes; stamens twelve, of which six are sterile and six fertile; and an ovarium, with from six to twelve cells. The fruit resembles an apple, with from one to twelve seeds, contained in hard bony nuts, which have a shining coat, and a long hard scar over the whole of their inner angle.

The genus contains only one species, which yields a copious milky fluid when wounded. Its leaves are entire, leathery, undivided, shining, of a lanceolate form, without stipules. The flowers are large, white, bell-shaped, and grow singly from the axils of the leaves. This is called, in the West Indies, the Sapodilla Plum. The fruit in size and shape resembles a bergamot pear; like the medlar, it is only eaten in a state of decay; before that period it is austere and uneatable, but in the proper state it is so rich and sweet as by some to be considered only inferior to the orange.

ACHYRA'NTHES, a genus of plants belonging to the order *Amarantaceæ.* *A. aspera* and *A. fruticosa* are used in India as remedies in dropsy. *A. globulifera* is used in Madagascar as a remedy in syphilis.

ACIDA'SPIS, a genus of fossil *Crustacea,* of the group of *Trilobites;* found in the Wenlock limestone. (Murchison.)

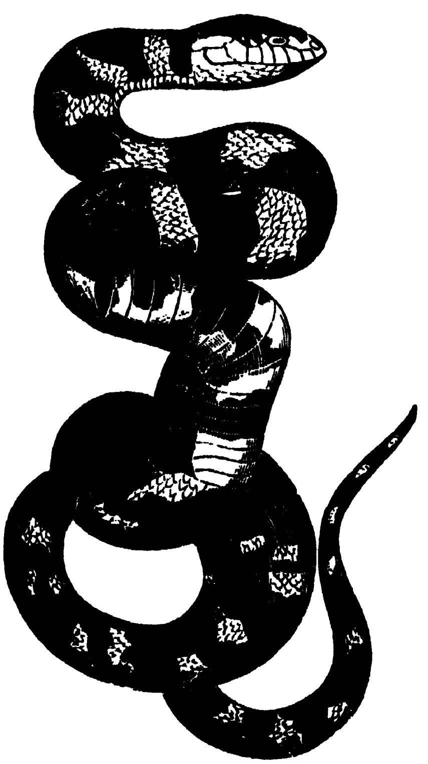
ACONITE, WINTER. [ERANTHIS.]

ACONI'TUM, a genus of plants belonging to the natural order *Ranunculaceæ.* From very early times it has borne the same name, and has been known for the dangerous properties of many of its species. They are all hardy herbaceous plants, many of them of great beauty; and are so easily cultivated, that one of them, *A. Napellus*, is found in every cottager's garden. The English call them Wolf's Bane. From all other ranunculaceous plants *Aconitum* is at once known by its having the very large uppermost segment of its calyx overhanging the petals and other parts in the form of a helmet.

Aconitum Napel us.

The common species, *A. Napellus*, is one of those in which the greatest degree of virulence has been found to reside. It is a native of alpine pastures in Switzerland and other mountainous parts of Europe. Its leaves are very dark green, deeply cut into from five to seven long segments. The stem is about three feet high. The flowers are in long, stiff spikes, and of a deep blue colour; they appear from May to July. All the parts of this plant are extremely acrid, especially the roots, which are scraped and mixed with food to form a bait for wolves and other savage animals. Poisonous properties are probably found in all the species of the genus. *A. cammarum*, *A. lycoctonum*, and *A. anthora* are certainly equally dangerous. None of them however, not *A. Napellus* itself, can be compared for fatal energy with the dreadful Bikh of Nepaul, the *Aconitum ferox*, which seems to possess the concentrated power of all the European species.

ACO'NTIAS (from ἄκων, a javelin), the name of a genus of serpents established by Cuvier, for the purpose of distinguishing certain species hitherto placed with the genus *Anguis*, or common snake. This genus is characterised by the absence of all the bones which represent the extremities in the genus *Anguis*, while it retains the structure of the head common to these animals and to the lizards, and has the body similarly covered with small scales only, without the horny plates which guard its under surface in the common serpents, and protect them from injury in the various rapid motions which they perform. The species of *Acontias* seem thus to afford a link between the common snakes and true serpents.



Acontias Meleagris

As might naturally be expected from this conformation, the progressive movements of the species of *Acontias* are very different from those of common serpents. They do not glide along the surface like these animals, but boldly carry their heads and breasts erect; and if closely pursued defend themselves courageously, and dart with the velocity of an arrow against their assailant. Though dreaded in their native countries, because confounded with their venomous congeners, these animals are perfectly harmless, and neither possess the means nor have the desire of being injurious. They have no poison fangs, and their cheek-teeth are so small as, in some species, to be barely perceptible. Their habits are gentle; and they are so timid that they generally fly at the least noise, or, upon the slightest appearance of danger, conceal themselves under some shrub or tuft of grass, or even bury themselves under-ground when no other refuge is at hand.

They are, generally speaking, of a small size; and, as their mouths are not susceptible of the enormous dilatation possessed by the true serpents, they are incapable of swallowing any animal approaching to their own dimensions, and feed upon worms and insects. Different species of *Acontias* are found in almost every part of the old world. The arid plains of Syria and Palestine produce a species which has been mentioned by the prophet Isaiah (xxxiv., 15), under the Hebrew denomination *Kippoz*, improperly translated 'the great owl' in our common version of the Sacred Scriptures, but which the learned Bochart ('Hierozoicon,' pars post. lib. iii. cap. xi.) has shown to refer more properly to the *Acontias*, or *Anguis jaculus*, the Dart Snake of the Greeks and Romans. Other species inhabit Asia Minor, Egypt, and Persia; India and China have also their *Acontias;* and the Cape of Good Hope produces a species without eyes.

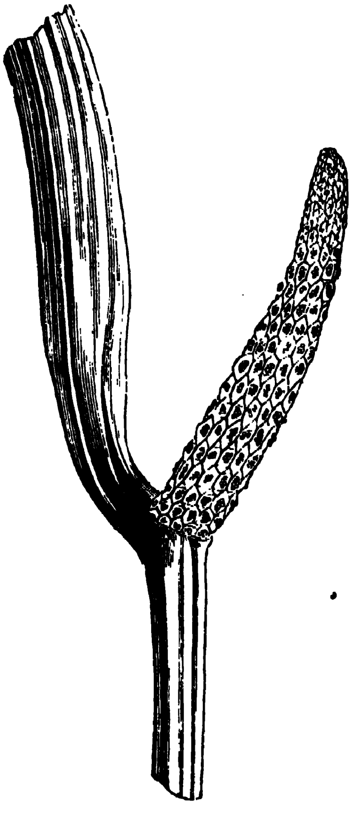
Of the common Egyptian Acontias many fables are recorded by ancient authors, principally arising from confounding this really harmless species with the more deadly and venomous serpents of the same localities.

ACORI'NÆ, ACORI'DEÆ, or ACORA'CEÆ, a small natural order of Endogens, with the following essential character:—The flowers are hermaphrodite, surrounded with scales. The spathe is leaf-like, but not rolled up. The stamens are complete, placed opposite the scales, and have two-celled anthers which are turned inwards. The ovaries are distinct. The fruit is baccate, juicy at first, but finally juiceless. The seeds have the embryo seated in the axis of a copious albumen. The rootstock is jointed; the leaves sword-shaped, and embracing each other in the bud. Such is the character given this order, which was

distra. The two last genera are now assigned by the same author to the order Liliacea. This small group of plants in its geographical distribution is confined to the eastern hemisphere. None of them have the acrid properties of some of the *Araceæ*. The *Acorus Calamus* is a British plant, and has slightly aromatic properties.—(Lindley, *Vegetable Kingdom.*)

ACORN, the English name of the fruit of the oak. [QUERCUS.]

A'CORUS, the botanical name of the plant that produces the drug called in the shops *Calamus aromaticus*. It is the type of the natural order *Acoraceæ*. It is found abundantly in the fresh-water marshes of many parts of England. It has a perennial, creeping, horizontal stem, as thick as the finger, the whole of the under side of which sends down roots into the mud or earth, in which the plant uniformly grows. From this spring many deep-green sword-shaped leaves, about three feet long. In the midst of all is a leaf-like stem, from below the point of which protrudes a cylindrical or rather conical spadix of greenish flowers, which are so closely packed together that the stalk is not to be seen. The leaves when bruised are fragrant; for which reason they were formerly employed to strew the floors of rooms, or of churches, under the name of rushes. This practice is still maintained in some places, where the plant is common, as at Norwich, the cathedral of which city is strewed with sweet rushes upon certain high festivals. The flowers are so seldom produced, that it is a common belief that they never are borne. *Calamus aromaticus* is slightly aromatic, and is occasionally used as a stimulant; but is of very little importance. The part employed is the dried creeping stem, or, as it is improperly called, root.



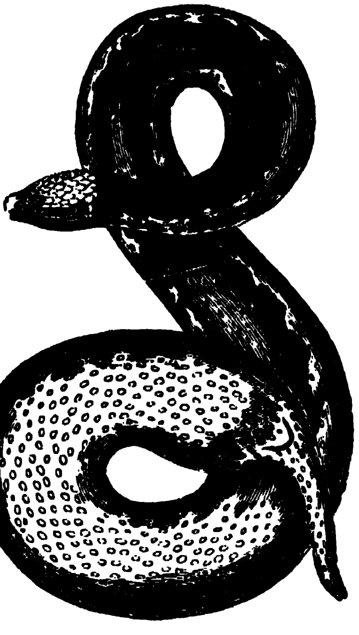
Acorus Calamus.

ACOTYLE'DONES, or ACOTYLEDONEÆ, the name of the first class in Jussieu's 'Natural System of Botany.' It is derived from the circumstance of all the plants which it comprehends vegetating without the aid of the seed-lobes called cotyledons. Such plants are also in all cases destitute of flowers, and are in fact the same as what Linnæus called *Cryptogamia*. They are also called *Cellulares*.

ACOUCHY, a small species of Cavy. [AGOUTI.]

ACRITA (from ἄκριτος, indistinct), a division of the class *Radiata*, adopted by Owen, and applied to the *Acalephæ*, the *Polypifera*, except the *Bryozoa*, the *Polygastrica*, and certain forms of *Entozoa*, in none of which are the indications of a nervous system decided, and they constitute the lowest forms of the radiate group of animals.

ACROCHO'RDUS (from ἀκροχορδὼν, a wart), a genus of serpents discovered in Java by the traveller Homstedt. It is easily distinguished from others of the innoxious family of serpents by the innumerable small scales which cover every part of the head and body both above and below, and which in preserved specimens, or when the live animal distends the lungs and body with air, assume the appearance of so many granulated warts or tubercles. This circumstance has suggested the name of *Acrochordus*. The head of the acrochord is flat, the mouth is provided with a double row of small sharp teeth, but without poison-fangs, and the throat is capable of enormous dilatation. The tongue is short and thick, the vent simple and without the horny spurs which are common to many other genera of serpents. The only species of which much is known is the *Acrochordus Javanicus* of Lacépède and others. This animal averages from six to ten feet in length, and the body grows gradually thicker from the head to the vent, and there suddenly contracts, so as to form a very short slender tail. In the thickest part of the body, immediately above its junction with the tail, the individual procured by Homstedt, of which the entire length was eight feet three inches, measured three inches in diameter, whilst the greatest breadth of the tail did not exceed half an inch, and its length was scarcely a ninth part of that of the whole body. This individual was a female, and, when opened, was found to contain five young ones perfectly formed, and about nine inches in length. It was caught in a plantation of pepper-trees, and the Chinese, who accompanied Homstedt, cooked and ate its flesh, and reported it to be of a most delicious flavour. The stomach contained a quantity of half-digested fruit, from which it has been inferred that this serpent is frugivorous. Cuvier, however, doubts on this point.



Acrochordus Javanicus.

ACROCU'LIA, a fossil genus of *Gasteropoda*, allied to the *Neritadæ*. It occurs in Palæozoic strata. (Phillips.)

A'CRODUS, a genus of fossil Placoid fishes, established by M. Agassiz. The species occurs almost exclusively in the lias and oolite. One British species (*A. minimus*) is referred to the keüper series by M. Agassiz. It occurs at Aust Cliff in the bone-bed. The others abound at Lyme Regis, Bath, and Stonesfield.

ACRO'GASTER, a fossil genus of fishes. (Agassiz.)

ACROGENS (from *ἄκρος*, the topmost, and *γεννάω*, to produce), in Botany, one of the primary classes of the Vegetable Kingdom, according to the Natural System. This class, with identical limits, is also known by the following designations:—

Acotyledons (Jussieu), so named from the fact of the absence of cotyledons amongst this class of plants.

Exembryonatæ (Richard), designating the absence of any regular embryo in the reproductive cells, or spores.

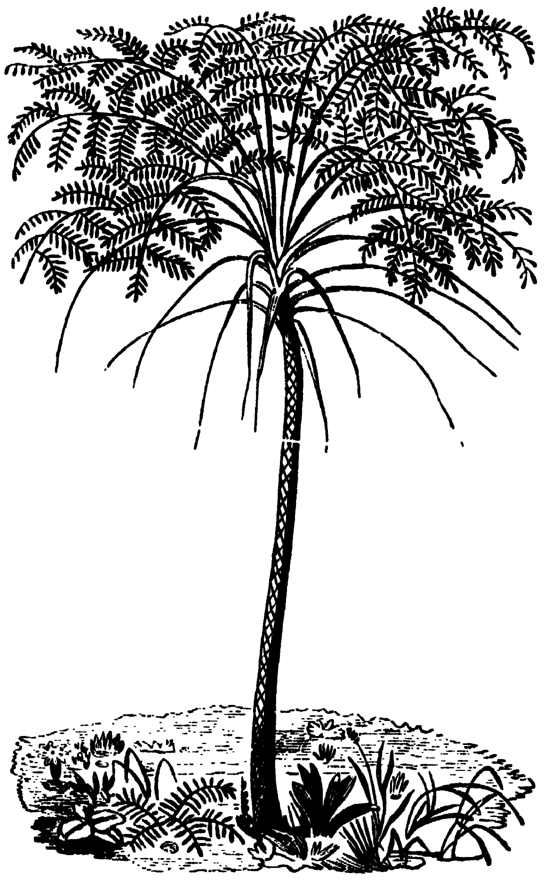
Cellulares (De Candolle), denoting the general absence of vascular tissue and the prevalence of cellular tissue in these plants.

Agamæ, of various authors, implying the absence of the necessity of the union of two cells in order to reproduce a new individual.

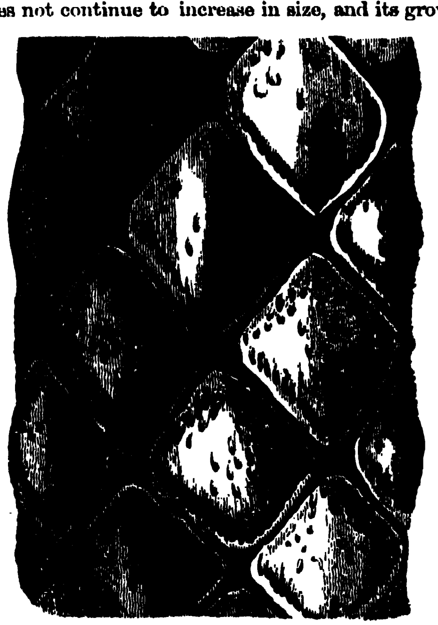
Cryptogamia (Linnæus), intended to convey the idea that if two cells were necessary to the reproduction of the new plant in this class, it was not obvious, as in the Phænogamous plants.

The *Acrogens*, as equivalent to the above expressions for the same class, embrace all those plants which are included in the above definitions. This term itself is, however, only applicable literally to those plants which, destitute of flowers, possess a stem growing in a manner distinctive from those called *Exogens* [Exogens] and *Endogens* [Endogens]. It has been thus restricted by Lindley in his 'Vegetable Kingdom,' and he places the stemless flowerless plants in another class, called *Thallogens*. The structure of the stem, however, is at best an artificial character, and the adoption of the terms for the classes expressive of its characters, has rather been accidental than necessary. On this account it is perhaps better to regard the *Thallogens* as a section of *Acrogens* than an independent and equal group.

The stems of *Acrogens* differ much in appearance from those of Exogens and Endogens. The wood is not secreted from layers of tissue, which have the power of reproducing regular zones of wood, as in Exogens, or a regular arrangement of vascular and cellular tissue, as in Endogens. There is generally but a single ring of vascular bundles even in the Ferns. These vascular bundles do not go on increasing in size, but are all developed together. The lower part of the stem does not continue to increase in size, and its growth is determined by the development of new vascular bundles in connection with the leaves of the point or upper part of the stem: hence their name. In the Liverworts and Mosses there is only a simple vascular bundle in the centre of the stem. In *Isoetes* too there is a ring of vascular bundles. Science is very deficient in good observations on the structure of the stems of these plants.



Chnoophora excelsa, an acrogenous stem.



Portion of outside of stem of *Chnoophora excelsa.*

The reproduction of the Acrogens is not so simple as was at one time believed. The recent researches of Suuinki, Hoffmeister, and others, show that in the Ferns and many other Acrogens the spore is but a transitionary condition, which results in the production of two sets of cells, by the union of which alone can a new individual be produced. [Plants, Reproduction in.]

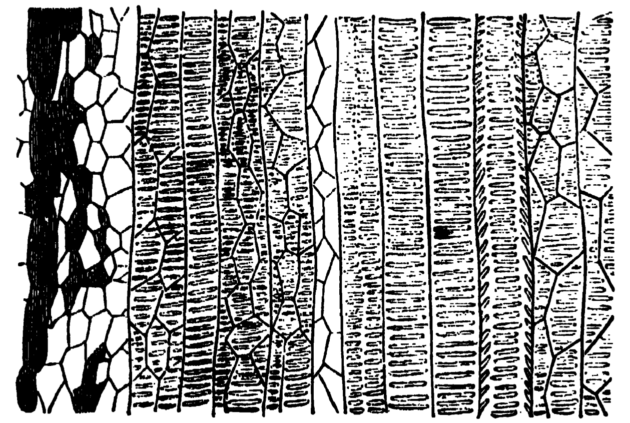
Section of stem of *Alsophila vestita.*



Tissue of an Acrogenous stem.

The following is an analysis of the alliances and orders found in the class of Acrogens, according to the system adopted by Lindley in his 'Vegetable Kingdom.' Thus

Asexual (?) or flowerless plants,	Acrogens.
Stem and leaves distinguishable,	True Acrogens.
Stem and leaves indistinguishable.	Thallogens.

Alliances of Thallogens.

Algales.—Cellular flowerless plants, nourished through their whole surface by the medium in which they vegetate; living in water, or very damp places; propagated by zoospores, coloured spores, or tetraspores.

Fungales.—Cellular flowerless plants, nourished through their thallus (spawn or mycelium); living in air; propagated by spores colourless or brown, and sometimes enclosed in asci; destitute of green gonidia.

Lichenales.—Cellular flowerless plants, nourished through their whole surface by the medium in which they vegetate; living in air; propagated by spores usually enclosed in asci, and always having green gonidia in their thallus.

Natural Orders of Algales.

1. *Diatomaceæ.*—Crystalline angular fragmentary bodies, brittle, and multiplying by spontaneous separation.

2. *Confervaceæ.*—Vesicular filimentary or membranous bodies, multiplied by zoospores generated in the interior, at the expense of their green matter.

3. *Fucaceæ.*—Cellular or tubular unsymmetrical bodies, multiplied by simple spores formed externally.

4. *Ceramiaceæ.*—Cellular or tubular unsymmetrical bodies multiplied by tetraspores.

5. *Characeæ.*—Tubular symmetrically-branched bodies, multiplied by spiral-coated nucules filled with starch.

Natural Orders of Fungales.

6. *Hymenomycetes*, or *Agaricaceæ.*—Spores generally quaternate on distinct sporophores; hymenium naked.

7. *Gasteromycetes*, or *Lycoperdaceæ.*—Spores generally quaternate on distinct sporophores; hymenium enclosed in a peridium.

8. *Coniomycetes*, or *Uredinaceæ.*—Spores single, often septate on more or less distinct sporophores; flocci of the fruit obsolete, or mere peduncles.

9. *Hyphomycetes*, or *Botrytaceæ.*—Spores naked, often septate; thallus floccose.

10. *Ascomycetes*, or *Helvelaceæ.*—Sporidia contained (generally eight together) in asci.

11. *Physomycetes*, or *Mucoraceæ.*—Spores surrounded by a vesicular veil or sporangium; thallus floccose.

Natural Orders of Lichenales.

12. *Graphidaceæ.*—Nucleus breaking up into naked spores.

13. *Collemaceæ.*—Nucleus bearing asci; thallus homogeneous, gelatinous, or cartilaginous.

14. *Parmeliaceæ.*—Nucleus bearing asci; thallus heterogeneous, pulverulent, or cellular.

Alliances of Acrogens.

Muscales.—Cellular (or vascular) spore-cases immersed or calyptrate, *i. e.* either plunged in the substance of the frond, or enclosed within a hood, having the same relation to the spores as an involucre to a seed vessel.

Lycopodales.—Vascular; spore-cases axillary or radical, one- or many-celled; spores of two sorts.

Filicales.—Vascular; spore-cases marginal or dorsal, one-celled, usually surrounded by an elastic ring; spores of but one sort.

Natural Orders of Muscales.

1. *Hepaticæ.*

15. *Ricciaceæ.*—Spore-cases valveless, without operculum or elaters.

16. *Marchantiaceæ.*—Spore-cases valveless, or bursting irregularly, without operculum, but with elaters.

17. *Jungermanniaceæ.*—Spore-cases opening by a definite number of equal valves, without operculum, but with elaters.

18. *Equisetaceæ.*—Spore-cases peltate, splitting on one side, without operculum, and with an elater to every spore.

2. *Musci.*

19. *Andreæaceæ.*—Spore-cases opening by valves, with an operculum, without elaters.

20. *Bryaceæ.*—Spore-cases valveless, with an operculum, without elaters.

Natural Orders of Lycopodales.

21. *Lycopodiaceæ.*—Spore-cases one- to three-celled, axillary, reproductive bodies similar.

22. *Marsileaceæ.*—Spore-cases many-celled, radical (or axillary), reproductive bodies dissimilar.

Natural Orders of Filicales.

23. *Ophioglossaceæ.*—Spore-cases ringless, distinct, two-valved; formed on the margin of a contracted leaf.

24. *Polypodiaceæ.*—Spore-cases ringed, dorsal or marginal, distinct, splitting irregularly.

25. *Danæaceæ.*—Spore-cases ringless, dorsal, connate, splitting irregularly by a ventral cleft.

(Lindley's *Vegetable Kingdom;* Schleiden's *Principles of Scientific Botany,* translated by Dr. Lankester; Henfrey's *Report on the Higher Cryptogamous Plants,* at the Twenty-first Meeting of the British Association.)

ACRO'GNATHUS, a genus of fossil Cycloid fishes, found in the chalk of Sussex. (Agassiz.)

ACRO'LEPIS, a genus of fossil Ganoid fishes, found in the magnesian limestone of Durham. (Agassiz.)

ACRO'PTERIS (from ἄκρος, a point, and πτέρις, a fern), a genus of Ferns allied to *Asplenium*.

ACROSALE'NIA, a genus of Fossil *Echinodermata*. (Agassiz.) It occurs in the Isle of Sheppy.

ACROSTICHON (from ἄκρος, a point, and στίχος, a row), a genus of Ferns, most of which require stove heat in cultivation. The whole of the species now referred to this genus are extra-European, being inhabitants of the West and East Indies, and Australia.

ACROTE'MNUS, a genus of Fossil Ganoid Fishes. *A. Faba* is found in the chalk of Sussex. (Agassiz.)

ACT'ÆA. Under the name of ἀκτῆ, the Greeks described a medicinal plant, which the moderns have ascertained to be what is now called *Sambucus Ebulus*. [SAMBUCUS.] Linnæus applied the name to a genus of perennial herbaceous plants found in various parts of Europe, and the north of Asia, and America, belonging to the natural order *Ranunculaceæ*, and only in a slight degree resembling the species intended by classical authors. The genus thus understood is known from all others of the Ranunculus tribe by its anthers being turned inwards, so that when they burst the pollen may immediately fall upon the stigma, while its flowers have only four sepals and four petals. The properties of all the species are nauseous and deleterious, as might be expected from their affinity to the poisonous Aconite.

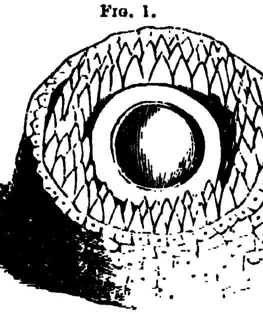
One species, *Actæa spicata*, a common European plant, is found occasionally in the north of Yorkshire among bushes; it is popularly called Black Baneberries and also Herb Christopher. It has purplish-black juicy fruits, which would be dangerous from their tempting appearance, if the fetid odour of the leaves did not prevent their being touched.

Another species, the *A. cimicifuga*, a North American plant, derives its name from the belief that its fetid leaves have the power of driving away bugs.

ACTINIA. [ACTINIADÆ.]

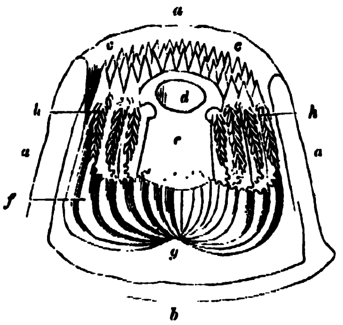
ACTINI'ADÆ, a family of Helianthoid Polypes, having for its type the old genus *Actinia*, the *Sea Anemonies*. It has the following characters. Animal single, fleshy, elongate or conical, capable of extending or contracting itself, fixed by its base, but with the power of locomotion; mouth in the middle of the upper disk, very dilatable, surrounded by one or more rows of tentacula; oviparous and viviparous; marine.

FIG. 1.



Small Leathery Animal-Flower (*Actinia coriacea*).

FIG. 2.



Vertical section of the above, to show its interior structure.

- *a a a.* The skin.
- *b.* The base, by which the animal is fixed to the rocks.
- *c.* The three rows of feelers (tentacula).
- *d.* The mouth.
- *e.* The stomach.
- *f.* Longitudinal muscles.
- *g.* Point in which they unite.
- *h h.* The ovaries, which open by their oviducts into the stomach.

The internal structure of the *Actiniæ* has been carefully investigated by Spix, Teale, and others. They possess an alimentary cavity, with a single aperture, very large at the lower end, and so elastic and contractile that it can easily be turned inside out. The cavity is surrounded with flat muscles, running lengthwise and parallel.

The egg organ (*ovarium*), according to Teale's observations in *Actinia coriacea*, forms elongated masses attached along the inner border of a series of organs called leaflets, fig. 2, *h h*. "Each ovary is composed of several folds or plaits, which, when unfolded, show this structure to be about three times the length it assumes when attached to the leaflet. By carefully spreading out these folds, the ovary, with the assistance of a lens, is seen to consist of two very delicate layers of membrane, enveloping a closely compacted layer of ova. After enveloping the ova, the membranous layers are placed in apposition, and form a kind of mesentery, by which the ovary is attached to the internal border of the leaflet." The *Actiniadæ* propagate all the year round, although perhaps in some species the ova are deposited most abundantly in autumn. The ova are roundish, and like those of polypes in general, are moved by means of vibratile cilia, which cover their surface. After being discharged from their parent they move about actively for several days, during which they undergo some change in form. They then relax their activity, the cilia are absorbed, they attach themselves to a spot, and pass through a series of forms, before arriving at maturity.

Although Spix has described in *Actinia coriacea* a nervous system, this has not been confirmed by more recent observers.

The habits of the *Actiniæ* have been studied by the Abbé Dicquemare and others. The forms of *Actiniæ* vary according to their contraction or expansion, presenting innumerable varieties. Their expansion is said to be a more certain indicator of fine weather than the rise of the barometer; but this cannot be practically taken advantage of except during summer, as the cold of winter drives the *Actiniæ* from the shore to the deeper waters, where the temperature is more equable and mild. On changing their place of abode, some abandon themselves to the mercy of the waves, others creep along the bottom, turning themselves inside out, and making use of their tentacula as feet. When they find a suitable place, they fix themselves, often so firmly, that they cannot be detached without tearing their bodies.

FIG. 3.

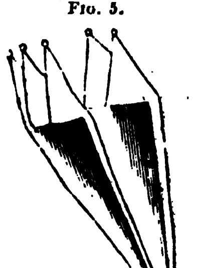
- *c.* Nerves of communication between the ganglions.
- *d.* The longitudinal muscles.

FIG. 5.



Longitudinal Muscles, with the feelers (magnified).

Our distinguished English naturalist, Ellis, has given a very minute and, so far as it goes, an accurate account of these animals in the 'Philosophical Transactions,' vol. lvii., part of which it may be interesting to quote:—

"The lower part," he says, "of these bodies have a communication with a firm, fleshy, wrinkled tube, which sticks fast to the rocks, and sends forth other fleshy tubes, which creep along them in various directions. These are full of different sizes of these remarkable animals, which rise up irregularly in groups near to one another.

"This adhering tube, that secures them fast to the rock or shelly bottom, is worthy of our notice. The knobs that we observe are formed in several parts of it by its insinuating itself into the inequalities of the coral rock, or by grasping pieces of shells, part of which still remain in it, with the fleshy substance grown over them. This shows us the instinct of nature, that directs these animals to preserve themselves from the violence of the waves, not unlike the anchoring of mussels, by their fine silken filaments that end in suckers; or rather, like the shelly basis of the *Serpula*, or worm-shell, the tree-oyster, and the slipper-barnacle, &c., whose bases conform to the shape of whatever substance they fix themselves to, grasping it fast with their testaceous claws, to withstand the fury of a storm.

"When we view the inside of this animal dissected lengthwise, we find a little tube leading from the mouth to the stomach, from whence there rise eight wrinkled small guts, in a circular order, with a yellowish soft substance in them; these bend over, in the form of arches, towards the lower parts of the bulb, from whence they may be traced downwards to the narrow part of the upright tube, till they come to the fleshy adhering tube, where some of them may be perceived entering into a papilla, or the beginning of an animal of the like kind, most probably to convey nourishment till it is provided with claws: the remaining part of these slender guts are continued on their fleshy tube, without doubt, for the same purpose of producing and supporting more young ones from the same common parent.

"The many longitudinal fibres that we discover lying parallel to each other, on the inside of the semi-transparent skin, are all inserted in the several claws round the animal's mouth, and are plainly the tendons or muscles for moving and directing the claws at the will of the animal: these may be likewise traced down to the adhering tube."

A strong light incommodes the *Actiniæ*, noise startles them, they are affected by odours, and fresh water causes them to die. These various feelings originate in their great irritability, which appears to increase according to their sufferings. They can support a temperature as low as 45°, and up to 140°, Fahr.; but beyond these extremes they perish. They are often left exposed to the air during spring-tides; but in such cases they always retain a great quantity of water, which they squirt out with force when molested.

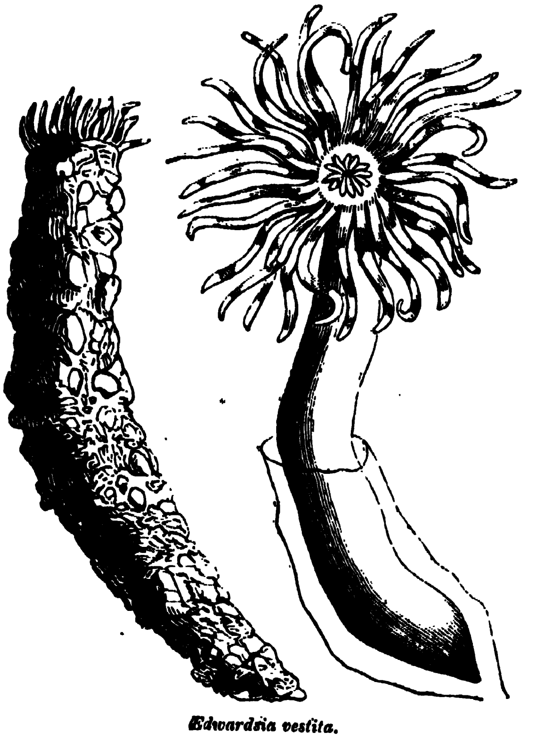
These singular creatures have a power of reproduction equal to that so well known in the Fresh-Water Polyp (*Polypus viridis*, Bory., *Hydra viridis*). They may be cut perpendicularly or across, and each cutting will give origin to a new animal. The young *Actinia* are seen issuing, already formed, sometimes from the mouth; and sometimes the base of the old animal is dissevered, a portion remaining attached to the rock, where it continues to live, increasing in size, becoming more and more rounded, while, in a short time, a mouth, stomach, and tentacula are formed, presenting a complete *Actinia*. At length, the side-portions of this base give out globules, which are detached, fix themselves upon adjacent rocks, where they grow, and produce a new colony like the parent animal.

The *Actiniæ* feed upon small crustaceous and molluscous animals and fishes, which they seize with their tentacula, and afterwards disgorge what they cannot digest. They are found in every sea, some suspended from the vaults of sub-marine reefs, others covering the more exposed sides of rocks with a sort of flower-like tapestry, and some confining themselves to the smooth sands, on the surface of which they spread out their tentacula, and even withdraw under the sand when danger threatens. Each species, indeed, generally selects a peculiar haunt. Some of the species have the power of stinging, like the *Acalephæ*, which depends on their possessing in their structure the same organ as the *Acalephæ*, and other forms of polypes, and known under the name of Thread-Cells, or Stinging Hairs.

Many of the species are used as food in tropical countries, on the coasts of which they are more numerous than in colder climates.

The genera comprising the family *Actiniadæ* form several natural groups:

A. Such as have the tentacula reduced to the form of tubercles. A single species, constituting the genus *Discosoma* of Leuckart, belongs to this division, which cannot be regarded as certainly established, the genus referred to having been founded on a specimen preserved in alcohol, which alters materially the forms of sea-anemonies. Ehrenberg asserts that it is his *Actinia brevicirrhata*, which has very small and numerous tentacula. Ex. *Discosoma nummiforme.*



Edwardsia vestita.

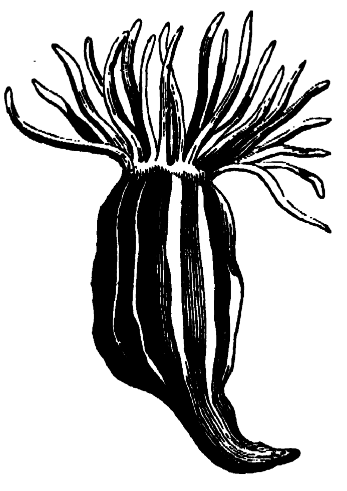
B. Such Sea-Anemonies as have simple tentacula. Of these the following are the principal genera:—

1. *Minyas*, Cuvier (*Actiniata*, Blainville), *Free Actiniæ* having more or less globose bodies inflated at one end, and having at the other a disk covered by a great number of very short tentacula. Cuvier placed this genus among the *Echinodermata*, but the observations of Lesueur and Quoy, who have seen the living animal, place it without a question among the true *Actiniadæ*. As many of the usually fixed species are capable of swimming and of inflating their suctorial disks, it is by no means sure that such is always the habit of *Minyas*; indeed, we have observed an allied and undescribed animal which inhabits the Mediterranean, swimming at the surface of the sea in winter, but when confined in a glass of water it adhered to the sides in the manner of an *Actinia* properly so called.

Example, *Minyas cyanea.*

2. *Moschata*, Renieri, vermiform and free, and, according to De Blainville, incrusted with adhering substances. It is said to live floating in the sea. Both Ehrenberg and Dujardin have supposed that there was some mistake regarding this genus, and that it might have been founded on specimens of *Actinia* (*Cribrina*) *bellis*. It is more probably however identical with the *Edwardsia* of M. de Quatrefages ('Annales des Sciences Naturelles,' 1842), founded on some remarkable vermiform *Actiniadæ* which are invested with a sort of tube to which sand and gravel adhere. Three species of *Edwardsia* have been discovered by the author of the genus on the west coast of France, and a fourth in the Grecian Archipelago by Professor E. Forbes, the habits of which are very remarkable. It can move up and down freely in its membranous tube, and when kept for some time in sea-water, the tube having been injured, it came out of it altogether and moved about twisting its body in the manner of some *Annelides*. On being supplied with sand and gravel, it proceeded to construct another tube, rolling itself up in the sand and secreting glutinous matter for the membranous lining. It eats voraciously, and attacks such animals as come within reach of its tentacula. It lives buried in sand, and in places a few inches below sea-level.

3. *Iluanthus*, Forbes ('Annals of Natural History,' vol. v., 1840.) A single species only is known. The body is free, and tapers posteriorly to a point, which is probably buried in the soft mud among which it lives. The mouth is round, and surrounded by numerous long filiform tentacula. The *Iluanthus Scoticus* was found in four fathoms of water in Loch Ryan.



Iluanthus Scoticus.

4. *Actinia*, Linnæus, now restricted to such species as have simple tubular retractile tentacula, and adhere by a broad base. Ehrenberg has separated such *Actiniæ* as have a glandular epidermis, under the name of *Cribrina*. From the glands protrude long filaments, the uses of which are unknown. The tentacula of all the species are (contrary to the supposition of Ehrenberg) perforated at their extremities. The subgenus *Adamsia* has been constituted, by Professor E. Forbes, for the reception of the curious parasitical *Actinia maculata*, which envelopes the mouths of dead shells, generally selecting such as have been previously invested by the *Alcyonidium echinatum*. As such shells are frequently inhabited at the same time by the Hermit Crab, not a few naturalists have mistaken the coincidence for some necessary and mysterious friendship of the zoophyte for the crustacean.

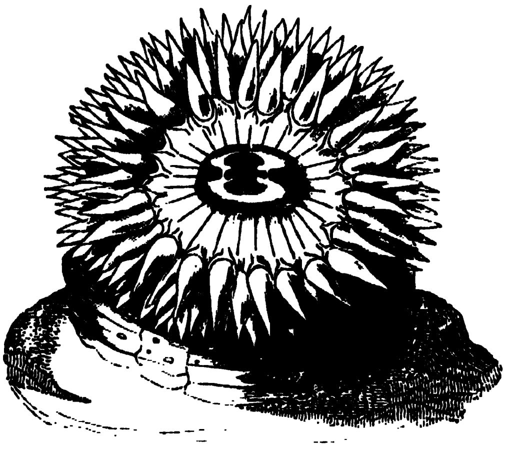
A large number of species of *Actiniæ* have been described, but many of them not with sufficient distinctness, and it is probable many more will be ultimately ascertained. The following are common species on the British coasts:

The Stout-Armed Animal-Flower (*Actinia crassicornis*, Müller) is three inches broad, with a leathery unequal envelope of an orange colour; the tentacula in two ranges, usually marked with a rose-coloured ring. Its abode is commonly in the sand.

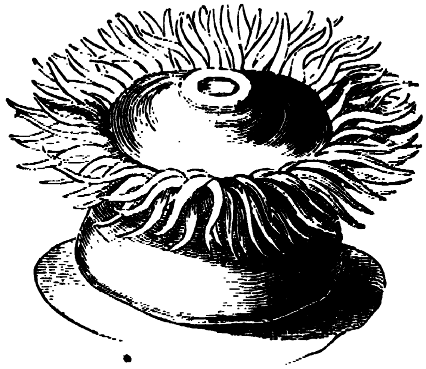
The Purple Animal-Flower (*Actinia Mesembryanthemum*) has a soft skin, finely striated, usually of a beautiful purple, often clouded with green. The tentacula, to the number of a hundred, vary much in colour. When the tide retires this species may be seen ornamenting the sea-rocks with its beautiful colours—"purple, violet, blue, pink, yellow, and green, like so many flowers," says M. Lamouroux, "in a meadow."

The White Animal-Flower (*Actinia Dianthus*, Ellis) is four or more inches broad, of a white colour; the margins of the mouth are expanded into lobes, all furnished with innumerable tentacula. There is an inner row of these, still larger.

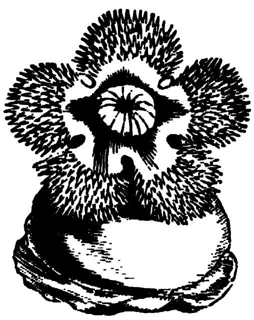
In his 'British Zoophytes,' Dr. Johnstone enumerates twenty species of the genus *Actinia*, as found in the British islands. It is, however, a question whether all these are really different species; as few animals have a greater tendency to assume different forms than the members of this genus.



Stout-Armed Animal-Flower (*A. crassicornis*).



Purple Animal-Flower (*A. equina*).



White Animal-Flower (*A. Dianthus*).

5. *Anthea*, Johnstone, includes such *Actiniæ* as have not the power of retracting their tentacula. Several of the species grow to a large size.

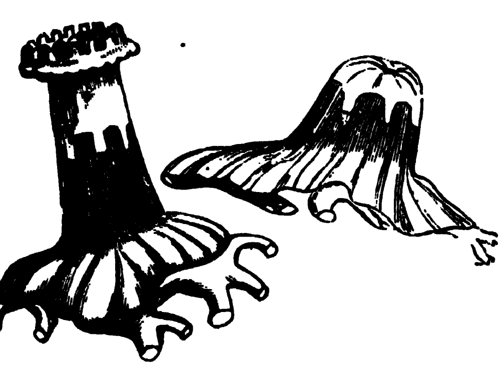
Example, *Anthea Tuediæ*, Johnstone, 'Brit. Zoophytes,' p. 222, fig. 33.

6. *Actinoloba*, Blainville (*Metridium*, Oken), species in which the oral disk is divided at the margin into more or less rounded lobes, which bear short simple tentacula.

Example, *A. dianthus*, 'Phil. Trans.,' vol. lvii., tab. 19, fig. 8.

7. *Capnea*, Forbes, of which one species only is known. The disk is round, with several circles of exceedingly short tubercular retractile tentacula, and the body is in part invested with a peculiar epidermis, which is divided at the margin into eight lobes.

Example, *C. sanguinea.* ('Annals of Natural History,' vol. vii., pl. 1, fig. 1.) Irish Sea.



Capnea sanguinosa.

C. Sea-Anemonies having more or less pinnate tentacula.

8. *Actineria*, Quoy and Gaimard. Such as have the entire disk covered by very small villose ramified tentacula.

Example. *A. villosa*, Quoy and Gaimard. ('Voy. Astrolabe, Zooph.,' pl. 49, figs. 1, 2.) Tonga islands.

9. *Actinodendron*, Quoy and Gaimard. Species having very long arborescent tentacula disposed in one or two series on the oral disk.

Example, *A. alcyonoideum.* ('Voy. Ast.,' pl. 48, figs. 1, 2.) This animal is more than a foot in height, and secretes a stinging mucus.

10. *Thalassianthus*, Leuckart. One species only is known, the *T. aster*, an inhabitant of the Red Sea, figured in the plates to Rüppell's 'Voyage.' Its tentacula are numerous, short, and pinnate. It is probably identical with the *Epicladia* of Ehrenberg.

11. *Heterodactyla*, Ehrenberg. The tentacula are of two sorts, some simple and others pinnate.

Example, *H. Hemprichii.* Red Sea.

12. *Megalictis*, Ehrenberg, founded on an animal from the same locality with the last, and characterised by having all the tentacula arborescent, but the internal ones are the larger and more pinnate, and have their extremities hollowed into a sort of socket.

Example, *Megalictis Hemprichii.*

ACTI'NOCAMAX, a division of Belemnites, proposed by the late Mr. Miller of Bristol, upon the supposition that the species which he ranked in it had no true alveolar cavity or phragmacone. The correctness of this view is doubtful. The species belong to the cretaceous strata. [BELEMNITE.]

ACTINOCARPUS (from ἀκτὶν, a ray, and καρπός, a fruit), a genus of plants belonging to the order *Alismaceæ*. One of the species of this genus, *A. damasonium*, is a British plant, though rare. Like the order, it is an aquatic plant, and has cordate, oblong, floating leaves, with white flowers. Another species, *A. minor*, is sometimes found cultivated in our gardens.

ACTINO'CERAS, a genus of Fossil *Cephalopoda*, separated from *Orthoceras* by Mr. Stokes. The species belong to the Palæozoic strata. *A. Simmsii* occurs in Ireland.

ACTINOCRINI'TES, a genus of *Crinoidea* [ENCRINITES], containing many species. It occurs in Silurian and Carboniferous strata. (Miller.)

ACTI'NOLITE, a crystallised mineral of a green colour, a variety of hornblende, found in primary stratified rocks, and occasionally in trap-rocks. The name is derived from ἀκτὶν, a ray of light, and λίθος, a stone, from the crystals being arranged in the form of rays. It occurs in masses or asbestiform.

ACU'LEUS, or *Prickle*, in Botany, is a hard, conical, often curved expansion of the bark of some plants, such as the rose, and is intended either for their defence against enemies, or to enable them to hook themselves upon their neighbours, so as to gain a more free access to light and air, or for other purposes unknown to us. The prickle is composed entirely of cellular tissue, which is at first soft and flexible, and only acquires its hardness and rigidity when old. In some respects it may be compared to a hair, from which it chiefly differs in its large size and greater permanence. Care must be taken by the young botanist not to confound the prickle with the spine or thorn, which is of a totally different nature. [SPINE.] They may be distinguished by the prickle breaking readily from the bark, and leaving a clean scar behind; while the spine cannot be torn off without rending through the bark into the wood itself. Leaves are often metamorphosed into spines, but never into *aculei*.

ADAMAN'TINE SPAR, a simple mineral, more commonly denominated *Corundum* by mineralogists, the name given to it in India, from which country it was first brought to Europe. The first specimens of it were sent by Dr. Anderson, of Madras, to Mr. Berry, a lapidary in Edinburgh, as the substance used in India to polish masses of crystal and all other precious stones, except the diamond. It was examined by Dr. Black, who ascertained its peculiar nature, and from its great hardness he called it Adamantine Spar. With the exception of the diamond, it is the hardest substance known. It contains about 90 per cent. of alumine, a little iron, and a little silica, is usually of a pale grey or greenish colour, but is also found of various tints of red and brown. It is usually met with in rough ill-defined crystals, in granite, and sometimes in primary limestone, and is found in China, many parts of India, and occasionally in different parts of Europe. *Emery*, the well-known substance used in the cutting and polishing of glass, in polishing steel, making razor-straps, and similar purposes in the arts, is a granular variety of Corundum, usually very much mixed with iron ore. It is chiefly imported from the Isle of Naxos, in the Grecian Archipelago, but is also found in Saxony. The *Sapphire* is a remarkable instance how the mysterious chemistry of nature in the mineral kingdom produces from the same elements substances the most different in external form; this beautiful precious stone yielded by the analysis of Chenevix 94 per cent. of alumine; and Tennant found in emery, when freed from its admixture of iron, 92 per cent. of the same earth. The sapphire is, after the diamond, the most valuable of gems; it is usually dark blue, but also occasionally colourless, and the precious stones called by lapidaries *Oriental Ruby, Oriental Topaz, Oriental Amethyst*, and *Oriental Emerald*, are red, yellow, violet, and green Sapphires, distinguishable from the other gems of the same name which have not the prefix Oriental, by their greatly superior hardness and greater specific gravity. Sapphires are found in gravel and sand in the island of Ceylon and in Pegu, but they have never been seen in a matrix. They are also occasionally found in gravel in different parts of Europe, and they have been met with of a clear blue colour and crystallised, in the lava of Nieder Mendig, near Andernach on the Rhine.

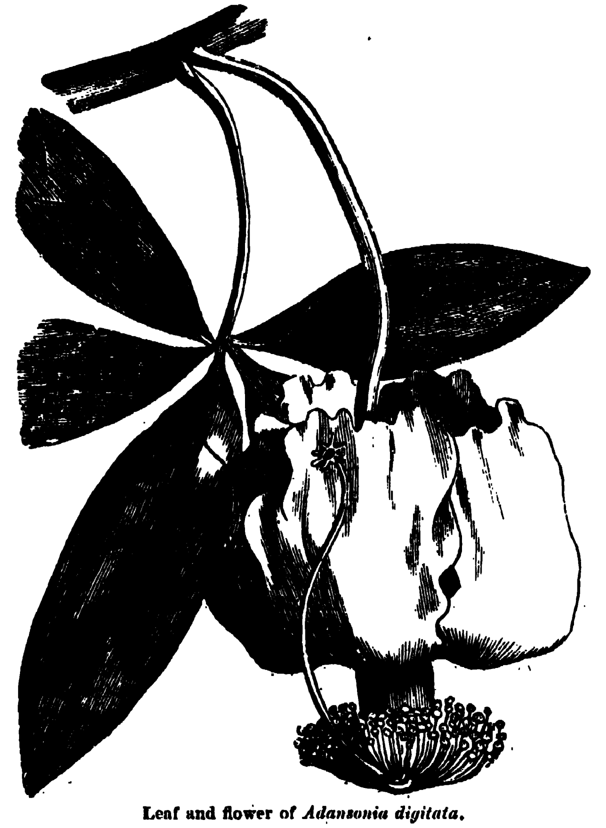
ADANSONIA, so called in honour of Michael Adanson, the French naturalist, is an extraordinary tree found in Africa within the tropics, particularly in Senegal, where it is called *Baobab*.

The celebrated traveller Humboldt considers it as the 'oldest organic monument of our planet,' in consequence of the calculations of Adanson that specimens, still found on the north-west coast of Africa, are probably 5000 years old; these calculations are, however, open to many objections.

In appearance, *Adansonia* is unlike any other known tree: the enormous dimensions of its trunk bear a striking disproportion to the other parts. It is not unusual to find a trunk not more than 12 or 15 feet from the root to the branches, with a circumference of 75 or 78 feet. The lower branches are very long, and at first horizontal, extending perhaps 60 feet; the consequence of which is that they bend down to the ground, entirely hiding the trunk, and giving the tree the appearance of a huge mass of verdure. The wood is very soft, even when in perfection, and is subject to a disease, which may be compared to the very malady of which its celebrated discoverer died—a sort of softening of all the hard parts, so that the least storm is sufficient to overthrow and dismember its enormous bulk. A curious practice prevails among the negroes of hollowing its trunk out into chambers, and therein depositing the bodies of malefactors, or of persons to whom the usual rites of sepulture are denied. In this situation the bodies become dried up, and soon acquire the state of perfect mummies.

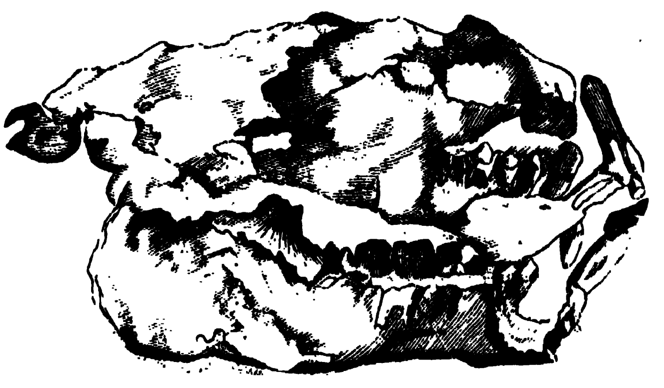
Adansonia belongs to the natural order *Bombaceæ*, among which it is at once known by a broad tube of stamens and deciduous calyx, combined with a woody closed fruit, containing a soft pulp.

The only species is *Adansonia digitata*, the Monkey-Bread, Sour Gourd, Lalo Plant, &c., of the African negroes. The leaves are deep green, and divided into five unequal parts, each of which is of a narrow lanceolate figure, and radiates from a common centre, the outermost divisions being the smallest. The flowers grow singly in a pendulous position from the bosom of the leaves, are very large, white, crumpled at the edge, and have the petals very much reflexed. The stamens are very numerous, and are collected into a tube, which spreads at the top into a sort of umbrella-like head, from the midst of which arises a slender curved style, terminated by a rayed stigma. The fruit is an oblong, dull green, downy body, eight or nine inches long, containing several cells, in each of which there is a number of hard shining seeds immersed in a soft pulp, which is scarcely juicy. From this pulp the negroes prepare an acidulous drink, much used in the fevers of the country. The bruised leaves, in a dry state, form a substance called *lalo*, which they mix with their food and imagine is useful in checking, or counteracting, the effects of profuse perspiration. Like the rest of the order, *Adansonia* is emollient and mucilaginous in all its soft parts.



Leaf and flower of *Adansonia digitata.*

ADAPIS, in Zoology, the name of a genus of Fossil Pachydermatous (thick-skinned) mammals, described by M. Cuvier, in his great work 'Sur les Ossemens Fossiles,' vol. iii. p. 265. The word is found in Gesner, as a synonyme of the common rabbit (not, as stated in the reference to Cuvier just given, of the *Hyrax*), and is appropriated to the present genus, from the presumed similarity in size, organization, and habits, which probably existed between the hedgehog (*Hyrax* and the fossil species.



Skull of the Fossil *Adapis.*

The remains, upon which M. Cuvier has founded this genus Adapis, the only specimen which he was able to procure during a period of twenty-five years devoted to researches after fossil bones, consist of three fragments of skulls, found in the plaster quarries of Montmartre, Paris, celebrated for the enormous quantity and variety of the remains of extinct animals which they have produced, and which, in the hands of M. Cuvier, have effected such improvements in the kindred sciences of zoology and geology. The first of these fragments is a head, nearly perfect on the side, imbedded in the mass of gypsum which contained it; and exhibiting the dentition nearly in a perfect form. The general outline of this skull closely resembled that of the hedgehog, but it was about one-third larger: there were four incisor teeth in each jaw, trenchant or edged and oblique; followed, on each side, by a canine tooth, of a conical form, but in other respects differing little from the molar teeth in length and figure. Of these latter there appear to have been seven in each side of each jaw. Two other fragments procured by M. Cuvier—one a portion of a lower jaw, another of an upper jaw—served to complete his description, by supplying some of the back teeth which were wanting in the more perfect specimens.

ADDA, the Arabic name of a small species of lizard (*Scincus officinalis*) celebrated by the eastern physicians on account of its pretended efficacy in the cure of elephantiasis, leprosy, and other cutaneous diseases, to which the Arabs and inhabitants of Egypt are peculiarly subject; and of which, according to Bruce, they are more afraid than of the plague itself.

The Adda, as described by Bruce, is about six inches and a half in length; the body and tail are cylindrical, the latter thick at the base, and ending in a very sharp point; the head is conical, and the mouth provided with two rows of small feeble teeth; the face is covered with five black lines, which cross one another like a net; the body is of a light straw colour, crossed with eight equidistant bands of black, and the scales are so finely polished that they almost appear as if they had been varnished. The adda is found in Arabia, Egypt, and Nubia; it is particularly abundant in the neighbourhood of the ancient Meroë (near the Nile, about 17° N. lat.); and, in short, throughout every part of the sandy deserts of Asia and Africa, wherever the slightest traces of moisture exist. "It burrows," says Bruce, "in the sand, and performs the operation so quickly, that it is out of sight in an instant, and appears rather to have found a hole than to have made one: yet it often comes out during the heat of the day to bask itself in the sun; and, if not very much frightened, will take refuge behind stones, or in the withered, ragged roots of the absinthium, dried in the sun to nearly its own colour."

ADDAX. [ANTELOPE.]

ADDER, a name of the common viper. [VIPERIDÆ.]

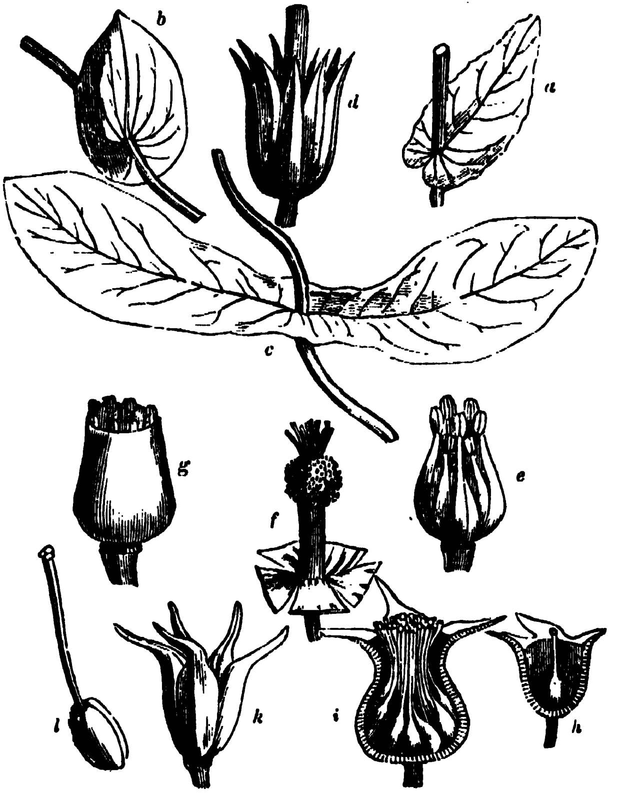
ADELFORSITE, a variety of mineral, included under Heulandite. [HEULANDITE.]

ADELO'CRINUS, a fossil genus of *Crinoidea*, from North Devon. (Phillips.)

ADHESION, in Botany, is applied to the union of parts which are separate in other plants, or in younger states of the same plant. Many of the characters which cause the diversity of appearance in the vegetable kingdom originate in the adhesion of a few very simple organs; and what we are accustomed to consider parts of extremely different nature, only seem so in consequence of the way in which such adhesion occurs. Thus, the stem of a tree is not a homogeneous mass of vegetable matter, perforated by holes, or filled by little cavities caused by the extrication of air in it when in a soft state, but is produced by the adhesion of certain elementary bodies, called Cellular Tissue and Vascular Tissue [TISSUES, VEGETABLE], arranged in a definite manner, which varies in every species; neither is a leaf, or a fruit, or a flower, a mere mass of pulp, or an expansion, like the horn of an animal, but also consists of these same elementary organs in a state of adhesion.

Guided by these facts, modern botanists have made use of this property of adhesion to explain the nature of every organ that plants bear, and there are few anomalies that are not due in a great measure to the union of contiguous parts.

Some leaves are said to be stem-clasping, or amplexicaul, when their base partially surrounds the stem (*fig. a*); while some stems are said to be perfoliate, when they seem as if they pierced through the leaf, as in *Bupleurum rotundifolium* (*fig. b*); but the latter differ from the former only in this, that in the first the lobes at the base of the leaf embrace the stem without adhering, while in the second they not only clasp the stem but grow together where their margins come in contact. Some leaves are hollow, as in the Pitcher Plant, and these were formerly thought to be special organs with which no analogy could be discovered; they are now known to be leaves which have rolled up so that their opposite margins come in contact and adhere. Other leaves, growing from opposite sides of a stem, adhere in consequence of their bases becoming connate (*fig. c*), as in the honeysuckle; and finally there are others, many of which grow in what botanists call a whorl, that is to say, all round a stem upon the same plane, and adhere by their margins into a sheath (*fig. d*), as in *Casuarina*.



Adhesion.

In other organs adhesions of a similar nature occur.

In the calyx, all the sepals, or parts, are often distinct, as in the *Ranunculus*; but they also often adhere by their edges, into a sort of cup, as in the cherry. In the corolla the petals are either all separate, as in the rose, or they adhere by their edges into a cup or bell, as in the different heaths, *Campanula*, and the like.

Similar adhesions take place between the stamens. In the rose they are all distinct from each other; in the geranium they slightly adhere at the base (*fig. e*); in the mallow they adhere into a tube, except near the upper extremity, where they are not united, and have their ordinary appearance (*fig. f*); in other plants they grow together into a solid tube in which no trace of separation can be discovered, as in the genus *Guarea* (*fig. g*).

Finally, in the pistil there are certain parts called carpels, each of which is a hollow body terminated by a style and stigma. These carpels are hollow, because they are formed of a flat organ, doubled up so that its edges come in contact and adhere to each other. Sometimes only one carpel is present in a flower, as in the cherry (*fig. h*); sometimes several, as in the rose (*fig. i*). In the *Nigella*, the styles of the carpels are all distinct (*fig. k*), but in the lily and the myrtle (*fig. l*) the styles of the carpels adhere so completely that there seems to be but one. In the apple, the calyx seems to grow from the top of the fruit; this is caused by the carpels having at a very early period adhered to the inside of the calyx, which afterwards grows with their growth, and, finally, leaves its extremities in a withered state near the top of the carpels: in the cherry, on the contrary, no adhesion ever takes place between the carpel and the calyx; and, consequently, when the fruit is ripe, there is no trace of the latter upon its upper end. In the raspberry, the fruit is enabled to slip like a thimble from off the receptacle, because the carpels all adhere by their sides.

(De Candolle, *Théorie Elémentaire de la Botanique*; Lindley, *Introduction to Botany*; Schleiden, *Principles of Scientific Botany*.)

ADIANTUM (ἀδίαντον), a genus of Ferns, so called by the Greeks because the leaves are of such a nature that water will not readily moisten them. The plant described by Hippocrates and his successors under this name appears to have been the *A. Capillus Veneris*, or the Maiden-Hair Fern—a rare European species, occasionally met with on moist rocks, and old damp walls, even in this country. From other genera of the same tribe it is known by its size, or masses of reproductive particles, being situated upon the margin of the leaves, and covered over by a thin curved scale which separates from the leaf by its inner edge.

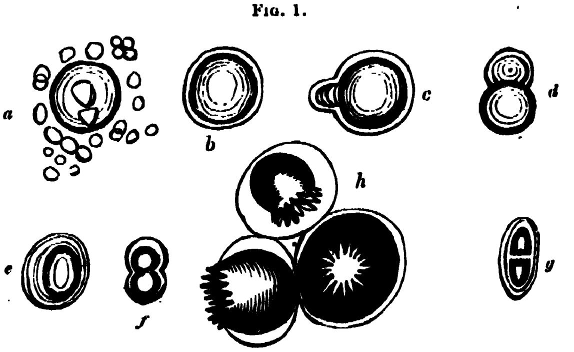
The number of species is very considerable, probably not far from 80 or 90, and, as is the case in all extensive genera of Ferns, comprehends every degree of division of the leaves, from perfect simplicity to the most compound conditions. All those in which the leaves are much divided are remarkable for the very delicate elastic stalks on which the broad leaflets are attached; it is to this circumstance that the name of Maiden's Hair has been given to the European species. The genus is scattered over all the world, from Europe to New Zealand, but is not found in any high latitudes in either hemisphere. By far the greater part of the species inhabit damp tropical woods.

A. Capillus Veneris is a dark-green stemless plant, found in damp, rough rocky places, by the side of water-courses, and on the edge of wells, where the air is keen and dry. Its leaves, which are from six to fifteen inches high, have a blackish-purple highly-polished stalk, divided into a great number of very slender ramifications, from the extremities of which proceed the thin, delicate, wedge-shaped leaflets, which are notched irregularly upon their upper edge, and have the most graceful appearance imaginable when growing a little above the eye, and gently agitated by the wind. Wonderful medicinal properties were once ascribed to this species, but they have long since been discovered to have no existence except in the exaggeration of fanciful practitioners. All that can be discovered in it is a slight but pleasant aromatic flavour; the French occasionally use it in slight coughs. *Capillaire* is prepared by pouring boiling syrup upon the leaves of this species, or of *A. pedatum*, an American plant of larger growth and far less divided leaves; a little flavour is afterwards given with orange-flowers.

ADINOLE, a laminated variety of Felspar, sometimes called Fusible Hornstone, Leelite, and Petro-silex. [FELSPAR.]

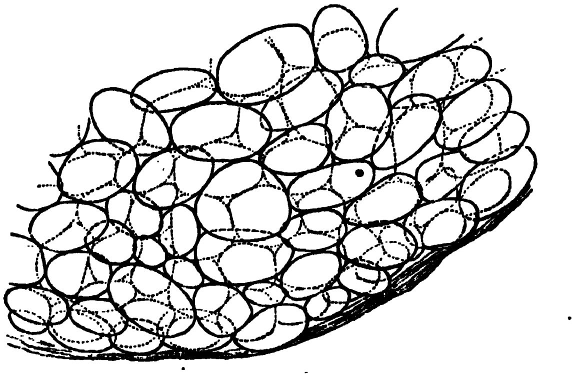
ADIPOSE TISSUE is usually associated with *Areolar Tissue* [AREOLAR TISSUE], the two being generally known collectively as *Cellular Tissue*. It must be distinguished from *Fat* [FAT], adipose tissue being a membrane of extreme tenuity in the form of closed cells or vesicles, while fat is the material contained within them. The membrane of the adipose vesicle does not exceed the 20,000th of an inch in thickness, and is quite transparent; it is moistened by watery fluid, for which it has a greater attraction than for the fat it contains. Each vesicle is a perfect little organ, varying, when fully developed, from the 300th to the 800th of a line; minute capillaries may be observed on their external surface. (*Fig.* 2). When fat-vesicles are deposited together in large numbers, as is usually the case, they assume a more or less regular polyhedric form from their mutual pressure.

FIG. 1.



When the first traces of fat appear is not accurately known. In a well-formed five-months' human fœtus, Valentin found in the subcutaneous cellular tissue of the sole of the foot not merely fat cells, such as occur in adults, varying from the ordinary size to the 125th or 100th of a line, within and around which were numerous small vesicles (*fig.* 1, *a*), but other forms which threw more light on their structure and development. In some the surrounding cell-membrane was much more distinct than as it occurs in adults (*b*). In others there appeared to be a deposition of fat, not occupying the whole space of the cell (*c*); the remainder of the cell having often a striped or streaky appearance, and forming a lateral projection; this is seen in *c*, and in a more marked degree in *d* and *e*. In other fat-cells there were observed to be two vesicles, separated by a septum, against which they were partially flattened by pressure (*g*), or merely separated by a constriction in the external walls, as in *f*. This form leads us to conclude that fat-cells increase by division. The fat-vesicle of the human subject contains *Margarin*, a solid fat, and *Olein*, a fluid fat. These sometimes separate spontaneously, presenting a very beautiful microscopic appearance. The margarin collects in a spot on the inner surface of the cell-membrane, and presents the appearance of a small star, whilst the olein occupies the remainder of the vesicle, unless when the quantity of fat in it is rather smaller than usual, in which case we may observe a little aqueous fluid between the olein and the cell-membrane. (*Fig.* 1, *h*.)

FIG. 2.



The chemistry of the substances *Margarin* and *Olein* is somewhat complicated, but the function of the adipose tissue cannot be explained without it. These two substances, with *Stearin*, are the most widely distributed fats in the organic kingdom, but they are not the only ones. They were formerly regarded as salts formed by fatty acids with *Glycerin*. Recent investigations have however shown that this view requires a slight modification. Berzelius thinks that glycerin does not exist ready formed in the neutral fats, but that it is a product of the formation of soap; and he considers the base of the neutral fats to be the oxide of a radical ($C_3 H_2$) which he terms *Lipyle*. Glycerin is then formed from two equivalents of the oxide of lipyle, with three equivalents of water: $2\,C_3 H_2 O + 3\,H O = C_6 H_7 O$. If to this we add one equivalent of water, we obtain the usual formula.

According to this view, which is supported by Redtenbacher, Varrentrap, and Mulder, the base of every neutral fat yielding glycerin is a compound which is represented by $C_3 H_2 O$.

The most important of the fatty acids are :—

Stearic Acid	$C_{68} H_{66} O_5 + H O$
Margaric Acid	$C_{34} H_{34} O_3 + H O$
Oleic Acid	$C_{44} H_{40} O_4 + H O$

These are universally diffused in plants and animals; and, combined with the oxide of lipyle ($C_3 H_2 O$), they form the neutral fats—stearin, margarin, and olein; and this is the form in which they most commonly occur in the organic kingdom. Sometimes, however, a more powerful base (potash, soda, &c.) removes the oxide of lipyle, and there are then formed compounds of the fatty acids with alkalies.

In connection with this subject, Mulder observes that "when salad-oil is conveyed into the stomach, it may pass unchanged into human fat, for both consist of margarin and olein, although in different proportions; and as margarin and olein are found in many vegetables used for food, nothing is more simple than to assume that these substances are directly transferred, without change, into the fats of the animal body.

"But if these same vegetables are eaten by a sheep, the olein and margarin must undergo some change in the body of the animal, since mutton-fat contains a large amount of stearin. In this case the change is easily understood, for 2 eq. margaric acid ($C_{68} H_{68} O_6$) = 1 eq. stearic acid ($C_{68} H_{68} O_5$) + 1 eq. oxygen. Thus, from two equivalents of margaric acid one equivalent of stearic acid is produced, and one equivalent of oxygen is given off. In all probability such a deoxidation of the margaric acid in the food of the sheep is really effected; and on the contrary, when mutton-fat is used for food by man, stearic acid is most probably converted into margaric acid by the absorption of oxygen." It is now believed by our first physiologists, that the neutral fats taken as food do not directly form fatty tissue, but that they enter the blood in a saponified state. In fact the alkaline character of the bile as it enters the duodenum renders it impossible for the fat to enter the blood without undergoing this change. If it be saponified, we readily understand how compounds of fatty acids and soda should exist in the blood and in various parts of the body. When a soda-soap however exists in the blood, it cannot form a neutral fat, such as margarin or olein, without combining with glycerin. This leads to the inquiry, in the first place, whether these soaps meet with glycerin; and secondly if they do, whether the glycerin would combine with the fatty acids and form neutral fats. There is good reason for believing that both these questions may be answered in the negative,

for the glycerin set free when the soda-soap is formed, is most probably at once decomposed; and further, glycerin will not remove the soda from the fatty acid and form a neutral fat.

It has been suggested by Mulder, that although glycerin will not enter into this combination, the oxide of lipyle in a nascent state may do so, and that in this manner the fatty acids may be converted into neutral fats, and deposited in the cellular tissue, and other parts of the body. We have already shown that (according to the opinion of Berzelius) glycerin is the oxide of the radical ($C_3 H_2$) lipyle. The second oxide of this radical exists in lactic acid, which is supposed by the great majority of chemists to be present in most parts of the body. When lactic acid ($C_6 H_5 O_5$) is sublimated, we obtain a white sublimate, the composition of which is $C_3 H_2 O_2$; while the composition of the oxide of lipyle is $C_3 H_2 O$.

It may happen that there are causes of deoxidation at work in the system, by which some of the substances usually converted into lactic acid are made to produce oxide of lipyle, which in the nascent state unites with the fatty acids, forming neutral fats.

Hence in all probability the neutral fats are not deposited directly and unchanged in the cellular tissue, but are first saponified, and entering the blood as margarate and oleate of soda, are again reduced to neutral fats by the influence of lactic acid.

The next question for our consideration is *the formation of fat*—a subject which has given rise to much angry and intemperate discussion between the leading chemists of France and Germany. Dumas, who may be regarded as the representative of the French school, maintains that all the fat of animals originates in and is obtained from plants; while Liebig, on the contrary, maintains that a portion of it is formed by the animal itself, from starch, sugar, and gum. The goose was the animal respecting which the dispute originated. When fattened with Indian corn, the starch must, according to Liebig, have been changed into fat, because he had found but a minute quantity (about 1 part in 1000) of fat in that kind of grain. Dumas however extracted 9 per cent. of fat from Indian corn (or ninety times as much as Liebig), and thus he found in the food which the goose had eaten much more fat than had to be accounted for. The actual fact is, that the amount of fat in this grain is so variable that no conclusion can be drawn from the experiment. Liebig quotes many examples of substances which, although they contain little fat, are well known by experience to be especially fit for fattening the animal body. Rice, peas, beans, and potatoes are all known to possess this property; yet rice gives only 0·2 to 0·8 per cent. of matters soluble in ether (the ordinary means of determining the amount of fat); peas 1·20 to 2·1; beans 0·70, and dried potatoes 0·35 per cent. Thus any animal that has eaten 1000 pounds of one of these substances may obtain from them 2 to 8, 12 to 21, 7, or 3½ pounds of fat respectively. He makes the following calculations:—Three pigs to be fattened in thirteen weeks require 1000 pounds of peas, and 6825 pounds of boiled potatoes, the latter being equal to 1638 pounds of dry potatoes. These contain in all 26 pounds of fat, the peas yielding 21 pounds, and the potatoes 5. One fattened pig gives on an average 50 to 55 pounds of fat, the three yielding 150 to 165 pounds. Each pig before fattening contains on an average 18 pounds of fat—that is, 54 pounds for the three. If to these 54 pounds be added 26 pounds contained in the food, we get 80 pounds; and if we subtract these from 150 to 165 pounds, there is a remainder of 70 to 85 pounds of fat produced from the starch, &c., of the food. Liebig's opinion is further strengthened by the circumstance that some fats are undoubtedly produced in the body, as, for instance, the fats peculiar to the brain, *Cholesterin*, *Cetine*, *Phocenine*, &c. To obtain these from other fat requires just as much a new arrangement as if they were produced from starch; hence, in a scientific point of view, there is nothing improbable in the supposition that animals are able to produce fats.

With regard to the formation of fat in plants, it is worthy of observation that all seeds which yield oil on pressure—as the castor-oil seed, hemp-seed, &c.—contain starch in their early stages, this starch disappearing as the oil increases, and when the seed is completely developed not a trace of the starch remaining. This renders it probable that these fatty matters are formed from starch. From their ultimate composition it is obvious that whenever fats are produced from any substance there must be produced at the same time either highly oxidised compounds, or else that oxygen must be itself liberated. Liebig observes that if from the formula for starch, $C_{12} H_{10} O_{10}$, we take nine equivalents of oxygen, there will remain in 100 parts—

C_{12}	79·4
H_{10}	10·8
O	9.8

The empirical formula for fat which comes nearest to this is $C_{11} H_{10} O$, which gives in 100 parts—

C_{11}	78·9
H_{10}	11·6
O	9·5

According to this formula an equivalent of starch, in order to be converted into fat, would lose one equivalent of carbonic acid and seven of oxygen, or (expressed in symbols) $C_{12} H_{10} O_{10} = C_{11} H_{10} O + C O_2 + 7\,O$.

The same point is also clearly shown by contrasting the ultimate composition of starch and fat.

	Starch.	Human Fat. (Chevreul.)
Carbon	44·91	79·00
Hydrogen	6·11	11·42
Oxygen	48·98	9·58

As we are not acquainted with any constituent of plants which can take up the oxygen thus liberated in the formation of fat, we must regard this as one of the sources of the oxygen given off by plants. Mulder has given the following scheme as illustrative of the mode in which starch may possibly be converted into fat or oil in the vegetable kingdom :—

	C	H	O
To 7 equiv. of starch	84	70	70
Add 8 equiv. of water		8	8
And we have	84	78	78
Which are equal to			
1 equiv. of margaric acid	34	34	.3
1 equiv. of oleic acid	44	40	4
2 equiv. of oxide of lipyle	6	4	2
69 equiv. of oxygen			69
Making as before	84	78	78

As to the mode in which fat is deposited, there is reason to believe that it is immediately formed out of the blood, without any glandular apparatus for secreting it, by the capillary arteries of the adipose vesicles. By chemical analysis, the materials of fat, like those of all the other secretions, are found to be contained in the blood.

As diffused over the body, the adipose membrane consists of masses which vary considerably in their magnitude and shape. In some places they are rounded, in others pear-shaped, and in the median line of the abdomen, egg-shaped. The distribution of the membrane is exceedingly unequal. There is, in general, a considerable layer immediately beneath the skin; and especially between the skin and the abdominal muscles, where it occasionally accumulates in enormous masses. Between the folds of the membranes which form the omentum and mesentery there is usually a large quantity; also around the heart and the kidneys; on the face, and especially on the cheeks, and in the orbits of the eyes; in the palms of the hands, the soles of the feet; the pulp of the fingers and toes, the flexures of the joints, the fibres of muscles, and the sheath of vessels. In most of these organs it never entirely disappears, whatever be the degree of leanness to which the body may be reduced; while in the cranium, the brain, the eye, the ear, the nose, and several other organs, there is none, whatever be the degree of corpulency.

The functions of the adipose tissue are manifold and apparent. 1. It fills up interstices, and acts as a kind of pad or cushion for the protection of organs which would be otherwise injured by the movements of the body; so essential does it appear in some parts that even where there is great emaciation it does not wholly disappear. 2. By its non-conducting power it assists in maintaining the heat of the body when exposed to external cold. It is found in immense quantities in the animals inhabiting the Arctic Seas, as in the whale tribe, and also in all animals living in the colder parts of the earth. 3. It acts as a storehouse for fuel during times of necessity. Some animals are exposed to a want of combustible food in the winter time, and they accordingly become fat in the autumn, and are thus supplied with material for maintaining their animal heat. It is well known that fats are amongst the most important agents of food by which animal heat is maintained. Animals that hybernate depend solely for their existence upon the fat deposited in their bodies, which is gradually consumed during hybernation. 4. The presence of fat seems to favour the development of protein tissues. It is always found in the ova of animals before the embryo is formed. The administration of oils in certain diseases attended with emaciation, as in phthisis, has been found most beneficial, and appears to act favourably, by assisting the development of protein tissues.

ADJUTANT. [CRANES.]

ADO'NIS, a genus of plants belonging to the natural order *Ranunculaceæ*, and containing many species of very great beauty. The name is merely poetical. *Adonis* is distinguished from *Ranunculus* by the want of a little scale at the base of the petals, and from other genera of the order by the numerous hard, dry, sharp-pointed grains of which its fruit consists.

Botanists divide the genus into two sections, the first of which comprehends all the annual kinds, the second all the perennials. Ten species are spoken of as belonging to the first section, inhabiting cornfields and similar dry exposed places, chiefly in the south of Europe and north of Africa. Some of them have deep crimson flowers, as *A. autumnalis*, the common Pheasant's-Eye of our gardens; in others the blossoms are yellow: it is not improbable that they are all varieties of the same species.

Of the perennial kinds, *A. vernalis*, which is common in gardens in England, is found in a wild state abundantly on all the mountains of middle Europe. Its flowers have from ten to twelve petals of a yellow colour, and of a brilliancy which is rendered the more dazzling by the deep green tuft of finely-divided leaves among which they expand. It is only a few inches high, and is one of the early harbingers of spring. Three others are described, all mountain plants, resembling *A. vernalis* in general appearance, but perhaps still more beautiful. They seem to have been occasionally brought to this country, but to have been soon lost again.

Nothing has been remarked as to the sensible properties of these plants; they doubtless partake of the acridity so prevalent in their tribe.

ADO'XA, a genus of plants belonging to the natural order *Araliaceæ*. The only species of this genus is the *A. Moschatellina*, which is a little inconspicuous plant found in woods and groves in all parts of Europe. It is common at Charlton and Hampstead, near London, and in many other spots in England.

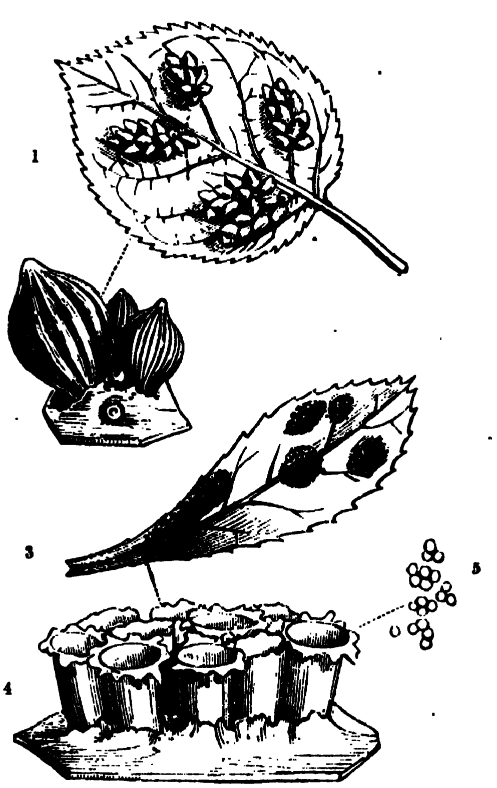
From a granular root, which when dry is white as snow, arise, early every spring, a few leaves about four or five inches high, divided into three principal divisions, each of which is also three-leaved, with every lobe deeply cut into roundish segments. The stem that supports the flowers has two opposite leaves, like those of the root, only they have a short stalk, and consist of but three leaflets. The flowers have a musky smell, are pale green, and are collected in little round heads. Each one consists of a superior calyx of five lobes; there are no petals; the stamens are ten; the styles five; and the ovarium contains five cells. This last changes to a succulent berry, having five compressed seeds.

In English this is called Moschatel; it is a pretty, interesting plant, much sought after by the curious for the sake of its delicate, modest appearance. No known properties belong to it.

ADULARIA, a synonym of Felspar. [FELSPAR.]

ÆCI'DIUM, a genus of minute parasitic plants belonging to the natural order *Fungi*, found in great abundance in this and other northern countries. By some modern writers it has been combined with *Uredo* and others; but it appears distinctly characterised by its peridium, or enveloping membrane, having a tubular form, and being altogether distinct from the cuticle of the plant on which it grows.

The species are universally parasitic upon the leaves or flowers or bark of living plants, where they are generated beneath the cuticle. Their structure is of the most simple kind; consisting of nothing more than a little mass of excessively minute sporules, or reproductive particles, much smaller than the finest sand, inclosed in a thin bag, of either a fibrous or reticulated structure, which in time pierces the cuticle under which it lies, gradually assumes a tubular appearance, and finally bursts at the apex for the purpose of enabling the sporules to escape.



1. *Æcidium cancellatum*, on a leaf, natural size. 2. Peridia, magnified. 3. *Æcidium Berberidis*, natural size. 4. Peridia, magnified. 5. Sporules.

A great many species are found upon the weeds and trees of Europe, varying in colour, size, and form. Of these the two following are among the most common:—

Æcidium cancellatum, the Pear Æcidium. This plant is often very common in the latter months of autumn on the back of the leaves of the cultivated pear-tree, to which it gives a singularly warted aspect. It makes its appearance, crowded in little patches of a pale brown colour, which, when examined with a microscope, are seen to consist of numerous oval bodies, about a line long, rather the broadest towards the upper end. These bodies are, when young, slightly furrowed, but at a more advanced period they divide into tough parallel fibres, which open at the sides, but do not separate at the apex. Through the passages thus formed between the fibres fall the sporules, or seed-like particles.

To inaccurate observers this species would appear an aggregation of the nests of some minute insect, for which we know it to be often mistaken. It probably does not produce any injurious effect upon the plants it attacks, for it generally makes its appearance late in the season, when the leaves have nearly completed their office for the year.

Æcidium Berberidis, the Barberry Blight. The bright orange powder that collects upon the leaves and flowers of the common Barberry consists of the sporules of this species, which are discharged from thousands of little tubular apertures, that spread in patches over all the tender parts. These apertures are the open ends of the peridia in a state of maturity, and are bordered at first by a ragged toothed membrane, which finally falls away. There is a popular notion that Barberry bushes blight corn. The rust of corn is a species of *Puccinia* [PUCCINIA], and it is not improbable that the spores of *Æcidium* from the Barberry may produce *Puccinia* on the corn.

(Henslow's *Journal of the Royal Agricultural Society*, 1841.)

ÆGA'GRUS, a wild species of Ibex, called Paseng by the Persians. [GOAT.]

ÆGOPODIUM (from αἴξ, a goat, and ποδίον, a little foot), a genus of plants belonging to the order *Umbelliferæ*. One species, *Æ. podagraria*, is common throughout the whole of Europe, and grows abundantly in Great Britain. It has a stem one or two feet high, with furrows. The leaves are two or three times ternate; the leaflets unequal at the base and acutely serrate. It has a creeping root, and grows in damp places. Although well known, and having the names of Goat-Weed, Ash-Weed, Herb Gerard, and Wild Masterwort, it seems to possess no medicinal properties. Linnæus says that it is boiled when young, and eaten as greens in Sweden.

AE'LODON, the generic title applied by H. von Meyer to the fossil crocodile or gavial of Monheim.

AEROLITES, called also *Meteoric Stones*, are bodies which have fallen on the earth from the atmosphere, and are named from ἀήρ, atmosphere, and λίθος, a stone. We possess historical records from very remote antiquity, and numerous writers in all ages have mentioned instances of the remarkable phenomenon of stony bodies having been seen to fall from the sky; yet, till within the last fifty years, all such accounts were treated as tales of the ignorant and superstitious. The first man of science who directed attention to the subject of aërolites was Chladni, a German philosopher, who, in a tract published at Riga and Leipzig, in 1794, upon the mass of native iron found by Pallas in Siberia, maintained the credibility of the traditions of that and other stony bodies having fallen from the air. His sagacious inductions, although they failed at the time to make any great impression, prepared philosophers for a more willing reception of the evidence as to two instances of the same extraordinary event, which were shortly afterwards brought under their notice. In 1796 a stone was exhibited in London, weighing 56 pounds, which fell at Wold Cottage, in Yorkshire, in December of the preceding year; but, although the fact was attested by several credible witnesses, the possibility of such an occurrence was still doubted. It was remarked, however, by Sir Joseph Banks, that there was a great resemblance between the Yorkshire stone and one in his possession, sent to him from Italy, with an account of its having fallen from the clouds, along with many others of a similar nature, near Sienna, in July, 1794. In the year 1799 Sir Joseph Banks received a circumstantial account, accompanied by specimens, of a fall of stones from the atmosphere, which was said to have taken place near Benares, in Hindustan, in the preceding December; and as these specimens were also nearly identical with the Yorkshire stone, incredulity began to give way. It was not, however, till the appearance of the celebrated paper of Howard, in the 'Philosophical Transactions' for 1802, giving an account of his analysis of the Benares stone, that men of science declared their belief in the phenomenon, supported, as the evidence then was, by the researches and opinion of so cautious and accurate an inquirer; and a fall of stones at L'Aigle, in Normandy, which took place in the following year, at the time the memoir of Howard was in the hands of the public, removed all doubt. The Institute of France deputed the celebrated Biot to examine, on the spot, the whole circumstances attending this remarkable event; and the result of his labours will be found in his report, in the seventh volume of the 'Mémoires de l'Institut.' He satisfied himself of the authenticity of the facts which had been narrated; and the specimens he collected on the ground, being analysed by Vauquelin and Thénard, yielded the same result as the analysis of the Benares stone by Howard.

An account of the circumstances that attended the fall of stones at Benares and at L'Aigle will convey the best idea of the phenomenon, not only as it occurred in these two cases, but in most other instances of which a circumstantial description has been preserved. They are always accompanied by a meteor, which at night appears like a burning fiery ball, surrounded by a brilliant vapour, and [illegible]h a tail like a comet; in the day, on account of the strong light of the sun, and the smoke and vapour evolved, the meteor looks more like a small cloud of different colours, and of a singular form, which, after a powerful explosion, seems to burst and scatter its contents.

At a short distance from Benares, on the 19th of December, 1798, a very luminous meteor was observed in the heavens, about eight o'clock in the evening, in the form of a large ball of fire; it was accompanied by a loud noise, resembling that of thunder, which was immediately followed by the sound of the fall of heavy bodies. On examining the ground, it was observed to have been newly torn up in many places, and in these stones were found of a peculiar appearance, most of which had buried themselves to the depth of six inches. At the time the meteor appeared the sky was perfectly serene; not the smallest vestige of a cloud had been seen since the 11th of the month, nor were any observed for many days after. It was seen in the western part of the hemisphere, and was only a short time visible. The light from it was so great as to cast strong shadows from the bars of a window upon a dark carpet, and it appeared as luminous as the brightest moonlight. Many of the stones were collected, and some of them weighed two pounds each.

On the 26th of April, 1803, at one o'clock in the afternoon, the sky being clear, with the exception of a few light clouds, a ball of fire was observed in Normandy, in many places far distant from each other—namely, Caen, Falaise, Alençon, Verneuil, and Pont Audemer—which moved rapidly from south-east to north-west; and about the same time, in the district of L'Aigle, loud explosions were heard, which lasted from five to six minutes, resembling the sound of cannon and musketry, and were followed by a long-continued noise, like that of many drums. The meteor from which the noise proceeded appeared not so much like a ball of fire, but rather like a small rectangular cloud, which, during the phenomenon, seemed not to move; but the vapour of which it consisted was sent out, after each explosion, in all directions. It seemed to be about half a league north-west from L'Aigle, and must have been at a very considerable elevation, as it appeared to the inhabitants of two villages, more than a league distant from each other, to be immediately over their heads at the same instant. Throughout the whole district over which the cloud hung there was heard a hissing noise, like that of a stone from a sling, and a vast number of stones fell to the ground. The space on which they fell formed an ellipse of two leagues and a half long by one broad, the larger diameter being from south-east to north-west, the direction in which the meteor moved: the largest stones were found at the south-east end of the ellipse, and the smallest at the opposite extremity. Above 2000 were collected, and they varied in weight from 2 drachms to 17 pounds and a half.

Aërolites, when taken up soon after their fall, are extremely hot. They are generally angular, of prismatic and pyramidal forms, the angles being rounded; their broken irregular surface is coated with a fused black crust, like varnish, seldom exceeding a quarter of a line in thickness. When broken, they differ a little in appearance; but they are, for the most part, composed of a collection of small spherical bodies, of a grey colour, imbedded in a gritty substance, and often interspersed with yellow spots. One of the most remarkable circumstances is the great similarity of composition of all the meteoric stones, on whatever part of the earth they have fallen. Iron is found in all, and in a considerable proportion, partly in a malleable state, partly in that of an oxide, and always in combination with a greater or less proportion of the rare metal called nickel. The earths silica and magnesia and sulphur constitute the other chief ingredients; but the earths alumina and lime, the metals manganese, chrome, and cobalt, together with carbon, soda, and water, have also been found in minute and variable quantities, but not in the same specimens. The variations discovered by analysis are never, however, sufficient to destroy that affinity of external character by which they are instantly recognised. No new substance, nothing with which we are not already acquainted, has ever been discovered in their composition. But, although all the constituent elements are found in different mineral substances, no combination of them, similar to that in meteoric stones, has ever been met with, either among the stratified rocks of any period of formation, or among the unstratified rocks, or among the products of any volcano, extinct or in activity. Their specific gravity is about 3·50, but varies according to the proportion of iron which they contain. They are sometimes very friable, sometimes very hard; and some that are friable when they first fall, become hard afterwards. In size they vary from 2 drachms weight to 300 pounds. One of the stones which fell at L'Aigle yielded by the analysis of Thénard,—

Silica	46	per cent.	
Magnesia.	10	,,	,,
Iron.	45	,,	,,
Nickel	2	,,	,,
Sulphur	5	,,	,,

and Laugier afterwards discovered the presence of chrome in it. Frequently small detached portions of malleable iron are disseminated through the mass, and the black crust acts powerfully on the magnet.

The appearance of these bodies is not periodical, nor connected with any particular state of the atmosphere, nor of the weather; and they have fallen in all climates, on every part of the earth, at all seasons, in the night and in the day.

Chladni has compiled a very copious catalogue of all recorded instances, from the earliest times: of which twenty-seven are previous to the Christian era; thirty-five from the beginning of the first to the end of the 14th century; eighty-nine from the beginning of the 15th to the date of the fall at L'Aigle at the beginning of the present century. In 1837 M. Quetelet, of Brussels, published a catalogue of remarkable meteors, and again in 1841. Mr. Henick, in America, and M. Chasles, in France, also published lists in 1841. The latest accounts have been published by Professor Baden Powell, in the 'Transactions of the British Association,' since the year 1847. Numerous as the instances are in which these phenomena have been witnessed they can form but a small proportion of the whole amount, when we compare the small extent of surface occupied by those capable of keeping a record of such events, with the wide expanse of the ocean, the vast uninhabited deserts, mountains, and forests, and the countries possessed by savage nations. Many of those which occur in the night must also escape observation even in civilised countries.

Among the more remarkable instances to be met with in ancient authors, the following may be mentioned. Livy states that, in the reign of Tullus Hostilius (about 654 B.C.), a shower of stones fell on the Alban Mount, not far distant from Rome. Plutarch, in the 'Life of Lysander,' describes a stone that fell at Ægos Potami, in the Hellespont, near the modern Gallipoli, about 405 B.C., which is also mentioned by the elder Pliny (ii.), who says that it was to be seen in his time, that is, five hundred years afterwards, and that it was as large as a waggon, of a burnt colour, and its fall was accompanied by a meteor. It is also recorded in the 'Parian Chronicle.' The mother of the gods was worshipped at Pessinus, in Galatia, under the form of a stone, which was said to have fallen from heaven; and that stone, in consequence of a treaty with Attalus, king of Pergamus, was solemnly brought to Rome by Publius Scipio Nasica, about 204 years B.C., and placed in the temple of Cybele. The sun was worshipped at Emesa, in Syria, under the form of a large, conical, black stone, which, as the people about the temple reported, fell upon the earth. It was afterwards brought with great pomp to Rome by Elagabalus, who had been high-priest of the temple; and the description of it, given by Herodian (v.), accords with the appearance of a meteoric stone. In China records exist of occurrences of this kind during a period of 2400 years. These were translated by M. Priot; and to give an instance of the nature of these records we may state that between the years A.D. 960 to 1270 no less than 1479 meteors are registered. Of course these were not all aërolites. The great stone at Cholula in America was asserted by the Mexicans to have fallen from heaven.

One of the cases of more modern date, most circumstantially described, is that of the stone which fell at Ensisheim, in Alsace, in 1492. The emperor Maximilian being there at the time, ordered an account of the event to be drawn up. It weighed 270 pounds; and was afterwards suspended by a chain in the church at Ensisheim for three centuries. During the French Revolution, it was carried off to Colmar, and many pieces were broken from it. One of these is in the museum at the Jardin des Plantes, in Paris; it is identical in composition with other meteoric stones, and contains native or malleable iron. What remained of the precious relic has since been restored to the good people of Ensisheim, and it now stands near the great altar in their church.

Besides aërolites properly so called, masses of malleable iron, often of vast size, have been found in situations, which, together with their composition, leave no doubt as to their being of meteoric origin. An immense mass, seen by Pallas in Siberia, which forms the subject of Chladni's tract in 1794 above alluded to, was found quite insulated, at a great elevation on a mountain of slate near the river Yenesei, removed from everything that could excite suspicion of its being a production of art, and totally different from any ore of iron seen either before or since that time. The tradition was, that it had fallen from heaven, and, as such, was held in veneration by the Tartars; but it was removed in 1749 to the neighbouring town of Krasnojarsk by the inspector of the iron mines there. The mass, which weighed about 1400 lbs., was of an irregular form, not solid, but cellular like a sponge, the cells containing small granular bodies of a glassy nature, afterwards found to be the simple mineral olivine, so common in basalt. The iron was tough and malleable, and, according to the analysis of Howard, yielded 17 per cent. of nickel; but Klaproth and John found a much smaller proportion of nickel, and Laugier found, by another analysis, silica, magnesia, sulphur, and chrome. The disagreement of such skilful operators shows that the mass was not uniform in its composition. Another vast mass of meteoric iron was found in South America, in the jurisdiction of Santiago del Estero, about 500 miles north-west from Buenos Ayres, and is described in a memoir in the Spanish language, printed in the 'Philosophical Transactions' for 1788, by Don Rubin de Celis, who was sent by the governor of the province to examine it. It lay in a vast plain of above 100 leagues in extent, half sunk in the ground, and the size was such as, estimating it by the specific gravity of iron, would give a weight of more than 13 tons. According to the analysis of Proust and of Howard, it contains 90 per cent. of iron, and 10 of nickel. Specimens of this mass, which were sent to the Royal Society by Don Rubin de Celis, are in the collection of the British Museum. A mass of meteoric iron at the Cape of Good Hope, mentioned by Barrow in his 'Travels in Africa,' as an artificial production, is described by Van Marum in the 'Haarlem Transactions,' a large portion of it having been sent to the public museum there by the governor of the colony. The mass, when found, was equal to about 177 lbs., but much had been carried away. The specific gravity is 7·604. Tennant found it to contain 1·10 per cent. of nickel, and a trace of carbon, and Stromeyer detected cobalt in it, which last metal has also been found by Dr. Turner in some meteoric iron from Buenos Ayres. Another mass was found in Brazil, about 50 leagues from Bahia, the weight of which was estimated at 14,000 lbs.; a fragment of this, analysed by Dr. Wollaston, yielded 4 per cent. of nickel. Many other instances of similar masses of iron might be mentioned, which are evidently of meteoric origin; but the only instance on record of iron having been actually seen to fall from the atmosphere, is that which took place at Agram, in Croatia, in 1751. On the 26th of May, about six o'clock in the evening, the sky being quite clear, there was seen a ball of fire, which shot along with a hollow noise from west to east, and after a loud explosion, accompanied by a great smoke, two masses of iron fell from it, in the form of chains welded together.

Aërolites and meteoric iron are not the only products of meteors which have fallen upon the earth after explosion. Numerous instances are mentioned of black and red dust, which has covered great tracts of land; and it is remarkable that such dust has generally been found to contain small angular grains resembling augite. There have also been cases of the fall of a soft gelatinous matter of a red colour like coagulated blood, which have given rise to the stories of the sky having rained blood. Such appearances have not unfrequently accompanied the fall of stones. On the 15th November, 1775, rain of a red colour fell around Ulm and the Lake of Constance, and on the same day in Russia and Sweden. The red water was of an acid taste, probably from the presence of sulphuric acid; and the precipitate, which was flaky like snow, when dried, was attracted by the magnet. In the night of the 5th March, 1803, a red dust, in some places accompanied by rain, fell in different parts of Italy. In Apulia, there was first a very high wind with much noise, and then a reddish-black cloud appeared coming from the south-east, from which there fell a yellowish-red rain, and afterwards a quantity of red dust. It continued the whole of the following day and part of the succeeding; the dust was examined, and was not found to be volcanic. Fabroni, in the 'Annales de Chimie,' tom. lxxxiii, says, that near Arezzo, in March, 1813, the ground being then covered with snow, there was a shower of fresh snow of a red colour, which continued for many hours, accompanied the whole time with a sound like that of the violent dashing of waves at a distance; the greatest fall was accompanied with two or three explosions like thunder. The red snow being melted, a precipitate was obtained of a nankeen colour, which yielded silica, lime, alumina, iron, and manganese.

The origin of this remarkable class of natural phenomena is involved in great obscurity, and many different theories have been proposed to account for them. By some they have been supposed to be bodies ejected from distant volcanoes belonging to our earth,—a conjecture which is refuted by every circumstance connected with them. No substance in the least resembling aërolites has ever been found in or near any volcano; they fall from a height to which no volcano can be supposed to have projected them, far less to have given them the horizontal direction in which meteors invariably move for a considerable part of their course. Another hypothesis is, that meteoric bodies are formed in the atmosphere, which is equally untenable; for, in the first place, there is no ground for supposing, from any discoveries yet made in chemistry, that the elements of which they are composed exist in the atmosphere; and even if they did, the enormity of the volume of the atmosphere, attenuated as it is at the great height from which the meteors fall, which would be required to produce a solid mass of iron of thirteen tons weight, places the conjecture beyond all credibility. A third hypothesis is, that they are bodies thrown out by the volcanoes which are known to exist in the moon, with such force as to bring them within the sphere of the earth's attraction. This hypothesis was so far entertained by Laplace, that he calculated the degree of lunar volcanic force that would be necessary for this purpose. He calculated that a body projected from the moon with a velocity of 7771 feet in the first second would reach our earth in about two days and a half; but Olbers and other astronomers are of opinion that the velocity of the meteors, which has been estimated in some cases to be at first equal to some miles in a second, is too great to admit of the possibility of their having come from the moon. The theory which is most consistent with all known facts and laws of nature is that proposed by Chladni, namely, that the meteors are bodies moving in space, either accumulations of matter as originally created, or fragments separated from a larger mass of a similar nature. This opinion has also been advanced by Sir Humphrey Davy, at the conclusion of one of his papers in the 'Philosophical Transactions' for 1817, giving an account of his researches on flame. It is also the opinion of Sir John Herschel and Alexander von Humboldt; the latter of whom, in his 'Cosmos,' devotes a large space to the consideration of this highly interesting subject.

Those who wish to investigate this curious subject will find it most ably and copiously treated in Chladni's work, *Ueber Feuer-Meteore, und über die mit denselben herabgefallenen Massen*, Vienna, 1819, which is a second edition of his first treatise. The *Lithologie Atmosphérique* of Izarn may also be consulted; also a good compilation by Bigot de Morogues, entitled *Mémoire Historique et Physique sur les Chûtes des Pierres*, Orleans, 1812; Humboldt's *Cosmos*; and the *Quarterly Review* for December, 1852.

AESCHINITE, a mineral of which the principal salt is a titanate of zirconia. [TITANIUM.]

Æ'SCULUS, a genus of plants belonging to the natural order *Hippocastaneæ*. It consists of trees found in the temperate parts of America and Asia, remarkable for the beauty of their flowers and leaves, and for their forming in some sort a type of tropical vegetation in northern latitudes. It must not be confounded with the Æsculus of the Romans, which was a kind of oak. [QUERCUS.] The best known species is the Common Horse-Chestnut (*Æsculus Hippocastanum*), a very handsome timber-tree, formerly much used for avenues, and still extensively planted wherever round masses of wood, or gay flowering trees, are required. Its bark and its nuts are also among the more useful products that the hardy trees of this climate afford. It is very singular that the native country of this species should be unknown. One writer says it inhabits the northern parts of Asia; another, that it is found in the cold provinces of India; and a third assigns it to the mountain-chains of Asia Minor; while all the positive information that books really afford is, that it was brought to Vienna from Constantinople in the beginning of the 16th century, and was thence dispersed through all Europe. The popular name of Horse-Chestnut has arisen from the custom among the Turks of grinding the nuts and mixing them with the provender given to horses that are broken-winded. Starch is also yielded in very considerable quantity by the nuts; and, deprived of its bitterness by maceration in weak ley, has been recommended as excellent nutritious food for horses, goats, oxen, and sheep. The general characters of the Horse-Chestnut are too well known to require description. As a forest-tree, it is well adapted to light lands, upon which it will thrive, although they may be very sterile; in tenacious clay, it is always stunted and unhealthy, as in the Regent's Park; in rich alluvial soil, it acquires its greatest beauty. The timber is soft and spongy, and therefore of little value. There are no very old specimens in this country, the species having been introduced, as it is said, only in 1683.

Horse-Chestnut (*Æsculus Hippocastanum*).

A second species, the *Æsculus Ohiotensis*, is found wild in North America, on the banks of the Ohio, between Pittsburg and Marietta. In stature it varies from 10 to 35 feet; and differs from the common kind in having larger and much more undulated leaves. It has been cultivated for some years in this country, but has never flowered.

Besides these, a third species, *Æsculus carnea*—or, as it is sometimes called, *Æsculus rubicunda*, or *rosea*—is occas[illegible]ally met with in gardens. Its origin is unknown. For all purposes of ornament, this is much superior to the common kind.

The Buck's-Eye Chestnuts of North America belong to the genus *Pavia*. [PAVIA.]

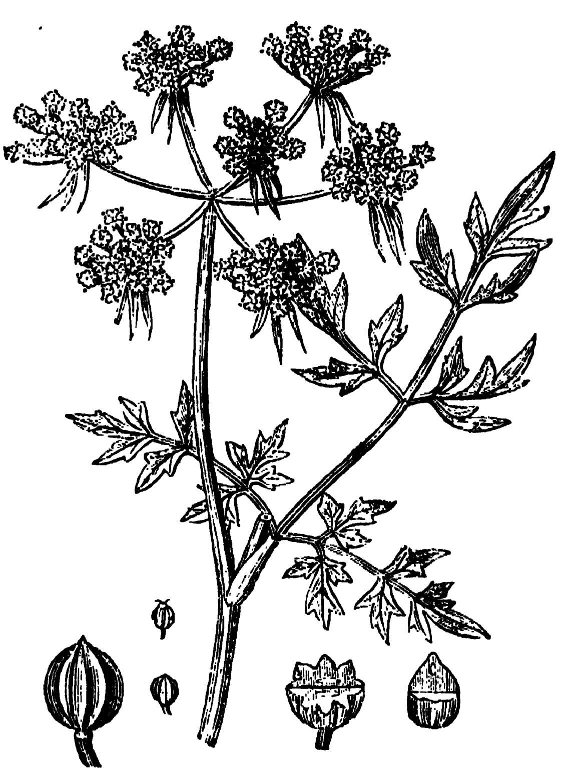
The first two species of Horse-Chestnut are propagated by sowing their seeds either in the autumn at such a depth below the surface as to be secure from the attacks of mice, or else in the spring; but in the latter case they must be preserved during the winter in heaps of sand. The seeds should not be placed less than six inches apart in the beds, because the leaves are so large as to require more than usual space to expose themselves to light. The last species, and the varieties of the first, not yielding seeds, are multiplied by budding upon the common Horse-Chestnut.

AESHNA. In this recent genus of *Libellulidæ* Mr. Strickland ranks a fossil insect from the Lias of Warwickshire.

AETHOPHY'LLUM, a fossil genus of plants from the Keuper Sandstone. (Brongniart.)

ÆTHU'SA is a genus of plants belonging to the natural order *Umbelliferæ*, which includes among its species one of the most poisonous plants known in Europe.

Æthusa Cynapium is a little annual plant, found commonly in gardens and fields, resembling the common parsley so much that it has acquired the vulgar name of Fool's Parsley. From a taper whitish root arises an erect branchy stem, about a foot high, generally stained with purple near the ground. This is covered by finely-cut shining leaves of a deep green, much resembling those of Garden Parsley, from which they are known thus: in the true Parsley, the leaves are twice pinnated or divided, and the leaflets are broad, and cut into three wedge-shaped toothed lobes; in the Fool's Parsley, on the other hand, the leaves are thrice pinnated, and the leaflets are narrow, sharper, and jagged; besides which, the leaves of Fool's Parsley have a disagreeable nauseous smell, instead of the fine aromatic odour of Common Parsley. When in flower, *Æthusa* has its principal umbels destitute of involucra, while the partial umbels are furnished with an involucrum, consisting of four or five narrow sharp leaves, hanging down from one side only of the common stalk; this last circumstance will distinguish it when in flower, not only from parsley, but from all other British umbelliferous plants.



Æthusa Cynapium.

Many dangerous accidents have occurred from mistaking this plant for parsley. The symptoms attendant upon poisoning by *Æthusa* are, swimming of the head, nausea, cold perspiration, and chilliness at the extremities. To counteract its effects, emetics are recommended, and the immediate use of weak vegetable acids, such as lemon-juice, vinegar, or sour wine.

AETO'BATES, a genus of fossil fishes allied to the Rays. The species are found in the London clay of Sheppey. (Agassiz.)

AGALLOCHUM. [EXCÆCARIA; AQUILARIACEÆ.]

AGALMATOLITE (also *Pagodite, Bildstein, Lardite*). This mineral is found in China, and is seldom brought into this country except cut into various figures. Less characteristic varieties have been found in Transylvania and Saxony; it is found also in Wales. Occurs massive. Fracture coarse splintery, imperfectly slaty. Soft. Colour white, with a shade of gray, green, yellow, red, or brown, none of them bright. Streak shining. Unctuous to the touch. Slightly translucent, but in most cases only the edges. Specific gravity 2·815.

Before the blowpipe infusible, but becomes white. Partly soluble in sulphuric acid, leaving a residue, chiefly of silica.

Analysis of the Chinese variety by Vauquelin:—

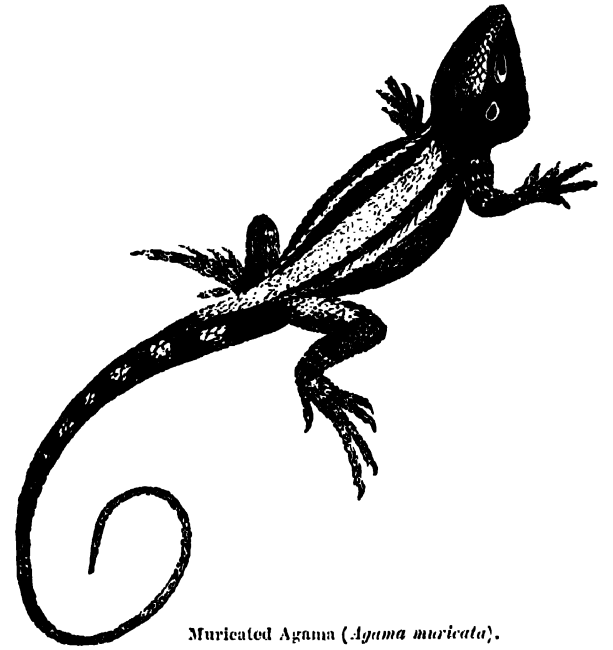
A'GAMA, in Zoology, a genus of reptiles belonging to the order *Saurians*, and family *Iguanians*, of Baron Cuvier.

In the form of their heads and teeth the species of *Agama* resemble the common lizards, but differ in the imbricated scales which cover their tails. These animals have the body thick, and shorter in proportion than the generality of the saurian family; the skin is lax, and capable of being distended or puffed out with air at the will of the reptile; the whole body, as well as the head, neck, and feet, is covered with minute rhomboidal or hexagonal scales, often prolonged in the form of little spines, and bristling when the body is inflated with air. The head is short, broad, and flat, particularly towards the occiput; the neck also is short, and the tail seldom longer than the body. These proportions give the Agamas much of the hideous and disgusting appearance of toads. In many parts of South America they are called Chameleons, from their power of dilating the skin with air, and imitating, to a certain extent, those animals in the various hues which they are capable of assuming. In other respects the various species of Agamas differ so considerably from one another, as to have induced Baron Cuvier to arrange them in separate subgenera, distinguished by the form of their scales and the presence or absence of pores in the thighs. Generally speaking, the Agamas have no thigh pores; some however are provided, as is the case with many other saurian reptiles, with a row of these pores along the inner surface of each thigh; some species have the toes so short and rigid as to compel them to live entirely on the surface of the earth, where they reside among rocks and heaps of stone, and conceal themselves in the crevices; others again, which have long and flexible toes, ascend trees with great facility, and sport among their branches with the utmost security. All are of a diminutive size, and, like most other reptiles, feed upon insects and other small animals: one or two species however are reported to be herbivorous. Their geographical distribution is very extensive, and embraces all the hot and most of the temperate parts of the known world: Asia, Africa, Australia, and South America have each their appropriate species, which often differ from one another very slightly.

The most remarkable species are, of those without pores on the interior face of the thighs:—The Muricated Agama (*Agama muricata*, Cuvier), first described by the celebrated John Hunter in the zoological part of White's 'Voyage to New South Wales.' It is one of the most common lizards of that colony; measures upwards of a foot in length, comprehending the tail, which is twice as long as the body, and, from the great length and perfect division of its toes, readily ascends trees, and lives entirely in the woods, where it hunts about for insects and caterpillars. Its general colour is a brownish gray, marked with dusky bars, which run in a longitudinal direction on the body, but transversely on the legs and tail. The scales which cover the upper and outer parts of the trunk and extremities are rhomboidal and carinated, or elevated into sharp-pointed ridges, forming parallel lines or rows of spines upon the back and sides, from the shoulders to the very point of the tail. The head is covered with similar scales, all directed backwards and prolonged upon the occiput into a crest of weak spines. The toes of all the feet are well separated, and furnished underneath with small pointed scales; the two middle toes of the hind feet are nearly twice the length of the others.

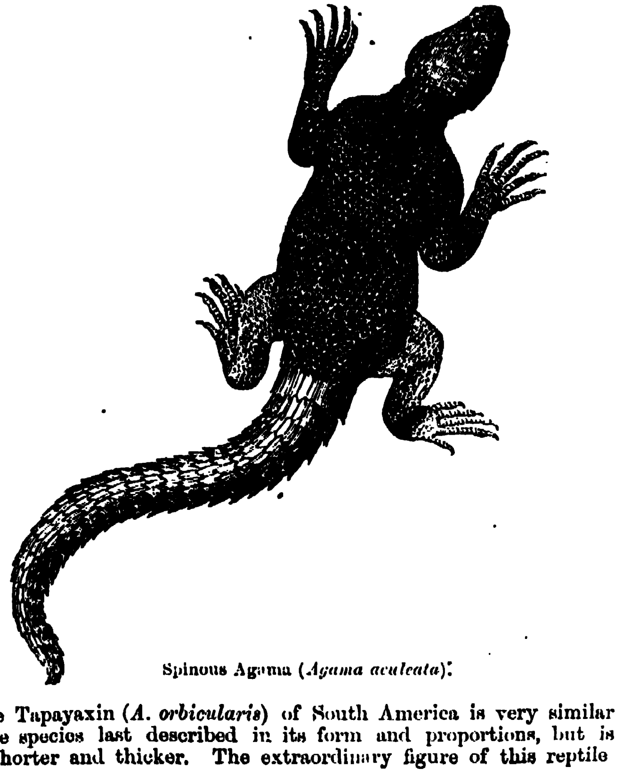
The *Agama barbata* of Cuvier is another species from the same locality. It is rather larger than the Muricated Agama, but preserves the same relative dimensions, and lives in the forests in the same manner. This species is figured and described in White's 'Voyage,' p. 255, but was considered by Mr. Hunter as a mere variety of the former.

Other species of this division, having pores on the inner surface of the thighs, are the *Leiolepis* (*A. guttata* of M. Cuvier) of Cochin-China, with white rays and spots on a bright blue ground; the *Tropidolepis* (*A. undulata*), of a uniform dark blue colour with a white cross on the throat, and which, as well as the kindred species, *A. nigri-collaris* and *A. cyclurus*, described by Spix, inhabits various parts of South America; the *Brachylophes* (*A. vittata*), which seems to form the connecting link between this genus and the guanas, from which latter it is distinguished only by the absence of teeth in the palate; it is found in India, and has light blue bands upon a dark blue ground: and lastly the *Physignathes* (*A. cocincinus*), from the Malayan Peninsula, remarkable for its large size, uniform blue colour, but more particularly from being one of the very few species of saurian reptiles which feed upon vegetable substances. Baron Cuvier assures us that it lives entirely upon fruits and nuts.



Muricated Agama (*Agama muricata*).

Of the Agamas without pores in the thighs, the principal species are, the Spinous Agama (*A. aculeata*) of a yellowish gray colour with numerous transverse brown bands. All the upper parts of the body are covered with elevated scales, forming small pointed pyramids of four-sides; the body is short and thick, the tail likewise short, the head broad and flat, and the belly protuberant. Excepting in the length of the tail, and the body being covered with scales, the whole animal has much of the form and appearance of a frog or toad: it is found at the Cape of Good Hope, and is of larger size than the generality of the other species.



Spinous Agama (*Agama aculeata*).

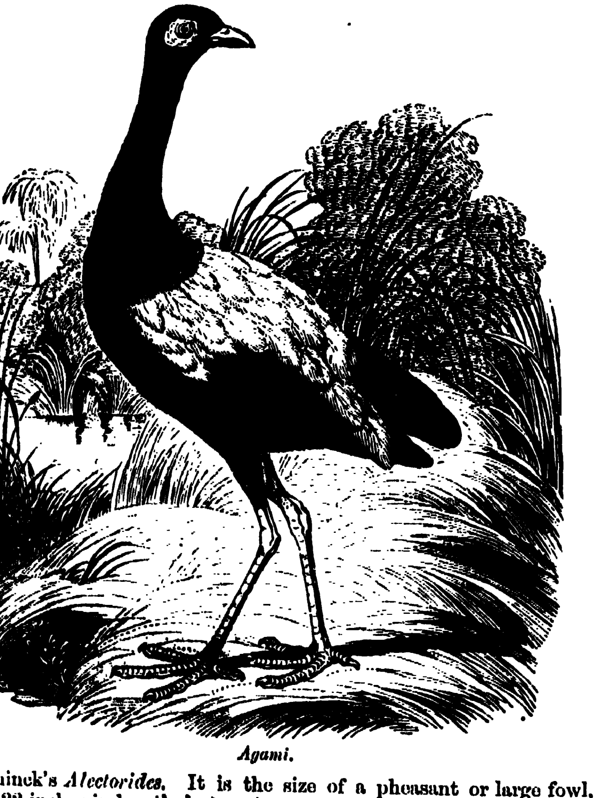
The Tapayaxin (*A. orbicularis*) of South America is very similar to the species last described in its form and proportions, but is still shorter and thicker. The extraordinary figure of this reptile approaching almost to the form of a perfect sphere, its broad flat head, its skin covered with small tubercles or warts interspersed among the scales, and the faculty which it possesses of distending its body with air, and to a certain degree assuming different shades of colour, have caused it to be sometimes compared to a toad, and sometimes to a chameleon; but the truth is, that it has no actual relation or affinity to either of these animals, but is indebted solely to its naturally disgusting aspect for the calumnies which the early Spanish writers have heaped upon it. The Tapayaxin inhabits the mountainous and rocky parts of South America, from the Isthmus of Darien to Patagonia.

Other sub-genera and species belonging to this division of the Agamas are—*Trapelus* (*A. Ægypticus*), remarkable for its change of colour, even more sudden than that of the true chameleon; the *A. calotes*, of a bright blue colour with transverse white marks on the sides, from the Molucca Islands; the *Lophyres* (*A. gigantea*, Kuhl), with a crest of long elevated spines on the neck; and the *Lyriocephalus* (*A. scutata*), which has a similar elevated crest along the back, and the tail keel-shaped. This latter species, in many respects a most singular reptile, inhabits Bengal, and lives upon fruits.

For ample details concerning the specific differences of the Agamas, we refer the reader to the works of Cuvier, Daudin, and Merrem.

A'GAMÆ, in Botany, is a name given by some authors to the large division of the Vegetable Kingdom called Flowerless Plants, and may be considered equivalent to the older term, Cryptogamic. [ACROGENS.]

A'GAMI (*Trophia crepitans*, Latham), an interesting bird, sometimes also termed the Gold-Breasted Trumpeter, classed by Pallas among Cranes, by Brisson among Pheasants, and making the first genus in Temminck's *Alectorides*. It is the size of a pheasant or large fowl, being 22 inches in length, but appears larger from having a long neck, and from standing high on its legs. It bears some slight resemblance to the pheasant in the glossy iridescent green on the breast, and in a space round the eyes naked of feathers; but has a very short tail, consisting of twelve black feathers, over which the long, loose, silky scapulary rump-plumes hang droopingly. Its long greenish legs assimilate it to wading birds (*Grallatores*), but it is said not to have the habits of these, never visiting fens and the margins of water, and living wholly in upland forests and arid mountains. It inhabits the forests of tropical America, and never visits the cleared grounds or the settlements. According to M. Mououcour, it is very gregarious, being found in numerous flocks, which walk and run, but rarely fly, and, when they do, seldom rise more than a few feet above the surface of the ground. Even when pursued they trust most to their speed in running.



Agami.

Several naturalists have given accounts of the Agami in a domestic state. Its docility and attachment to man are remarkable. "The Agami," says Mououcour, "is not only tamed easily, but becomes attached to its benefactor with all the fondness and fidelity of the dog; and of this disposition it shows the most unequivocal proofs. When bred up in the house, it loads its master with caresses, and follows his motions; and if it conceives a dislike to persons on account of their forbidding figure, their offensive smell, or of injuries received, it will pursue them sometimes to a considerable distance, biting their legs, and testifying every mark of displeasure. It obeys the voice of its master, and even answers to the call of all those to whom it bears no grudge. It is fond of caresses, and offers its head and neck to be stroked; and, if once accustomed to these familiarities, it becomes troublesome, and will not be satisfied without continual fondling. It makes its appearance as often as its master sits down to table, and begins with driving out the dogs and cats, and taking possession of the room; for it is so obstinate and bold, that it never yields, and often, after a tough battle, can put a middle-sized dog to flight. It avoids the bites of its antagonist, by rising in the air, and retaliates with violent blows with its bill and nails, aimed chiefly at the eyes; and after it gains the superiority, it pursues the victory with the utmost rancour, and, if not parted, will destroy the fugitive."

The peculiar noise which these birds make, without opening the bill, is one of their most remarkable characteristics. This noise is no doubt produced by a peculiar conformation of the organ of sound. According to Pallas, the larynx, which is on the outside of the breast, is about as thick as a swan's quill and almost bony, becomes much more slender, loose, and cartilaginous when it enters within the breast, where two semicyrindrical canals of a membranous texture, and capable of being extended, proceed from it. The air-bag on the right side descends to the pelvis, and within the breast it is divided into three or four cells by transverse membranes. The air-bag on the left side is narrower. Vosmaër tells us that the sound is sometimes preceded by a wild cry, interrupted by a call somewhat like 'scherck, scherck,' and then follows the characteristic noise somewhat resembling the cooing of pigeons. It utters, in this way, five, six, or seven times, with precipitation, a hollow noise nearly resembling the syllables 'too too, too, too, too, too,' resting upon the last a very long time, and sinking the sound gradually till it terminates. During this, the breast is seen to heave, as in birds while singing, though the bill remains shut. It is, no doubt, produced by the air pressed up from the lower air-bags on the right and left above described, which, meeting with the transverse membranes in its passage, causes them to vibrate and sound, and this is communicated to the surrounding muscles, and by these to the external air.

The Agami, like the rest of the *Alectorides*, builds no nest, but scratches a shallow place at the root of a tree where it deposits its eggs, from 10 to 16 in number, and of a light green colour. They are somewhat larger than a hen's egg, and of a rounder form. The down remains a long time on the young, and grows into long silky plumes, very close, like fur, and it is not till they are one-fourth the size of the adult birds that the true feathers appear.

Dr. Latham tells us, that "one of the Agamis, a young bird, found its way into a farm-yard in Surrey, and associated with the poultry. It was perfectly tame, and, on one occasion, accompanied the hounds for three miles, and kept up with them. It was last in the possession of Lord Stanley, but died on its way into Lancashire."

AGARIC-MINERAL, an earthy variety of calcareous spar, resembling chalk. It is also called *Rock-Milk*. [CALCAREOUS SPAR.]

AGARI'CIA (Lamouroux), the Mushroom Madrepore, a genus of coral madrepores, so called from its resemblance in form to mushrooms (*Agarici*). The animal inhabitants of *Agaricia* are unknown, with the exception of a single species observed by M. Lesueur on the shore of St.-Thomas in the Antilles. Lamarck enumerates five species, and Parkinson seven.

AGA'RICUS is the generic name by which all the species of Mushrooms properly so called are collectively known. It comprehends such plants of the fungus tribe, as have a cap (or pileus) of a fleshy nature, supported upon a distinct stalk, and a number of parallel unequal vertical plates or gills arising out of the cap, and inclosing the particles by which the species are reproduced; particles which the vulgar call seeds, and botanists sporules. This genus, now divided into a large number of sub-genera, consists of not fewer than 1000 species, inhabiting meadows, and heaths, and rocks, and masses of decaying vegetable matter, in the whole of Europe, and in many other parts of the temperate regions of the earth. Among them a large proportion are poisonous, a few are wholesome, but by far the greater number are altogether unknown in regard to their action upon the human constitution. The species are often extremely similar; there are no means of distinguishing botanically the tribes that are poisonous from such as are wholesome, but in every case practice is requisite to determine that point independently of general structure. It is for this reason that the use of wild mushrooms is so dangerous. Indeed there is this most remarkable fact connected with their qualities—a fact which seems to show that their properties depend upon climate and situation, and accidental circumstances, rather than upon any specific peculiarities—those kinds which are wholesome in one country are not so in another; thus, in Great Britain, the Common Mushroom, *Agaricus campestris* (*fig.* 1), the Fairy-Ring Agaric, *A. pratensis* (*fig.* 2), and the *A. Georgii*, are the only sorts that it is quite safe to eat; while the Fly Agaric, *A. muscarius* (*fig.* 3), and *A. virosus* (*fig.* 4), are extremely poisonous. But in other countries of Europe it is different. In Rome one of the few mushrooms excluded from the markets by the government inspectors is the *A. campestris*. In France, in Italy, and especially in Russia, a usual aliment is afforded by a great variety of species which, although very common in this country, it would be extremely dangerous to eat; and, on the other hand, even the dangerous *A. muscarius* is a species of food in Kamtchatka.

The following characters will serve to distinguish such Agarics as are poisonous or suspicious:—

1. Such as have a cap very thin in proportion to the gills.
2. Such as have the stalk growing from one side of the cap.
3. Those in which the gills are all of equal length.
4. Such as have a milky juice.
5. Such as deliquesce; that is, run speedily into a dark watery liquid.
6. And lastly, every one that has the collar that surrounds the stalk filamentous, or resembling a spider's web.

As to the rest, the eatable kinds that can be safely employed in Great Britain are the following:—

A. campestris, the Common Mushroom (*fig.* 1), the species that is so commonly raised artificially for food. This is readily known in any state by its fragrant odour, by which alone it may be always recognised, and the absence of which is extremely suspicious. When in a very young state it resembles little snow-white balls, which are called Buttons; afterwards it acquires a stalk, separates its cap, and becomes shortly conical, with liver-coloured gills, and a white thick fleshy cap, marked with a few particles of gray. At a more advanced age the cap is concave, the colour gray, and the gills black; in this state it is called a Flap. [MUSHROOM.]

A. Georgii is like the latter, but its gills are always very pale, and its flavour inferior. It is said occasionally to weigh as much as 14 lbs.

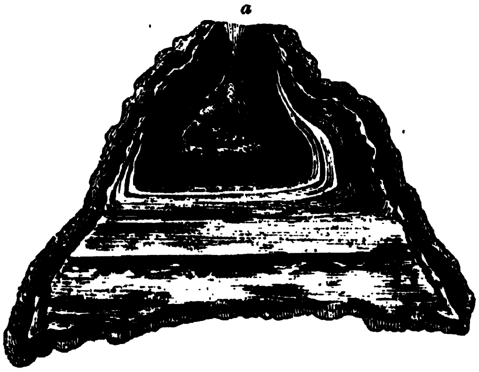
A. pratensis, or *oreades*, the Fairy-Ring Mushroom, is so well known by its popular designation as to require no description. Well may it have gained that name; for, in former times, there would, doubtless, be great difficulty in imagining how such productions could spring up in a few hours in the regular rings they appear in, without the aid of some supernatural agency. The use to which this species is usually applied is that of being powdered and mixed with rich sauces, after having been previously strung upon a line, and dried in the shade. Dr. Badham, in his work on 'The Esculent Funguses of Britain,' shews that a large number of other species may be eaten with impunity. Great caution is however necessary, and no person should venture on the eating of strange species unless practically acquainted with their distinctions. Dr. Badham's work contains drawings of the species which will greatly assist those who may be desirous of distinguishing the edible kinds.

Eatable *Agarici.*

Poisonous *Agarici.*

A'GATE, an ornamental stone used in jewellery, and for some purposes in the arts: it is sometimes called Scotch Pebble. The name is derived from the Greek ἀχάτης, a stone described by Theophrastus, and which, he says, came from the river Achates, in Sicily, now the Drillo, in the Val di Noto. It is one of the numerous modifications of form under which silica presents itself, almost in a state of purity, constituting in the agate 98 per cent. of the mineral. The silicious particles are not so arranged as to produce the transparency of rock crystal, but a translucent, sometimes almost opaque substance, with a resinous or waxy fracture; and a variety of shades of colour are produced by a minute quantity of iron. The same stone sometimes contains parts of different degrees of translucency, and of various shades of colour; and the endless combinations of these produce the beautiful and singular internal forms, for which, together with the high polish they are capable of receiving, agates are prized as ornamental stones. Although occasionally found in other rocks, they are most usually met with in that variety of the trap rocks called Amygdaloid or Mandelstein, forming detached rounded nodules, not cemented to the base or mass of the rock, but easily separable from it, and having generally a thin layer of green earth interposed, and a rough irregular exterior, as if moulded on the asperities of the sides of a pre-existing cavity. The silicious particles have often, but far from constantly, arranged themselves in thin layers parallel to the external surface of the nodule; sometimes the nodule is not solid, but a hollow space is left in it, studded with crystals of quartz; and not unfrequently crystals of carbonate of lime and other minerals, totally distinct in composition from that of the agate, are superimposed on the quartz crystals.

The theory of the formation of agates is a problem of great difficulty, and we must be much further advanced than we are, in our knowledge of the chemical processes of nature in the mineral kingdom, before we can expect to throw any light on this very obscure subject. The great supply of agates is from a class of rocks to which all geologists now assign an igneous origin, analogous to that of lava in existing volcanoes. The theory divides itself into two parts; first, the formation of the cavities in which the agates are found; and, secondly, the filling of these cavities. With regard to the first, we have many analogies from modern lavas, and from processes of art, to guide us to a pretty satisfactory conclusion. Gases are evolved in great quantities by volcanoes, and if produced at the same instant with a flow of lava, they would rise in bubbles in the melted mass; but in proportion as that became more viscid they would rise with greater difficulty to the surface, and when it consolidated would form cavities, the shape of which would be determined by the nature of the pressure of the surrounding viscid lava. To account for the filling up of the cavities three theories have been proposed: one supposes the silicious matter to have been introduced in aqueous solution from without, and to have been gradually deposited in the cavities; another, that, in obedience to some peculiar laws of attraction, it has separated from the rest of the rock, and insinuated itself into the hollows left by the gases; and a third, that these hollows were filled by the sublimation of the silica and other materials from the rest of the mass by the action of heat. Each hypothesis is supported by particular cases, which it satisfactorily explains, but there are probably as many against as in favour of each; all of them imply conditions of chemical action different from anything of which we have had experience. We frequently find, it is true, masses of silicious petrified wood in which hollows of the tree have been filled with agate, not to be distinguished from many nodules found in the trap rocks; and that the matter of the agate must have been introduced into the wood by aqueous infiltrations there can be no doubt: but, in this case, the whole substance of the sustaining mass, the wood, is penetrated by silicious matter; and the difficulty of the theory of infiltration, in the case of the trap rocks, consists in the absence of any trace in the rock of the channel by which the solution of silicious matter could have arrived at the cavity. The following section of an agate is a good example of the filling up of a cavity by infiltration, for it is evident that the silicious matter, in whatever way it may have arrived, was introduced at the point *a*, and that there was a gradual deposition of it. Such examples would be more frequently met with, if there was anything in the external coat to tell us in what direction to slit the stone: this same specimen might have been cut in many directions without throwing any light upon its mode of formation, and the section we now see was an accidental cut in the right direction. An attentive consideration of the products of volcanoes may lead to some satisfactory conclusion; for although agates have not been found in lavas, cavities in them are often partially or entirely filled with minerals distinct from any in the rest of the rock.



Agate.

Agates are often found as loose pebbles in the beds of rivers, or in gravel, but in these cases they have been derived from the disintegration of Amygdaloids, the base of which is very often subject to decomposition when exposed to air and moisture, and then the silicious nodules fall out. They vary in size from that of millet seed to a foot in diameter; but one, two, and three inches in diameter are the most common.

The stones distinguished by mineralogists and lapidaries by the names of Carnelian, Calcedony, Onyx, Sardonyx, Mocha-Stone, Bloodstone, Chrysoprase, and Plasma, are so closely allied to agate, that they may be conveniently described under this head. In chemical composition they are not distinguishable, except in the case of the chrysoprase by its colouring matter.—*Carnelian*, so called because some kinds are of a flesh colour (*carnis*, Latin for flesh), is that variety of a uniform colour which is of most common occurrence: carnelians are never figured or striped. The colours are shades of red and yellow, the deep clear red being the rarest and most valuable. The great supply of carnelians is from Japan, where they exist in vast quantities, and they are also imported from Bombay, being collected in the province of Guzerat; but the best, according to Niebuhr, come from the Gulf of Cambay. Many of the antique gems are engraved in carnelian, and it is now much used for seals.—*Calcedony*, so called from having been early found at Calchedon (sometimes incorrectly written Chalcedon) in Bithynia, opposite Constantinople, is also of a uniform colour, generally of a milky white or pale yellow, like turbid jelly, often with an internal wavy structure in the form of stalactites, and very generally with a peculiar mammillary surface. It is found in great abundance in the Faroe Islands, in Iceland, in Cornwall, and many places of Great Britain, as well as other countries; sometimes in large masses, from which cups and other vessels are formed. Pliny describes it as being found in the neighbourhood of Thebes in Egypt and as brought to Rome from Carthage.—*Chut* is a kind of granular calcedony, and forms a transition to the rock called *Hornstone*.—*Onyx*. In this agate the silicious particles are arranged in alternating horizontal layers of opaque white and translucent blue, gray, or brown; and because these have a resemblance to the marks on the human nail, the stone was called from the Greek word for nail, *ὄνυξ*. It was known to the ancients, and was employed by them, as it is now, for those beautiful gems called cameos, the figure being cut out of the opaque white, the dark part forming the ground, or the contrary. It is most valuable when the contrast of colours is strong, and when the layer is thick enough to give a high relief to the object to be engraved. In the royal library at Paris, there is an antique cameo cut out of an onyx with four layers, representing the apotheosis of Augustus, eleven inches by nine, which is supposed to be the finest in existence. Agates with an onyx structure are not uncommon, particularly among calcedonies, but the finest are brought from India. Cameos are sold at Rome which are made from a thick shell, having different coloured layers like an onyx.—*Sardonyx* is a variety of onyx which is supposed by some to have received its name from having been brought from Sardes, in Lydia. By others it has been said that the name comes from Sardo, the Greek name of Sardinia, there being some reason for thinking that the Carthaginians brought the stones from that island, and exported them during their occupation of it. In this the opaque white alternates with a rich deep orange brown of considerable translucency, and as this is of rare occurrence the sardonyx is of greater value. The finest are brought from the east, and some antique gems are formed of them.—*Mocha-Stones* and *Moss-Agates* are semitransparent calcedony, including various ramified forms, produced by iron, manganese, bitumen, and chlorite or green earth, but sometimes also, as has been proved by Daubenton and MacCulloch, produced by the presence of real vegetable bodies, such as *Confervæ* and mosses. The first are found in Guzerat, but received their name from having been brought from Mocha, in Arabia.—*Blood-Stone*, or *Heliotrope*, is a green agate coloured by chlorite, with numerous bright red spots like drops of blood. It is also called oriental jasper.—*Chrysoprase* (from *χρυσέος*, golden or beautiful, and *πράσον*, a leek) is a rare apple-green calcedony, found in Silesia, which owes its colour to the presence of the metal nickel.—*Plasma* is another scarce green semitransparent calcedony, but of a dark tint, which, in the opinion of MacCulloch, is coloured by chlorite.—*Sard* is a deep reddish-brown variety.

The great supply of the figured agates of commerce is from Oberstein, in the old Palatinate, about 30 miles east of Treves, and 45 miles south of Coblenz. When they were used as buttons, knife-handles, &c., the trade was more extensive than at present. They are found in many parts of Scotland, especially at the Hill of Kinnoul, near Perth, where there is an amygdaloidal trap very full of fine specimens.

A'GATHIS is the generic name given by botanists to the trees, known in common language by the name of Dammar and Kawrie Pines. These plants belong to the natural order *Coniferæ*, from all other species of which they are known, firstly, by their broad, lance-shaped, leathery leaves, the veins in which are numerous and nearly parallel, diverging a little at the base, and converging at the apex; and, secondly, by their seeds having a wing on one side instead of proceeding from the end.

The Dammar Pine (*Agathis loranthifolia*), or the *Pinus Dammara* of Linnæus, is a large tree found on the very summits of the mountains of Amboyna, Ternate, and in many of the Molucca Islands. When young it has something of the aspect of a young cedar, the wood of which it is said to resemble. It is occasionally cultivated in the hot-houses of curious persons; but is of little value except for its resin, which, when pure, is white, clear, and brittle as glass, but in time becomes amber-coloured.

Its timber is represented to be light and of inferior quality, wholly unfit for any situation exposed to wet, but answering tolerably well for in-door purposes.

The Kawrie Pine (*Agathis Australis*) grows only in New Zealand, in the forests of which it attains a considerable height, with a straight clean stem, which from its lightness and toughness, has been found well calculated for the masts of ships. It is distinguished from the Dammar Pine by its narrower and more acute leaves, and by its more rapid mode of growth.

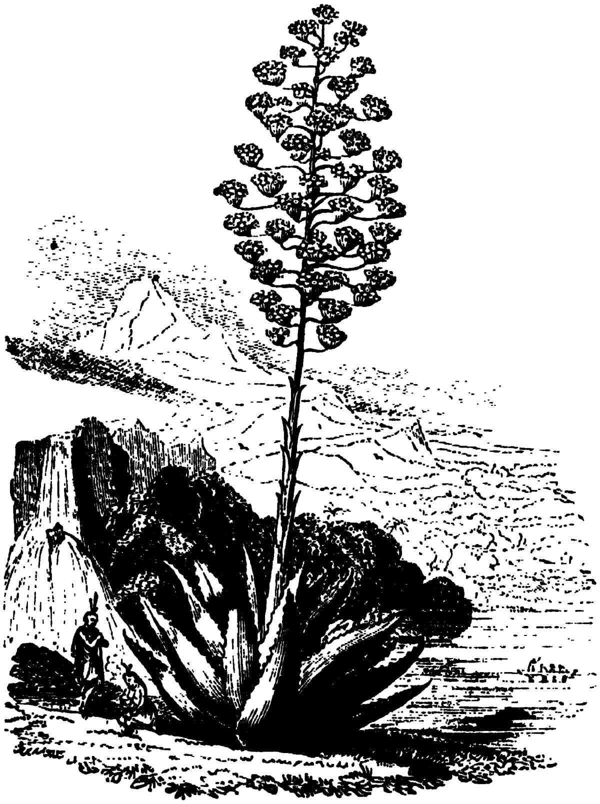
AGATHOPHY'LLUM (from *ἀγαθὸς*, good, and *φύλλον*, a leaf), a genus of plants belonging to the natural order *Lauraceæ*, one species of which, the *A. aromaticum*, yields the clove-nutmegs of Madagascar.

AGATHO'TES (from *ἀγαθότης*, goodness), a genus of plants belonging to the natural order *Gentianaceæ*. It is distinguished by having a rotate 4-parted corolla, with two pores at the base of each segment. *A. chirayta* is a well-known species, a native of Nepaul, Kumaon, and the Himalayas. The specific name is an imitation of the Sanscrit and Bengalee names. This plant has been known for a great length of time as a remedy in India, but has only recently been introduced into European practice. It is an annual plant, about three feet high, flowering in the rainy season. The whole plant is taken up, and the proper time for collecting it is just when the flowers begin to wither. When dried it has an intensely but agreeable bitter taste, and is destitute of aroma. The root is possessed of the greatest bitterness. The bitter principle is readily imparted to water and to alcohol. [CHIRAYTA, ENG. CYC., in ARTS AND SC. DIV.]

AGA'VE, a genus of plants belonging to the natural order, *Amaryllidaceæ*. The species are known by the name of American Aloes, and produce clusters of long stiff fleshy leaves, collected in a circle at the top of a very short stem, and bearing flowers in a long terminal woody scape. With *Doryanthes* and *Yucca* it forms in the natural order *Amaryllidaceæ* an instance of high development both in vegetation and fructification, compared with what is more generally characteristic of that tribe. If a *Crinum* or an *Amaryllis* had the stem elongated into a woody trunk, instead of being contracted into a short disk, lying at the bottom of a scaly bulb, the affinity between them and *Agave* would at once be obvious.

There are many species of this genus, one only of which requires to be mentioned.

Agave Americana, or the American Aloe, is a plant which, when full grown, has a short cylindrical woody stem, which is terminated by hard, fleshy, spiny, sharp-pointed, bluish green leaves, about six feet long, and altogether resembling those of the arborescent aloes. Each of these leaves will continue to exist for many years, so that but a small number have withered away by the time the plant has acquired its full maturity. It is commonly supposed that this occurs only at the end of one hundred years; but this, like many other popular opinions, is an error; the period at which the Agave arrives at maturity varying, according to circumstances, from ten to fifty, or even seventy years. In hot or otherwise favourable climates, it grows rapidly, and arrives sooner at the term of its existence; but in colder regions, or under the care of the gardener, where it is frequently



American Aloe (*Agave Americana*).

impracticable to attend to all the circumstances that accelerate its development, it requires the longest period that has been assigned to it. Having acquired its full growth, it finally produces its gigantic flower-stem, after which it perishes. This stem is sometimes as much as 40 feet high, and is surrounded with a multitude of branches arranged in a pyramidal form, with perfect symmetry, and having on their points clusters of greenish-yellow flowers, which continue to be produced for two or three months in succession. The native country of the American Aloe is the whole of America within the tropics, from the plains nearly on a level with the sea, to stations upon the mountains at an elevation of between 9000 and 10,000 feet. From these regions it has been transferred to almost every other temperate country; and in Italy, Sicily, and Spain, it has already combined with the date and the palmetto to give a tropical appearance to European scenery.

Independently of its beauty and curiosity, this plant is applicable to many useful purposes. Its sap may be made to flow by incisions in the stem, and furnishes a fermented liquor called by the Mexicans Pulque; from this an agreeable ardent spirit, called Vino Mercal is distilled. The fibres of its leaves form a coarse kind of thread, and are brought to this country under the name of Pita Flax; the dried flowering stems are an almost impenetrable thatch; an extract of the leaves is made into balls, which will lather water like soap; the fresh leaves themselves cut into slices are occasionally given to cattle; and, finally, the centre of the flowering stem split longitudinally is by no means a bad substitute for a European razor-strop, owing to minute particles of silica forming one of its constituents.

AGE. The term of human existence is divisible into distinct periods, each of which is distinguished by characters peculiar to itself. These characters, as far as they are external, are obvious to every one; but these external characters depend on internal states which are not obvious, and which have been discovered only by careful and persevering research. And the curious and interesting facts which those researches have disclosed, show that the different epochs into which life is divided are not arbitrary distinctions, but arise naturally out of constitutional differences in the system, dependent on different physiological conditions. The natural epochs of human life are six, namely, the period of infancy, childhood, boyhood or girlhood, adolescence, manhood or womanhood, and old age. The space of time included in the first four of these periods is fixed. In all persons after the lapse of a certain number of years, a definite change in the system uniformly takes place, in consequence of which the peculiarities which distinguish one period give place to those which characterise the succeeding. Thus the period of infancy, commencing at birth, extends to the end of the second year, the point of time at which the first dentition is completed: the period of childhood, commencing at the close of the second year, extends to the termination of the seventh or eighth year, the point of time at which the second dentition is completed: the period of boyhood or girlhood extends from the seventh or eighth year to the commencement of the age of puberty; that is, in general, in this country, in the female, from the twelfth to the fourteenth year, and for the male, from the fourteenth to the sixteenth year: the period of adolescence extends from the commencement of the period of puberty to the twentieth year of the female, and the twenty-fourth of the male: the period of womanhood extends from the twentieth, and of manhood, from the twenty-fourth year, to an age neither determined nor determinable with any degree of exactness; because the point of time at which mature age lapses into old age differs in every individual. It differs in many cases by a considerable number of years; and it differs according to primitive constitution, to the management of early infancy and childhood; according to regimen, exercise, occupation physical and mental, and the several other circumstances included under the general term 'mode of life.'

It is an observation familiar to every one, that some persons are older at fifty than others are at seventy, while instances every now and then occur in which an old man who reaches his hundredth year retains as great a degree of juvenility as the majority of those who attain to eighty. The period extending from the age of thirty or forty to that of extreme old age is then the only variable period in the term of human existence; the only period not fixed by limits which it is beyond the power of man materially to extend or abridge.

The changes which take place in the system at the different epochs of life consist of changes in the physical condition of the body, and are intimately connected with and mainly dependent on the operation of a principle of consolidation, the influence of which, commencing at the first moment of existence, continues, without intermission, until the last moment of life. By this principle the body is changed, first from the state of a fluid into that of a solid; and next, from a soft and tender solid, into a solid which slowly, imperceptibly, but nevertheless uninterruptedly, increases in firmness and hardness.

When first the human embryo becomes distinctly visible, it is almost wholly fluid, consisting only of a soft gelatinous pulp. [Fœtus.] In this gelatinous pulp solid substances are formed, which gradually increase, and are fashioned into organs. These organs, in their rudimentary state, are soft and tender, but, in the progress of their development, constantly acquiring a greater number of solid particles, the cohesion of which progressively increases, the organs at length become dense and firm. As the soft solids augment in bulk and density, bony particles are deposited, sparingly at first and in detached masses, but accumulating by degrees: these, too, are at length fashioned into distinct osseous structures, which, extending in every direction, until they touch at every point, ultimately form the connected bony frame-work of the system. This bony fabric, like the soft solid, tender and yielding at first, becomes by degrees firm and resisting, fitted, as it is designed, to be the mechanical support of the body, and the defence of all the vital organs.

While the osseous system is thus extending in every direction, and everywhere increasing in compactness, the progressive consolidation of the body is equally manifest in all the tissues which are composed of the cellular membrane as well as in all those which possess a fibrous nature. The membranes, the ligaments, the tendons, the cartilages, gradually increase in firmness and elasticity, and proportionally diminish in flexibility and extensibility; and this change takes place, to a considerable extent, in the muscular fibre also, as is manifest from the toughness of the flesh of animals that are used for food, the degree of which every one knows is in proportion to the age of the animal; and from the conversion in extreme old age, in many parts of the body, of muscle into tendon, a denser material being substituted for the proper muscular fibre.

The steady and increasing operation of the principle of consolidation is still more strikingly manifest in the deposition, as age advances, of bony matter in tissues and organs to which it does not naturally belong, and the functions of which it immediately impairs and ultimately destroys. The textures in which these osseous depositions most commonly take place are membranes, tendons, cartilages, and the coverings of the viscera, but above all the coats of the blood-vessels, in consequence of which these highly flexible, elastic, and moveable organs become firm, rigid, and immoveable. But even when not converted into bone, several of these structures lose their flexibility with advancing age, and acquire an increasing degree of rigidity. This is strikingly manifest in all the parts of the apparatus of locomotion; in the joints, the mechanical contrivances for facilitating motion, and in the muscular fibre, the generator of the power by which motion is produced. The joints in old age are less pliable, less elastic, and more rigid than in youth; first, because the ligamentous and cartilaginous structures of which they are composed are more dense and firm; and, secondly, because the oily matter which lubricates them, and which renders their motions easy and springy, is secreted in less quantity, and of inferior quality. Induration and proportionate deterioration take place then in the muscular fibre, the origin of the motive power, and in the joint, the instrument by which the operation of the motive power is facilitated; and consequently the movements become slower, feebler, less steady, less certain, and less elastic.

But among all the changes induced in the body by the progress of age, none is more remarkable, or has a greater influence in diminishing the energy of the actions of the economy, and in causing the ultimate termination of all those actions in death, than the change that takes place in the minute blood-vessels. The ultimate divisions, or the smallest branches of the arteries and veins, the capillary vessels, as they are termed, are exceedingly abundant in the early periods of life, and are as active as they are numerous. The capillary arteries, the masons and architects of the system, by the agency of which all the structures are built up, and all the parts of the body grow and are developed, are numerous and active in the early stages of life, while they are carrying on and completing the organisation of the frame. But from infancy to childhood, from childhood to youth, from youth to maturity, and from maturity to old age, the number and activity of these vessels progressively diminish. Their coats, like other soft solids, increase in density and rigidity; their diameter contracts, many of them become completely impervious and ultimately disappear. The diameter of the capillary veins, on the contrary, enlarges. The coats of the veins, originally thinner than those of the arteries, instead of thickening and contracting, seem rather to grow thinner and more dilatable: hence their fulness, their prominence, their more tortuous course, and their greater capacity. At the two extreme periods of life the quantity of blood contained in these two sets of vessels is completely inverted. In infancy, the proportion of blood contained in the capillary arteries is greater than that contained in the capillary veins; in youth, this disproportion is diminished; at the period of maturity, the quantity in one set, nearly if not exactly balances that in the other; in advanced age, the preponderance is so great in the veins, that these vessels contain probably two-thirds of the entire mass. This difference in the distribution of the blood, at the different epochs of life, affords an explanation of several important phenomena connected with health and with disease. It shows, for example, why the body grows with so much rapidity at the early periods of life; why it remains stationary at the period of maturity; why it diminishes in bulk as age advances; why a plethoric state of the system affects the arteries in youth, the veins in age; why hæmorrhage, or a flow of blood, is apt to proceed in the young from the arteries, and in the aged from the veins; and so on.

The growth of the heart does not keep pace with the extension of the sanguiferous system, nor does its force increase with the augmenting density and resistance of the solids; hence there is a disturbance of the balance between the forces of propulsion and of extension which increases with advancing age; the diminished energy of the heart being indicated by the languor and slowness of the pulse, often not exceeding fifty pulsations in a minute, and sometimes sinking even lower than this. Hence, not only is less blood sent to the several organs, but that which is sent is less completely acted upon by the air in respiration on account of the diminished quantity which is transmitted through the pulmonary system of vessels; hence, the diminution of all the secretions, and hence, finally, the failure of the function of digestion, the source of the materials from which the blood itself is prepared and its losses replenished.

Upon the whole, then, it is clear that two great changes take place in the physical condition of the body in the progress of age; first, a gradual diminution in the quantity of the fluids, both of the entire mass contained in the system, and of the proportionate quantity contained in each organ; and secondly, a progressive augmentation and induration of the solids. With this change in the physical condition of the body is uniformly combined a no less important change in its vital action. Progressively and proportionally as the solid parts increase in density and rigidity, they decrease in irritability and mobility; that is, they are less sensible to the influence of stimulants, and the power of contraction resident in the muscular fibre is less excitable.

AGE OF ANIMALS. It is often a matter of great practical importance to possess some means of determining the age of animals. The data that exist at present are, however, very inadequate to determine this point. Amongst domestic animals the age may be judged of by the presence, absence, or change of certain organs in the body.

The age of the horse is known principally by the appearance of the incisor teeth, or, as they are technically called, the nippers. Of these there are six in each jaw, broad, thin, and trenchant in the foal, but with flat crowns marked in the centre with a hollow disk in the adult animal. The foal- or milk-teeth appear fifteen days after birth; at the age of two years and a half the middle pair drop and are replaced by the corresponding permanent teeth; at three years and a half the two next, one on each side, fall and are likewise replaced; and at the age of four years and a half the two external incisors of the first set drop and give room to the corresponding pair of permanent teeth. All these permanent nippers, as we have already observed, are flattened on the crown or upper surface, and marked in the centre with a circular pit or hollow, which is gradually defaced in proportion as the tooth wears down to a level with its bottom. By the degree of this detrition, or wearing of the teeth, the age of the animal is determined, till the eighth year, at which period the marks are generally effaced; but it is to be observed that the external incisors, as appearing a year or two after the intermediate, preserve their original form proportionally for a longer period. After the eighth year the age of the horse may be still determined for a few years longer by the appearance and comparative length of the canine teeth or tushes. These, it is true, are sometimes wanting, particularly in the lower jaw, and in mares are rarely developed at all. Those of the under jaw appear at the age of three years and a half, and the upper at four; till six they are sharp-pointed, and at ten they appear blunt and long, because the gums begin about that period to recede from their roots, leaving them naked and exposed; but after this period there are no further means of judging of the horse's age, excepting from the comparative size, bluntness, and discoloured appearance of the tushes. The duration of the horse's life seldom surpasses thirty years, though there have been instances recorded in which it is said to have extended to double that period.

In cattle with horns, the age is indicated more readily by the growth of these instruments than by the detrition and succession of the teeth. The deer kind, which shed their horns annually, and in which, with the single exception of the rein-deer, they are confined to the male sex, have them at first in the form of simple prickets without any branches or antlers; but each succeeding year of their lives adds one or more branches, according to the species, up to a certain fixed period, beyond which the age of the animal can only be guessed at from the size of the horns and the thickness of the burr or knob at their roots which connects them with the skull. In the common stag, the pricket or first horn falls during the second year of the animal's life, and is replaced by one with a single antler, and called, from this circumstance, the fork. This again falls during the third year, and is replaced by the third horn, which, as well as the fourth or following pair, have commonly three or four, and sometimes even five branches. In the same manner the number of antlers goes on increasing till the eighth year of the animal's life, beyond which period they follow no fixed rule, though they still continue to increase in number, particularly towards the summit of the horn, where they are often grouped in the form of a coronet, and in this state they are called royal antlers. The fallow-deer, the roe-buck, and others of this genus, present similar phenomena; the number of the antlers increases according to certain fixed rules up to a certain period, beyond which the age can only be determined, as in the stag, by the comparative size and development of the burr and shaft, or that part of the horn from which the antlers grow. In the former species, the prickets of the second year are replaced by horns bearing two antlers, and already beginning to assume the palmated form which distinguishes them from the antlers of most other deer. Afterwards this palm increases in breadth, and assumes an indented form on the superior and posterior borders: these are the fourth horns, which are shed in the animal's fifth year, and are replaced by others in which the palm is cloven or subdivided irregularly into distinct parts, so that the horns of old animals frequently assume a great diversity and singularity of form. From this period the horns begin to shrink in size, and are even said to end in becoming simple prickets as in the first year.

The horns of oxen, sheep, goats, and antelopes, which are hollow and permanent, are of a very different form, and grow in a different manner, from those of the deer kind. These, as is well known, consist of a hollow sheath of horn, which covers a bony core or process of the skull, and grows from the root, where it receives each year an additional knob or ring, the number of which is a sure indication of the animal's age. The growth of the horns in these animals is by no means uniform through the whole year, but the increase, at least in temperate climates, takes place in spring, after which there is no further addition till the following season. In the cow kind, the horns appear to grow uniformly during the first three years of the animal's life; consequently, up to that age they are perfectly smooth and without wrinkles, but afterwards each succeeding year adds a ring to the root of the horn, so that the age is determined by allowing three years for the point or smooth part of the horn and one for each of the rings. In sheep and goats the smooth or top part counts but for one year, as the horns of these animals show their first knob or ring in the second year of their age; in the antelopes they probably follow the same rule, though we have very little knowledge of their growth and development in these animals.

There are very few instances in which the age of animals belonging to other classes can be determined by any general rules. In birds it may be sometimes done by observing the form and wear of the bill; and some pretend to distinguish the age of fishes by the appearance of their scales, but their methods are founded on mere hypotheses, and entitled to no confidence. The age of the whale is known by the size and number of laminæ of whale-bone, which increase yearly, and, if observation can be relied upon, would sometimes indicate an age of three or four hundred years for these animals.

AGE OF TREES. Plants, like animals, are subject to the laws of mortality, and seem mostly to have a limited period for their existence.

It is chiefly to annual and biennial plants that what may be called a precise period of duration is fixed; a period determined by the production of their fruit, and not capable of being prolonged beyond that event, except by artificial means. Plants that live for a long time belong either to the class of *Endogens* or *Exogens*.

To the first of these classes belongs the *Palm Tribe*, and some other tropical trees. There is scarcely any well-attested evidence of these plants ever acquiring any considerable age. It has indeed been supposed, that certain Brazilian cocoa-nut palms may be from 600 to 700 years old, and that others probably attain to the age of something more than 300 years. But the method of computing the age of palms, which is either by the number of rings externally visible upon their rind between the base and summit of the stem, or by comparing the oldest specimens, the age of which is unknown, with young trees of a known age, is entirely conjectural, and not founded upon sound physiological considerations; besides which, the date-palm which is best known to Europeans, does not at all justify the opinion that palms attain a great age; the Arabs do not assign it a greater longevity than from two to three centuries. Independently of this, the mode of growth of such endogenous trees as palms seems to preclude the possibility of their existing beyond a definite period of no great extent. The diameter to which their trunks finally attain is very nearly gained before they begin to lengthen, and afterwards all the new woody matter, which every successive leaf necessarily produces during its development, is insinuated into the centre. The consequence of this is, that the woody matter previously existing in the centre is displaced and forced outwards towards the circumference. As this action is constantly in progress, the circumference, which in the beginning was soft, becomes gradually harder and harder, by the pressure from within outwards, till at last it is not susceptible of any further compression. After this has occurred, the central parts will gradually solidify by the incessant production of new wood, which thrusts outwards the older wood, till at last the whole stem must become equally hard, and no longer capable of giving way for the reception of new matter; for what has once been formed always remains, and is never absorbed by surrounding parts. It is probable, for this reason, that endogenous trees, such as palms, attain no considerable age, and that the duration of their existence must be absolutely fixed in each species by the power they may respectively have of permitting the descent of woody matter down their centre.

In exogenous trees it is quite the reverse, and to their existence no limited duration can be assigned. In consequence, first, of the new woody matter which is constantly formed beneath the bark near the circumference of their trunk, and, secondly, of the bark itself being capable of indefinite distention, no compression is exercised by the new parts upon those previously formed; on the contrary, the bark is incessantly giving way to make room for the wood beneath it, while the latter is, in consequence, only glued, as it were, to what succeeds it, without its own vital powers being in any degree impaired by compression. It is in the newly-formed wood that the greatest degree of vitality resides: in the old wood near the centre life in time becomes extinct; but as each successive layer possesses an existence in a great degree independent of that which preceded it, the death of the central part of an exogenous tree is by no means connected with any diminution of vitality in the circumference. Hence it is that hollow trees are often so healthy; and that trees in the most vigorous state are often found decayed at the heart without any external sign, as timber-merchants frequently discover to their cost. Of the many remarkable cases upon record of aged trees the following are among the more interesting:—

At Ellerslie, the birth-place of Wallace, three miles to the south-west of Paisley, stands an oak, in the branches of which tradition relates that on one occasion that chieftain concealed himself with three hundred of his followers. However improbable the latter circumstance may be, it is at least certain that the tree may well have been a remarkable object even at the period assigned to it by tradition, namely, in the beginning of the 14th century; and if so, this individual must be at least 700 years old. Its branches are said to have once covered a Scotch acre of ground; but its historical interest has rendered it a prey to the curiosity of the stranger, and its limbs have gradually disappeared till little remains except its trunk.

The Wallace Oak.

Of ancient yews several authentic instances can be named. At Ankerwyke House, near Staines, is a yew older than the meeting of the English barons at Runnymede, when they compelled King John to grant Magna Charta. This tree, at 3 feet from the ground, measures 9 feet 3 inches in diameter; and its branches overshadow a circle of 207 feet in circumference. The yews of Fountains' Abbey, in Yorkshire, are probably more than 1200 years old, and to others an age of from 2500 to 3000 years has been assigned.

The Ankerwyke Yew.

Even this degree of antiquity is, however, much less than that of the Baobab trees of Africa, estimated by Adanson at 5150 years; and the deciduous cypress of Chapultepec in Mexico, which the younger De Candolle considers still older.

The following list of old trees is from Moquin Tandon's 'Teratologie Végétale:'—

There are known—

Palms of	200, 300	years.
Cercis	300	„
Chirodendron	327	„
Ulmus (Elm)	355	„
Cupressus (Cypress)	388	„
Hedera (Ivy)	448	„
Acer (Maple)	516	„
Larix (Larch)	263, 576	„
Castanea (Chestnut)	360, 626	„
Citrus (Oranges, Lemons, &c.)	400, 509, 640	„
Platanus (Plane)	720	„
Cedrus (Cedar)	200, 800	„
Juglans (Walnut)	900	„
Tilia (Lime)	364, 530, 800, 825, 1076	„
Abies (Spruce)	1200	„
Quercus (Oak)	600, 800, 860, 1000, 1600	„
Olea (Olive)	700, 1000, 2600	„
Taxus (Yew)	1214, 1466, 2588, 2880	„
Schubertia	3000, 4000	„
Leguminosæ	2052, 4104	„
Adansonia (Baobab)	6000	„
Dracæna (Dragon Tree)	6000	„

The way in which the age of some of these specimens has been computed is twofold: firstly, by comparing them with other old specimens, the rate of growth of which is known; and secondly, by cutting out a portion of their circumference, and counting the number of concentric rings that are visible. For in exogenous trees the woody cylinder of one year is divided from the succeeding one by a denser substance, which marks distinctly the line of separation of the two years.

In the course of inquiries into the method of computing the age of ancient trees, a discovery has been made of some importance to timber growers, inasmuch as it shows that those who plant for profit alone should not allow their trees to grow beyond a certain number of years, varying according to species: for it has been found that so far are exogenous trees from continuing always to increase in diameter at the same rate, that every kind diminishes in its rate of growth after a certain age:—the oak, for example, between its fortieth and its sixtieth year, the elm after its fiftieth, the spruce-fir after its fortieth, and the yew probably after its sixtieth. With reference to this subject, Professor De Candolle has constructed a table of rate of growth, which we subjoin.

Table of the rate of Increase in Diameter of certain Exogenous Trees, expressed in lines.

Yrs. to Yrs.	Quercus pedunculata, 130 years old.	Quercus sessiliflora, 210 years old.	Quercus sessiliflora, 333 years old.	Larch-Fir, 2[illegible] years old.	Elm 33[illegible] years old.	Spruce-Fir, 120 years old.	Yew 71 years old.
1 to 10	54	10	18	18	16	41	8
10 . 20	62	16	33	61	44	54	11½
20 . 30	54	22½	39½	58	58½	52	12
30 . 40	60	12	38	72	72	45	10½
40 . 50	48	13½	23	46	88	35½	7
50 . 60	41	14	12½	57	74	36	12½
60 . 70	56	10⅔	9	46	78½	18	8
70 . 80	44	11	9½	29	66	17	
80 . 90	32	9½	8½	30	59	13	
90 . 100	32	9½	8	24	45	13	
100 . 110	30	9½	7½	32	30	22

AGENEIOSES, in Ichthyology, a genus of Abdominal Malacopterygious fishes, separated from the *Silures* by Lacépède, and containing two species, both from the fresh-water lakes and rivers of Surinam.

AGGERZEEN. [ANTELOPE, *Strepsiceros.*]

AGILA-WOOD. [AQUILARIACEÆ.]

AGNO'STUS, the remarkable fossil genus of *Crustacea* usually found with *Asaphus Buchii* and other trilobites in the lower Palæozoic strata. (Brongniart.) Called *Battus* by Dalman. It abounds near Llandeilo and Christiania.

AGNOTHE'RIUM, a fossil genus of *Mammalia.* (Kaup.)

A'GONUS, in Ichthyology, a genus of Acanthopterygious fishes, first separated from the *Cotti* by Block, and afterwards adopted, by Lacépède and Pallas, under the different names of *Aspidophorus* and *Phalangistes.* The greater number of the species belonging to the genus *Agonus* are found in the northern Pacific Ocean, particularly along the coast of Japan, and northward as far as Behring's Straits. They are all of diminutive size, never exceeding nine or ten inches in length, and are nowhere used as an article of human food. One species only, the Pogge (*A. Europæus*), inhabits our own coast, as well as the coasts of France, Holland, Iceland, and even Greenland; it is also found in the Baltic, but, according to Baron Cuvier, never in the Mediterranean, though Brunnich expressly affirms the contrary. (*Histoire Naturelle de Poissons*, of Baron Cuvier and M. Volenciennes.)

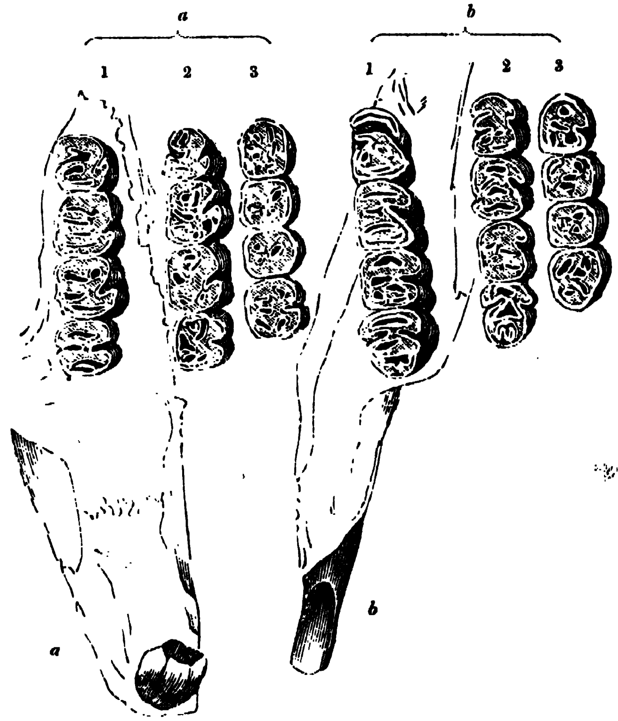
Agonus Accipenserinus.

AGOUTI (*Dasyprocta*, Illiger; *Chloromys*, F. Cuvier), in Zoology, a genus of animals belonging to the class *Mammalia* and order *Rodentia.*

The most prominent zoological characters of the Agoutis are found in the nature and conformation of the feet and toes. The toes are provided with large powerful claws, and yet the animals make no use of them in digging or burrowing; they are pretty long and perfectly separate from one another, enabling them to hold their food between their fore-paws, and in this manner to convey it to their mouth. Like all other animals which are thus accustomed to use the fore-paws as hands, they have a habit of sitting upright upon their hind-quarters to eat, and frequently also assume the same position when they would look around them, or are surprised by any unusual sound or occurrence. Their food is exclusively of a vegetable nature, and consists most commonly of wild yams, potatoes, and other tuberous roots: in the islands of the different West India groups they are particularly destructive to the sugar-cane, of the roots of which they are extremely fond. The planters employ every artifice for destroying them, so that at present they have become comparatively rare in the sugar islands, though on the first settlement of the Antilles and Bahamas they are said to have swarmed in such countless multitudes as to have constituted the principal article of food for the Indians. They were the largest quadrupeds indigenous in these islands upon their first discovery. The same rule of geographical distribution holds good generally in other cases, namely, that where groups of islands are detached at some distance from the mainland of a particular continent, the smaller species of inhabitants are usually found spread over both, whilst the larger and more bulky are confined to the mainland alone, and are never found to be indigenous in the small insulated lands.

Though the Agoutis use their fore-paws as hands to hold their food whilst they eat, yet their toes are nevertheless rigid and inflexible, and their claws large, blunt, and nearly straight. They are consequently deprived of the power of ascending trees; and as they also do not construct burrows, they wander at large among the woods, sheltering themselves beneath fallen timber, or in the hollow of some decayed tree. Here they produce and nurture their young, bringing forth, according to some accounts, three or four times in the year; according to others, never having more than a single litter in the same season, and even that consisting of not more than two or three individuals. It is probable, however, from the amazing numbers of these animals found in all the hotter parts of South America, notwithstanding the destruction made among them by small carnivorous animals, as well as by the Indians, and likewise from the close affinity which they bear to the hare and rabbit of our own country, that the Agoutis are tolerably prolific. The young are brought forth with their eyes closed, as in the case of most of the *Rodentia* and *Carnivora;* but they are covered with hair, or rather small bristles of the same colour as the mother: they soon acquire the use of their limbs, and learn to shift for themselves.

The hind legs of the Agoutis are considerably longer than the fore, and their pace is tolerably rapid for a short distance. But they seldom trust to speed of foot for their safety, but seek for shelter and security in the first hollow tree, or under the first rock they meet with. Here they allow themselves to be captured, without any other complaint or resistance than the emission of a sharp plaintive note. The head of the Agouti is large, the forehead and face convex, the nose swollen and tuberous, the ears round, short, and nearly naked, and the eyes large and black. The hair is annulated in different degrees with black, yellow, and green; it is generally coarse and bristly, like the weak spines of a hedgehog, though in one species it approaches in fineness to the fur of the rabbit; the tail is most commonly a mere naked stump or tubercle, which in the Acouchy alone attains any apparent length, and is covered with a few short scattered hairs. The teeth are twenty in all; namely, two incisors and eight molars, four on each side, in each jaw. The latter are all nearly of the same size, oval in figure, and with flat crowns, which exhibit the different convolutions of the enamel as it penetrates the softer materials of which the body of the tooth is composed. It is impossible from mere description to convey an idea of the intricate figures which these convolutions assume; and we, therefore, refer to the annexed figure, where *a* and *b* in the diagram represent respectively the upper and lower jaws, and the figures 1, 2, and 3, the appearances of the teeth at different ages, or after different degrees of trituration: No. 3, representing the teeth shortly after they begin to wear; No. 2, their intermediate state; and No. 1, when very much worn. The teeth are exclusively adapted for vegetable food; they are essentially formed for grinding and bruising, not for cutting and tearing. The stomach and intestines therefore, which are always in harmony with the organs of mastication, are fitted only for the digestion of vegetable substances. The flesh of these animals is white and tender; it is a very common and favourite article of food in South America, and is dressed like hare or rabbit. The following species are distinctly known:—

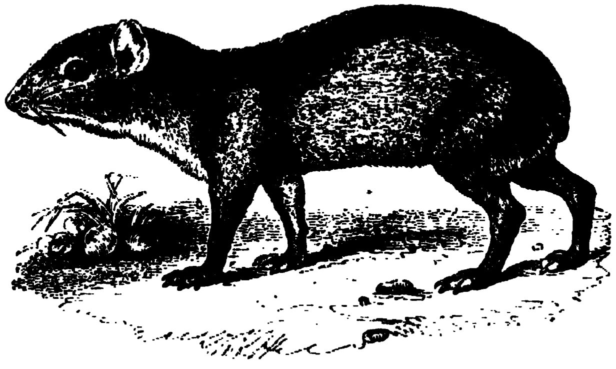


Teeth of the Agouti, from Cuvier's 'Dents des Mammifères.'

1. The Common Agouti (*Dasyprocta Aguti*), sometimes called the Long-Nosed or Yellow-Rumped Cavy, from its long nose and the prevalent colour of its back and shoulders, is the size of a middling hare, being one foot eight inches in length, and about eleven or twelve inches high at the croup. The head resembles that of the rabbit, the nose is thick and swollen, the face arched, the upper lip divided, the ears round and naked, the eyes large, the upper jaw considerably longer than the lower, and the tail a naked flesh-coloured stump. The hairs of the upper and fore parts of the body are annulated with brown, yellow, and black, which give the animal a speckled yellow and green appearance on the neck, head, back, and sides; on the croup however they are of a uniform golden yellow, much longer than on any other part of the body, and directed backwards; the breast, belly, and inner side of the fore-arms and thighs are light straw colour, and the moustaches and feet black. The general length of the hair on the upper and anterior parts of the body is about an inch, that of the croup is upwards of four inches long, and all, excepting the short coarse fur of the legs and feet, and that on the breast and belly, is of a stiff harsh nature, partaking more of the quality of bristles than of simple hair.

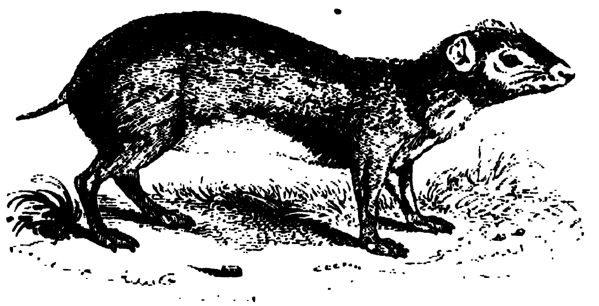
2. The Black or Crested Agouti (*Dasyprocta cristata*), is rather improperly called the Crested Agouti by M. Geoffroy St. Hilaire, since the hairs of its head and neck do not exceed those of the shoulders and back in length. It is considerably smaller than the Common Agouti, being about the size of a rabbit, whilst that species approaches the dimensions of the hare. Its general proportions and form, however, are the same; but the hairs of the back and sides, instead of being annulated with various-coloured rings as in that species, are nearly uniform black, whilst the long hairs of the croup are perfectly so: the belly and legs are equally covered with short dark hair. There is

not any appearance of crest, and the tail is still shorter than in the Common Agouti. Both this species and the former seem to inhabit the same climates—Surinam, Guiana, and Brazil; the Common Agouti, however, appearing to have a rather more extensive range, and to be likewise found in the West India Islands, and even as far south as Paraguay.



Black or Crested Agouti (*Dasyprocta cristata*).

3. The Acouchy, or Olive Agouti (*Dasyprocta Acuchi*), is considerably smaller than either of the foregoing species, and is at once distinguished by the greater length of its tail, which is upwards of two inches in length, not much thicker than a crow's quill, and covered with short scattered hairs like those on the tail of a rat. In other respects it is of the same form as the Agoutis; has the same naked round ears, the same large black eyes, and the same olive-green colour mixed with yellow and black. The hairs of the croup are not so long as in the Agoutis, but are perfectly black; and all the under-parts of the body, the breast, belly, and interior of the arms and thighs, straw-coloured with a tinge of red. The hair of the legs and feet is short and black, and that of the body much finer in quality than the hair of the Agoutis. It inhabits some of the West India Islands, Guiana, and the northern parts of Brazil.



The Acouchy (*Dasyprocta Acuchi*).

4. White-Toothed Agouti (*Dasyprocta croconata*, Wagler) is a species founded by Wagler upon a specimen brought by Spix from the river Amazonas. It is about the same size as the Common Agouti, but it differs in its incisor teeth being entirely white, in having the tarsi shorter, the nails shorter, and the general hue of its fur much richer.

5. *Dasyprocta prymnolopha* is a species described by Wagler, which inhabits Guiana. It is one of the most beautiful of the species, and is readily distinguished by the broad black band which runs along the hinder half of the back, and is continued to the tail.

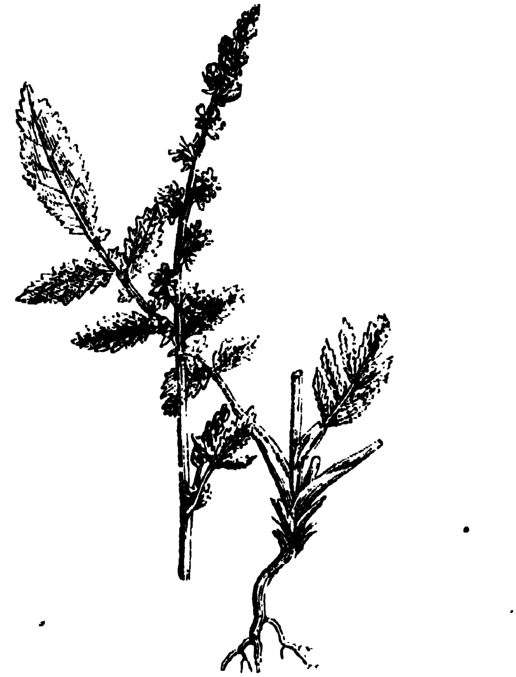
6. The Sooty Agouti (*Dasyprocta fuliginosa*, Wagler). This species is the same as the *D. nigricans* of Natterer and the *D. nigra* of Dr. J. E. Gray. It is readily distinguished by its black colour and large size. It inhabits the northern provinces of Brazil.

7. Azara's Agouti (*Dasyprocta Azaræ*), a species inhabiting Paraguay, Bolivia, and the southern parts of Brazil. Mr. Waterhouse says it is identical with Dr. Gray's *D. punctata*.

AGRIMO'NIA, a genus of plants belonging to the order *Rosaceæ*. It is known from all the other genera of the same tribe by its having only two or three pistils enclosed in the deep tube of its calyx, from 7 to 20 stamens, and small-notched petals.

The common species, *Agrimonia Eupatoria* (Common Agrimony), is an erect, hairy, herbaceous plant, frequent by the side of hedges in fields, on the skirts of woods, and in similar situations all over England. Its lower leaves are interruptedly-pinnated, with the leaflets of an oval form, and coarsely serrated. When bruised, they yield a slight but pleasant aromatic odour. The stem is nearly simple, and a foot and a half or two feet high. The flowers, which are small and yellow, are succeeded by little bur-like fruits.

The leaves, which are astringent and aromatic, have been found useful in the preparation of fever-drinks, and for the cure of slight inflammation in the mouth or throat; on this account Agrimony is always reckoned one of our wild medicinal plants, and is often employed as an ingredient in herb-teas.



Common Agrimony (*Agrimonia Eupatoria*).

AGRIMONY. [AGRIMONIA.]

AGRIOPES (*Agriopus*, Cuvier), in Ichthyology, a genus of Acanthopterygious fishes, belonging to the family which M. Cuvier denominates *Joues Cuirassées*, and which are distinguished from other families of the same order, by having the suborbital plates extending backwards over the cheeks, so as to cover either the whole or the greater part of them, and thus defending them, as it were, with a buckler or cuirass. But what particularly distinguishes the Agriopes from most other genera of fishes is, that they have only nine rays in the pectoral fins, a number very rarely found in this class of animals. Three species are enumerated by Messrs. Cuvier and Valenciennes:—

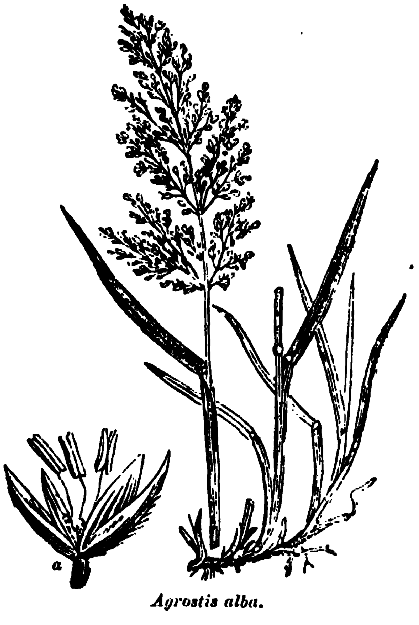
1. The *Agriopus torvus*. This fish inhabits Table Bay and the seas around the Cape of Good Hope, where it is called by the Dutch colonists Zee-Paard (or Sea-Horse). This fish exceeds two feet in length, and is common in the markets of Cape Town.

2. The Warty Agriope (*A. verrucosus*) is so called from having the skin of the head and body entirely covered with prominent conical tubercles, surrounded at the base with small papillæ. It grows to the same size, and inhabits the same localities, as the preceding species.

3. The *Agriopus Peruvianus* is found in the neighbourhood of Lima, and grows to the length of eight or nine inches.

AGROSTEMMA (from ἀγρός, a field, and στέμμα, a crown), a genus of plants belonging to the *Sileneous* division of the order *Caryophyllaceæ*. It has several species, the best known of which is the Corn Cockle, which is now referred to the genus *Lychnis* [LYCHNIS] or *Githago*.

AGRO'STIS, a genus of Grasses, consisting of a considerable number of species with loose-branched capillary panicles of flowers, and a creeping habit. Among British grasses, it is at once known by the glumes (*a*) or outer scales of each flower being two in number, unequal in size, of a membranous texture, and containing but a single floret; while the paleæ, or inner scales, are short, very thin, almost transparent, and two in number, the larger of them occasionally having an awn at its back.



Agrostis alba.

Two species only are natives of this country one of which, *A. vulgaris*, is found everywhere in dry, exposed, barren situations, and is of very little value to the farmer, except for its earliness; the other, *A. alba*, is equally abundant in marshy places, where it forms a valuable pasture. Under the name of Irish Fiorin Grass, this species has been the object of much attention from experimental agriculturists, some of whom have extolled its qualities very highly as a marsh-fodder; but the experience of others does not confirm their opinion; nor does it appear to thrive in England so well as it is represented to do in Ireland, where its vigour is such as to have led to the belief that the Irish plant is a distinct species, called *A. stolonifera*. In England it is best known, along with *A. vulgaris*, under the name of Quitch, or Quicks, and is generally extirpated as a troublesome weed, in consequence of the rapidity with which, by means of its creeping, rooting, vivacious stems, it spreads and overruns pasture- and garden-ground.

AI. [BRADYPUS.]

AIR-BLADDER, a peculiar organ with which the great majority of fishes are provided, and by which they are enabled to adapt the specific gravity of their bodies to the various pressures of the superincumbent water at different depths. It is composed of a lengthened sac, sometimes simple, as in the common perch, sometimes divided into two or more compartments, by a lateral or transverse ligature, as in the trout and salmon, and, at other times, furnished with appendices, more or less numerous according to the particular species. In all cases, it is composed of a thick internal coat of a fibrous texture, and of a very thin external coat; the whole being enveloped in the general covering of the intestines.

The modifications of this organ are infinitely varied in different genera and species of fishes. In the greater number of instances it has no external opening, and the air with which it is found distended is believed to be produced by the secretion of a certain glandulous organ, with which it is in all these cases provided. This air has been examined, and found to consist of *oxygen* and *nitrogen*, but with less oxygen than common air. In fresh-water fishes, the air-bladder communicates sometimes with the œsophagus, and sometimes with the stomach, by means of a small tube; and it is observable, that in the greater number of these instances, in which it has a direct external communication with the intestines, the secreting glands above mentioned do not exist; thus giving us strong reason to believe that its functions and uses are not uniformly the same in all the different classes of fishes. A very limited number of species, among others the common eel, have air-bladders not only opening by an external duct, but likewise provided with secreting glands; and thus occupying an intermediate station between the two larger classes, at least as far as the nature and functions of this organ are concerned.

In general, all fishes which enjoy great powers of locomotion, and have occasion to pass through various degrees of superincumbent pressure in their rapid transitions from the surface to the bottom of the ocean, are provided with this important organ; and so indispensable is it in their economy, that those which, for the sake of experiment, have been deprived of it, have sunk helpless to the bottom, and there remained incapable of moving, or even of maintaining their equilibrium. But to fishes whose habits and organization confine them either to the surface of the water or to the bottom of the sea, and which, therefore, do not require to pass through different depths, or to encounter different degrees of pressure, the possession of an air-bladder is by no means so essentially requisite. Accordingly we find, that all the different species of rays and *Pleuronectes* or flat-fish, such as skates, soles, turbots, brills, etc., which live only upon the coasts and sand-banks at the bottom of the ocean, as well as the mackerel and others which find their food entirely at the surface, have no air-bladder; and so small is the relation of this otherwise important organ to the general conformation of fishes, that we sometimes find it present in one species, and wanting altogether in another of the same genus. Although it does not appear that the air-bladder is connected with the function of respiration in fishes, it occupies the position, and has the same relations, as the lungs in reptiles. It is, in fact, the homologue of these organs. Fishermen are well acquainted with the nature and functions of the air-bladder, or, as they most commonly call it, the *Swim*. They are accustomed to perforate this vessel with a fine needle in cod and other species which require to be brought fresh to market, sometimes from a very great distance. By this operation, the confined air is allowed to escape, and the fish constrained to remain quiet at the bottom of their well-boats, where they live for a very considerable period. Cod-sounds, which are brought in great quantities from Newfoundland, are nothing more than the salted air-bladders of these fishes. The Iceland fishermen, as well as those of America, prepare isinglass of a very excellent quality from cod-sounds, though they are not acquainted with the method of clarifying it, which the Russians practise in preparing isinglass from the sound of the sturgeon.

(Owen, *Lectures on Comparative Anatomy*, vol. ii.)

AIR-CELLS, in plants, are cavities in the leaves or stems, or other parts containing air. In water-plants they have a very definite form, and are built up of little vesicles of cellular tissue, with as much regularity as the walls of a house; they no doubt enable the plant to float. They are well seen in the structure of the *Victoria regia*. In plants which do not float, the form of the air-cells is less definite; they often appear to be mere lacerations of a mass of cellular substance, and their object is unknown; well-known instances of their presence are the chambers in the pith of the walnut-tree, and the tubular cavities in the stem of the bamboo, and other Grasses.

AIR-PLANTS are so called because they possess the power of living for a considerable time suspended in the air. It is however a mistake to suppose that these plants are naturally suspended freely in the air, and that such a situation is that in which they will thrive; they will only exist in air for a shorter or longer period, according to the species and to other circumstances, but in the end they will perish. This arises from the fact that all plants require inorganic as well as organic constituents, and although these latter elements can be supplied from the air in the form of carbonic acid, ammonia, and water, the former cannot.

There are two different tribes to which the name of Air-Plants has been applied; of which one, containing the moss-like *Tillandsia usneoides*, which hangs in festoons from the branches of trees in the hot damp forests of tropical America, and the fragrant *T. xiphioides*, which adorns the balconies of the houses in Buenos Ayres, is called by botanists *Bromeliaceæ;* the other, abounding in species of the most different nature and appearance, is named *Orchidaceæ*.

Till within a few years the cultivation of Air-Plants of the *Orchis* tribe was supposed to be attended with insuperable difficulties; and of the many hundreds of beautiful species that are found in foreign countries, scarcely any were known in Europe, except from drawings, bad descriptions, and imperfect dried specimens.

The native country of these curious plants is wherever a climate is found in which heat and moisture are in excess. Within the tropics in Asia, Africa, and America, in damp and shady forests, by the side of fountains, within reach of the spray of waterfalls, perched upon the branches of trees, or clinging to rocks and stones by means of their long and writhing roots—creeping among moss, rearing their flowers in the midst of brakes and other moisture-loving tribes—in all such situations they are found in abundance. The principal stations for them are the woods of Brazil and Peru, the lower mountains of Mexico, the West Indies, Madagascar, and the adjoining islands, and the whole of the Indian Archipelago; in Java alone nearly 300 species have been discovered.

The conditions under which Air-Plants, of the kind now described, naturally thrive are—1, high temperature; 2, diffused light, like that of a shady grove, and not direct solar light; 3, a great degree of dampness; and, 4, a perfect freedom from stagnant water round their roots: for on the trunks of trees or on stones and rocks no water can lodge, and all the moisture they receive must necessarily be in the form of vapour or of falling rain. And it is to circumstances of this nature that the gardener has chiefly to attend. Damp, shade, heat, and good drainage will be his objects; the three former will cause him no trouble, but the latter will require him to alter entirely his usual mode of cultivation. Instead of considering in what kind of soil his Air-Plants are to be placed, he will endeavour to dispense with soil, and to supply its place with bits of rotten wood, chopped moss in very small quantities, fragments of half-baked pottery, such as garden-pots, and the like.

Another point of great importance in the cultivation of these plants is, securing for them a season of repose. In their native climates, although they have no winter, they have a period of comparative rest from growth, and securing for them this repose whilst under culture is a great secret of success. It is to a knowledge of this, taken in conjunction with the circumstances before explained, that we owe the remarkable improvement that has taken place in the mode of cultivating these plants in Great Britain.

(Lindley, *Observations in the Transactions of the Horticultural Society*, vol. i., New Series, p. 42, and the latter volumes of the *Botanical Register*.) [EPIPHYTES; ORCHIDACEÆ.]

AIR-VESSELS, in plants, are what botanists call *Spiral Vessels*. It is supposed by some that these are the only parts through which air is conveyed into the vegetable system, and it has been proved that, in some cases at least, the air that they contain consists of a larger proportion of oxygen than atmospheric air. But it is doubtful whether the action of these vessels is more than local, and it is certain that air has tolerably free access to many parts, as the leaves, for example, by means entirely independent of the spiral vessels.

AIRA, a genus of Grasses belonging to the tribe *Seslerieæ*, and distinguished by possessing a lax panicle, two-flowered glumes, the outer pale terete on the back, and a dorsal awn. There are several species, but that which is best known is *A. cæspitosa*, the Tufted Hair-Grass. It has long and flat leaves, with a fibrous perennial root. It flowers in the beginning of August, and reaches a height of four feet. It grows naturally on marshy damp soils, in the form of large tufts. It is a wiry harsh grass, and is rejected by domestic animals. It may, however, be advantageously sown as a cover for game, and also by the side of ponds and marshes for snipe and wild fowl. (Lawson, *Acrostographia*.)

AITONIA (after Mr. W. Aiton, for many years head-gardener at Kew), a genus of plants belonging to the order *Meliaceæ*. The *A. Capensis* is a native of the Cape of Good Hope, and is cultivated in our greenhouses.

AIZOON. [TETRAGONIACEÆ.]

AJOWAMS, or **AJWAMS**, the Indian name for the fruits of Umbelliferous plants belonging to the genus *Ptychotis*. They are chiefly employed in veterinary medicine.

ALABASTER, a white stone used for ornamental purposes. The name is derived from Alabastron, a town of Egypt, where there appears to have been a manufactory of small vessels or pots, made of a stone found in the mountains near the town. These vessels were employed for containing certain kinds of perfumes used by the ancients in their toilet, and with which it was the custom to anoint the heads of their guests, as a mark of distinction, at their feasts. There are in Horace many allusions to this custom. In like manner, Mary, the sister of Lazarus, poured upon the head of our Saviour, as he sat at supper, "very precious ointment" from an alabaster-box. Vessels of a similar form, although not made of the white stone, bore the same name amongst the Greeks and Romans.

There are two kinds of white stone to which antiquaries and artists give the name of alabaster: the one is a carbonate of lime; the other is gypsum, or sulphate of lime. Many of these ancient perfume-vessels are made of the compact crystalline mass deposited from water holding carbonate of lime in solution, which is found in many places in almost every country. When the deposition takes place on the ground, it forms what mineralogists call a *stalagmite*, from a Greek word signifying a drop, and it is often composed of layers distinguishable by different degrees of translucency, giving the stone the appearance of the striped agates, called onyx. [AGATE.] Hence, according to Pliny, the alabastrites was sometimes called onyx. But it is easy to ascertain of which of the two kinds a vessel is composed, for *carbonate* of lime is hard, and effervesces if it be touched by a strong acid; but *sulphate* of lime does not effervesce, and is so soft that it may be scratched with the nail. The term alabaster is now generally applied to the softer stone. This last, when pure, is a beautiful semi-transparent snow-white substance, easily worked into vases, lamps, and various other ornaments, but it is seldom found in masses large enough for statuary; and, indeed, artists would be unwilling to execute any great work in a material so very liable to injury. The finest quality known is found in the neighbourhood of Volterra in Tuscany, and it is cut into a variety of works of great taste and beauty at Volterra, Florence, Leghorn, and other places in that part of Italy, whence they are sent all over the world, and sold at very reasonable prices.

Alabaster is found in Derbyshire and Staffordshire, and is manufactured at Derby into small ornaments and toys. [GYPSUM.]

ALABAUDINE, a name for Manganese-Blende, a sulphuret of manganese.

ALABES, a genus of fishes belonging to the order *Malacopterygii*, and family *Apodes*. This genus, which consists of a single species of small size, a native of the Indian Ocean, resembles in most respects the common Conger-Eel (*Muræna*) of our own seas.

ALARIA, a genus of sea-weeds. [ALGÆ].

ALAUDA. [ALAUDINÆ].

ALAUDINÆ, a sub-family of birds belonging to the order *Passerinæ*, and the family *Conirostres*, is thus characterised by Mr. Swainson:—

Bill more lengthened than in any of the *Fringillidæ;* the tip entire or obsoletely notched. Tertial quills considerably lengthened, pointed, and generally as long as the quills. Claws very slightly curved; the claw of the outer toe always shorter than that of the inner toe; the hinder claw considerably lengthened, and either nearly straight or very slightly curved.

Alauda. (Linn.)

Bill cylindrical; nostrils concealed. Wings very long; no spurious quill; the first, second, and third quills longest, and nearly equal; the rest considerably graduated; tips of the lesser quills emarginate. Tail forked. Head crested. (Sw.)

The Larks are characterised by their having the hind-claw, which is like the fore-claws, somewhat straight, and longer than in the pipits and the wag-tails. The bill is straight, and rather short and strong, the upper mandible being arched without any notch, and not longer than the under. The nostrils, situated at the base of the bill, are oblong, and protected by small plumes and bristles directed forwards. The feathers on the back part of the head can be raised up at the will of the bird into the form of a crest.

Various species of larks are found in all parts of the globe, and are everywhere distinguished by their vigilance and their singing. They are peculiarly birds of the fields, meadows, and other open places. The conformation of their feet, except in a few instances, such as the woodlark, does not adapt them to perch upon trees. They accordingly always build on the ground, making in general a rather slight though neat nest, and laying about five eggs, usually of a grayish white, with specks of a brown colour. They frequently rear two broods of young during the summer.

They are almost all birds of passage; for even in Britain, where some remain during the winter, the greater number flock together and migrate, either southward or to the sea-coast. During these migrations immense numbers of them are caught in nets for the table, particularly on the continent, where small birds are more sought after for this purpose than in Britain.

Localities.—Europe and America.

Mr. Swainson considers this as the Fissirostral type.

Example:—*Alauda arvensis.* This is the *Alouette, Alouette Ordinaire*, and *Alouette des Champs* of the French; *Lodola, Lodola Canterina, Lodola di Passo*, and *Lodola di Montagna* of the Italians; *Feld Lerche* of the Germans; *Hedydd* and *Uchedydd* of the ancient British; and *Skylark* (in Scotch *Lavrock*) of the modern British.

The Skylark is too well known, from its inexpressibly beautiful song, chanted forth far up in the air when at liberty and in its natural state, to require any description.

Food.—Insects and their larvæ, with many sorts of seeds and grain.

Nest.—On the ground. Eggs four or five, greenish white, spotted with brown.

Localities.—All the parts of Europe; also in Asia and the northern parts of Africa, but not in the south of that vast continent (Temm.); the whole of Europe within the temperate zone, many parts of Asia, and the north of Africa. (Selby.)

Calendula. (Linn.)

Bill thick, much compressed; the culmen curved and convex; the commissure arched; the tip of the upper mandible wide above and inflexed. Wings long or moderate; the first quill very small and spurious; the second nearly equal to the third and fourth; lesser quills short, emarginate. Tail slightly forked. Lateral toes equal. Africa. The Dentirostral type—*C. magnirostris*, 'Ois. d'Afr.,' pl. 193. (Sw.)

Sub-genera:—*Myrafra*, Horsf.—Bill as in *Calendula*. Wings short, rounded; greater quills hardly longer than the secondaries and tertials; the first quills spurious, half the length of the second, which is shorter than the third; the third, fourth, fifth, and sixth equal, and longest. Tail short, even. Legs long.—*M. Javanica*, 'Linn. Tr.,' xiii. 159. (Sw.)

Braconyx, Sw. (*Brachonyx*).—Bill as in *Calendula*. Hinder claw very short. Wings and tarsi much lengthened. Africa. (Sw.)

Agrodroma. (Sw.)

Bill slender, considerably compressed; both mandibles of equal length; the tip of the upper one not reflected over the lower, and with a small notch, almost obsolete. Wings long; the first four quills nearly equal; the rest rapidly diminishing, and emarginate at their tips; tertials lengthened, pointed, as long as the quills. Tail moderate, even. Legs pale, long, slender. Tarsus longer than the middle toe. Lateral toes equal, but the outer claw shorter than the inner. Colour brown, lark-like. Distribution universal. The Insessorial or preeminent type—*Agrodroma rufescens*, 'Enl.,' 661, f. l. (Sw.)

Macronyx. (Sw.)

Bill slender, compressed, thrush-like, entire; nostrils large, naked, the aperture lateral. Wings short; the primaries not longer than the tertials, the first four of equal length; secondaries long, emarginate. Tail moderate, even. Feet enormous. Tarsus and hinder toes very long, and of equal length. Lateral toes unequal, the inner shortest. Africa. The Rasorial type—*M. flavicollis*, 'Ois. d'Afr.,' pl. 195; *M. flavigaster*, Sw., 'Birds of West Africa,' ('Naturalists' Library,' *Ornithology*, vol. vii., p. 215.)

Certhilauda. (Sw.)

Bill slender, lengthened, more or less curved; nostrils round, naked. Wings very long; the first quill spurious; the three next nearly equal. Tail moderate, even. Feet lengthened; the lateral toes equal; length of the hinder claw variable, although typically short and straight. Africa. The Tenuirostral type—*Certhilauda longirostra*, 'Ois. d'Afr.,' 192; *C. bifasciata*, Rüpp., 'Atlas,' plate 5; *C. nivosa*, Sw., 'Birds of West Africa' (vol. vii., p. 215.)

Such are Mr. Swainson's views as to the arrangement of this subgenus. [FRINGILLIDÆ.] The genus *Anthus*, Bechst., is placed by Mr. Swainson at the end of his sub-family *Motacillinæ* (Wagtails), under his family *Sylviadæ* (Warblers).

Fossil Larks.

Dr. Buckland figures a lark (*Alauda*) among the land Mammifers and Birds of the third period of the Tertiary Series, in the first plate of the illustrations of his 'Bridgewater Treatise.' He had previously noticed the remains of the lark in Kirkdale Cave. ('Reliquiæ Diluvianæ,' pp. 15, 34, plate xi., ff. 24, 25.)

ALBATROSS (*Diomedea*), a genus of web-footed birds, comprising three species—the Albatross of China (*D. fuliginosa*, Latham); the Yellow- and Black-Beaked Albatross (*D. chlororynchos*, Latham); and the Common Albatross (*D. exulans*, Linnæus.) The genus is principally distinguished by the following characters:—a very strong, hard, long beak, which is straight to near the extremity, when it suddenly curves. The upper mandible appears composed of many articulated pieces, furrowed on the sides, and crooked at the point; the lower mandible smooth and cut short; the nostrils lateral, and placed like small rolls in the furrow of the mandible; the feet short; the three toes long and completely webbed; the wings very long and narrow. The name Albatross is a word apparently corrupted by Dampier from the Portuguese Alcatraz, which was applied by the early navigators of that nation to cormorants and other large sea-birds.

The Common Albatross is the species which is most frequently met with in the seas of Southern Africa. It is the largest sea-bird known.

The top of the head is a ruddy gray; the rest of the plumage is white with the exception of several transverse black bands on the back, and a few of the wing feathers. The feet and membrane are of a deep flesh colour; the bill a pale yellow.

Common Albatross (*Diomedea exulans*).

The weight of this bird has been variously stated from 12 to 28 pounds; and a similar difference appears to exist in authors with respect to the distance between the extremity of the extended wings. Forster says above 10 feet; Parkins, 11 feet 7 inches; Cook, 11 feet; another says 12 feet; a specimen in the Leverian Museum measured 13 feet; and Ives (p. 5) mentions one, shot off the Cape of Good Hope, which measured 17½ feet from wing to wing.

We can, from this circumstance, readily understand the extensive range in which the Albatross is found; not being confined, as Buffon imagined, to the Southern Ocean, but being equally abundant in the northern latitudes, though Forster says he never observed it within the tropics. These birds are seen in immense flocks about Behring's Straits and Kamtchatka about the end of June, frequenting chiefly the inner sea, the Kurile Islands, and the Bay of Pentschinensi, whereas scarcely a straggler is to be seen on the eastern or American shore. They seem to be attracted thither by vast shoals of fish, whose migratory movements the albatrosses follow. On their first appearing in those seas they are very lean, but, from finding abundance of food, they soon become fat. Their voracity is so great, that they will often swallow a salmon of four or five pounds weight.

They do not, however, confine themselves to fish, but will prey on any other sea-animal; and Cook's sailors caught them with a line and a hook. The Kamtchatkadales take them by fastening a cord to a large hook, baited with a whole fish, which the birds greedily seize. Their usual food, however, seems rather to be fish-spawn and small shell-fish.

Notwithstanding their strength, they never venture to attack other sea-birds, but are, on the contrary, attacked by the gulls. "Several large gray gulls," says Cook, "that were pursuing a white albatross, afforded us a diverting spectacle: they overtook it, notwithstanding the length of its wings, and they tried to attack it under the belly, that part being probably defenceless: the albatross had now no means of escaping but by dipping its body into the water; its formidable bill seemed to repel them."

Their flesh is tough and dry; but the Kamtchatkadales take them for the sake of their entrails, which they blow up, and use as buoys for their nets. They employ the wing-bones also, which Edwards says are as long as their whole body, for tobacco pipes.

ALBIN, a white variety of *Apophyllite*. [APOPHYLLITE.]

ALBI'NOS, a word of Portuguese origin, by which the Portuguese voyagers denominated the white negroes whom they found on the coast of Africa. These negroes were also termed *Leucæthiopes*—a term signifying white negroes. Both names are now used, but the former popularly, to designate individuals who exhibit characters similar to those observed in the white negroes, among whatever race or in whatever country the variety may arise.

These singular beings are distinguished from other individuals of the human race by remarkable characters, which are invariably the same among whatever people or under whatever external circumstances the variety is found. Their most striking peculiarities consist in the colour of their skin and in that of their hair and eyes.

Their skin is of a pearly whiteness, without any admixture whatever of a pink or a brown tint. In the snow-white skin of the fairest European woman there is always some tint of a pink or brown colour, but in the Albinos the skin is wholly destitute of either tinge, and is of a dull pearly whiteness. It is often not soft and smooth in proportion to its whiteness, as is generally the case with the blonds of the European race; but, on the contrary, is rough, dry, and harsh.

The whiteness of the hair always corresponds to the whiteness of the skin. Not only the hair of the head, but also that of the eyebrows, eyelashes, beard, and even the soft down that covers the external surface of the body, has the same unnatural whiteness.

With this whiteness of the skin and hair is connected a still more striking peculiarity, namely, a redness of the eyes. That part of the eye called the iris is of a pale rose colour, while the pupil is intensely red: in a word, the eye is exactly similar to that of many forms of white animals, as the white rabbit, rat, mouse, &c.

This peculiarity depends upon the absence of certain cells in the body, called pigment-cells, which, wherever present, give a more or less dark colour to the surface on which they are developed. It is the formation of these cells in the skin and hair, and in the interior of the eye, that gives the various colours to these parts of the body; and when these cells are absent they present the appearances observed in Albinos. In the skin the part which secretes these cells is the upper surface of the *cutis*, or true skin. They are mixed, however, with varying proportions of colourless cells. These cells together constitute, when they lie flat upon the surface of the body, the *epidermis*, or scarf-skin. The cells which have not yet become hardened were supposed to form a soft layer, which was called the *rete mucosum*, or mucous layer. It is in the black races of mankind that the pigment-cells most abound, and just in proportion as the skin is fair do we find them deficient in quantity or less dark in colour: but in the fairest races these pigment-cells are found. In the same manner their presence in the hair produces the various shades of colour observed in this appendage of the skin, and they may be very numerous in the hair and not so in the skin generally. The eye requiring for its function a dark chamber, has developed in its interior a large quantity of pigment-cells, constituting the *pigmentum nigrum* of its interior membranes. What is true of man is also true of the lower animals, and the colour of their skin and hair depends on these peculiar cells.

The anatomical condition of Albinism is the absence of the pigment-cells. In the complete Albinos they are everywhere absent from the skin, the hair, and the eyes. It is this which gives the unnatural whiteness to the skin and the hair, and the redness to the eyes; this latter phenomenon resulting from the delicate blood-vessels reflecting the colour of the blood in them, an appearance which is entirely absent when the pigment cells are deposited as usual.

On the other hand it appears that there is a tendency in some animals which have naturally only a few pigment-cells to develop them in greater number than usual, as we see in the occasional presence of black sheep in a flock. Black varieties and white varieties, with a mixture of the two colours, are not at all uncommon amongst our domesticated animals. Of the causes which produce this peculiar affection of the organs in question we are ignorant; and the speculations of Buffon on this subject afford a striking example of the absurdities into which men, even of acute minds, fall when they substitute conjecture for investigation, or deem it consistent with the spirit of philosophy to place trust in fancy, when they are without knowledge. Thus, assuming that white is the primitive colour of nature, he says, that this colour may be varied by climate, food, and manners, to yellow, brown, or black; that these colours may, under certain circumstances, return to the primitive colour, but so much altered, that it has no resemblance to the original whiteness, because it has been adulterated by the causes that have been assigned. Nature, he tells us, in her most perfect exertions, made men white; and this same Nature, after suffering every possible change, still renders them white; but the natural or specific whiteness is very different from the individual or accidental. It is useful, occasionally, to recur to what was formerly considered, and is still sometimes considered, as an explanation of the phenomena of nature.

Some writers represent the peculiarities which distinguish the Albinos as altogether the result of disease. They found this opinion on the roughness and harshness of the skin, on the tenderness of the eyes, and the comparative physical weakness of these individuals. But the harsh and almost leprous appearance of the skin, though sometimes found, is by no means universal; the tenderness of the eyes arises from the increased sensibility of the organs in consequence of the abstraction of the dark-coloured substance by which, in the natural state, they are defended from the light: and, even admitting it to be a fact, which however does not appear to be fully established, that these persons are physically weaker than other men, it would not follow that this weakness is the result of disease. As far as can be judged from external appearance, and from their accounts of their own feelings, Albinos appear perfectly healthy, and many do not exhibit a single mark of disease whatever. It is also certain that domestic animals which exhibit varieties perfectly analogous to those of the human Albino are free from disease. This peculiarity has been observed in the sheep, pig, horse, cow, dog, cat, mouse, ferret, monkey, squirrel, rat, hamster, guinea-pig, mole, opossum, martin, weasel, roe, fox, rhinoceros, elephant, badger, beaver, bear, camel, buffalo, and ass; and even in the crow, blackbird, canary-bird, partridge, common fowl, and peacock. It is remarkable, however, that it has never been seen in any cold-blooded animal. In all the mammalia and birds just enumerated, the nature and characters of the deviation seem to be perfectly analogous to those of the human Albino. The pure whiteness of their skin and other integuments, and the redness of the iris and pupil, mark the same deficiency of colouring matter. A white mouse, possessed by Blumenbach, exhibited the same inability to bear the light which has been observed almost universally in the human examples; the animal kept its eyelids closed even in the twilight.

The physical, intellectual, and the moral qualities, associated with this singular conformation of the body, have not been stated with distinctness and accuracy. It would seem that the Albino is both physically and mentally somewhat weaker than other men. All accounts agree in representing his physical strength as inferior to that of persons of the ordinary conformation. Saussure, in his 'Voyage dans les Alpes,' expressly states, in relation to two boys whom he examined with much attention at Chamouni, that, when they were of a proper age, they were unable to tend the cattle like the other children; and that one of their uncles maintained them out of charity, at a time of life when others were capable of gaining a subsistence by their labour. Wafer, the old voyager, in his account of the Indian Albinos in the Isthmus of Darien, while he represents them as being as nimble in the moonlight as the other Indians, states that they are not so strong and lusty. But in what degree their intellectual powers are confined, or whether indeed there be any decided inferiority, we have at present no means of forming an accurate judgment.

Some inconvenience certainly arises from the conformation of the eye peculiar to the Albinos. A strong light cannot be borne, and even the full glare of day appears to excite some degree of uneasiness. Hence the eyelids are usually more drawn over the ball of the eye than is common with other persons, and the eyes are generally weak, tender, and watery; while vision is more agreeable and more perfect in twilight. But the inconvenience of an ordinary degree of light, and the advantage of imperfect darkness, have been exaggerated.

It would seem that there is a greater tendency to the formation of this variety in some parts of the world than in others. It is more common among the African and the Indian tribes than among the European people. In the Isthmus of Darien, and in some of the oriental islands, it is so frequent that some writers have conceived that those persons form a distinct and peculiar tribe; but for this opinion there is no foundation. Mr. Bowdich, however, states that the king of Ashantee, who seems to have considered persons of this description as a great curiosity, and to have indulged his taste for collecting them in a truly Oriental manner, had assembled about him nearly a hundred white negroes. Blumenbach states that he has himself seen sixteen Albinos in various parts of Germany; and examples have been not unfrequently found in Denmark, England, Ireland, France, Switzerland, Italy, the Grecian Archipelago, and Hungary. It is common in both sexes, but it would appear to be somewhat more frequent in males than in females.

ALBITE, a mineral of the Felspar group, in which the potash of felspar is exactly replaced by soda. It includes *Pericline, Tetartine, Carnatite*, and *Cleavlandite*. It occurs massive and crystallised. Primary form a doubly oblique prism. Cleavage parallel to the primary planes. Colour commonly white, sometimes gray, greenish, bluish, or red; streak white. Fracture uneven. Hardness 6·0. Lustre pearly on the cleavage planes, vitreous in other directions. Transparent, translucent. Specific gravity 2·6 to 2·68. The massive varieties have a laminar structure. Found in Norway, Sweden, Dauphiny, St.-Gothard, Scotland, and accompanying felspar in most of its numerous localities; from this it differs chiefly in containing soda instead of potash. Analysis, by Stromeyer: silica, 70·68; alumina, 19·20; soda, 9·06; lime, 0·23.

ALBUCA (*albus*, white), a genus of plants belonging to the natural order *Liliaceæ*. The species are mostly found at the Cape of Good Hope. They are cultivated in this country, and require the treatment of greenhouse bulbs.

ALBU'MEN. In plants this term has been improperly applied to the substance which in some seeds is interposed between the embryo and their coat. It varies very much in density, and other characters, and is often the most valuable part of a plant. In the cocoa-nut it is the meat, the milk being a fluid uncondensed portion of it; in the coffee-seed it is the part that is roasted; and in corn it is that which is ground into flour. The oil of the castor-oil plant, and of the poppy, the aroma of the nutmeg, and the greasy nutritious substance that forms chocolate are all the produce of albumen. In the ivory-nut it is the hard part from which it has acquired its name.

This substance in the beginning is of a pulpy nature, and is the matter in which the young embryo first makes its appearance; in this state it is present in all plants, but as the embryo, for the nutriment of which it is destined, increases in size, the albumen is gradually absorbed by it, either wholly, as in the turnip, the pea, the bean, and the like; or in part only, the residue being of a consistence varying between softness, as in the poppy, and extreme hardness, as in the date-palm. [Seed.]

Botanists find its presence in abundance, or its total or almost total absence, a character of very great importance in distinguishing the different tribes of plants.

ALBURNUM, in plants, is that part of the stem of trees which timber-merchants call *Sapwood*. It is the newly-formed unchanged wood lying immediately below the bark, and is always of a very light colour. It is the principal channel through which the crude sap is conveyed from the roots into the leaves, and is, therefore, an indispensable part in all exogenous trees. [Exogens.] It consists of delicate fibrous tissue; in which respect it differs from *Heartwood*, or *Duramen*, in which the tissue is combined with solid secretions, the nature of which varies with species. It is probably on the latter account that heartwood is so much more durable than sapwood; for simple fibrous tissue is in itself very perishable, and it only ceases to be so in consequence of the presence of secretions of a less destructible character.

While many plants have the alburnum and heartwood distinctly separated, there are others, technically called Whitewooded Trees, which consist of nothing but alburnum. This arises from their not forming any solid secretions which can give durability to the central parts; hence all such trees are quickly perishable, and are generally unfit for any but temporary purposes.

ALCA (Cuvier), the Auk, a genus of Web-Footed sea-birds, which has a singularly-formed bill, being very broad when viewed laterally, straight towards the base, but much curved towards the point. Both the mandibles are half covered by projecting feathers, and furrowed near the point. The upper mandible is crooked, and the under forms a projecting angle. The nostrils are towards the middle of the sides of the upper mandible, being very narrow and almost closed by a membrane covered with feathers. The legs are short, and placed far back, so that the birds when standing have their backs nearly perpendicular. There are only three toes fully webbed, the back toe being wanting. The claws are somewhat pointed. The wings are short, and the first quill is as long as the second, or perhaps a little longer.

Only two species are known, the Great Auk (*Alca impennius*), and the Razor Bill (*Alca Torda*), both natives of the British Isles. [Auk.]

ALCE'DO (Linnæus), Kingfisher, a genus of birds of which the characteristics are:—The bill long, straight, quadrangular, thick, and pointed; the tongue short, fleshy, flat, and slightly arrow-shaped at the point; the nostrils at the side of the base of the bill running obliquely, and nearly closed by a naked membrane; the legs with the shank (*tarsus*) short; the feet with three toes forward, the outer joined to the middle one as far as the second joint; the inner one similarly joined as far as the first joint. The hind toe is broad at the base. The wings have the first and second quills nearly equal, but these are shorter than the third, which is the longest in the wing.

There is only one species of Kingfisher (*Alcedo Ispida*) indigenous to Britain. It is the most beautiful of our native birds. More than sixty species have been described by naturalists, chiefly natives of Asia and Africa, and all distinguished by the splendid colours of their plumage. [Kingfishers.]

ALCES, the Elk. [Deer.]

ALCYNOE. [Acalephæ.]

ALCYONELLA (diminutive of *Alcyonium*), a genus of animals belonging to the Fresh-Water *Polyzoa*, or *Ascidian Zoophytes*. The species of this genus were originally regarded as plants. They are composed of a fleshy sponge-like mass, which consists of vertical, aggregated, membranaceous tubes, which open on the surface. In these tubes the polypes are seated, which are ascidian; the mouth is encircled with a single series of filiform tentacula, which, like those of the whole family, are depressed or incomplete on one side. The eggs are contained in the tubes, and are coriaceous and smooth.

The most common species is the *A. Stagnorum* of Lamouroux, which is commonly found in stagnant waters, especially when they contain iron in solution. The polype-mass of this species is a sponge-like substance, somewhat elastic, of a blackish green colour, and is more or less apparently porous. It is composed of tubes which rise from the base to the surface, and are connected together by a firm transparent gelatinous substance. The walls of the tubes are composed of a thin pellucid colourless membrane, through which the ova in their interior can be easily seen. The ova are very numerous, although the animal itself is comparatively rare, abounding at one season, and almost absent at another, in the same pond.

This animal was originally described by Trembley in 1741, and although he was perfectly aware of its nature at that early period, it has been often described since both as a plant and a sponge. One of the best modern accounts is that of Mr. T. P. Teale, in the first volume of the 'Transactions of the Leeds Philosophical and Literary Society.'

(Johnston, *British Zoophytes.*)

ALCYONIDÆ, a family of the Asteroid Polypes, containing the genera *Alcyonium* and *Sarcodictyon*. They are distinguished from the *Pennatulidæ* (Sea-Pens), and the *Gorgoniadæ* (Sea-Fans), by the polype-mass being tough and fleshy, without any distinct axis, but strengthened by the irregular distribution of calcareous spiculæ. The polype-cells are placed in the fleshy mass, and scattered over its surface.

The best known of the species of this family is the *Alcyonium digitatum*, which was described by Ellis under its popular name of Dead Man's Hand, or Dead Man's Fingers. It has been described by naturalists by other names, especially *Lobularia*: but this is inadmissible, as having been previously employed to name a plant. *Alcyonium* is derived from Alcyon, the kingfisher; and this word means sea-foam, of which the kingfishers were supposed to make their nests.

The species in question is one of the most common of our maritime productions, and is found on stones and shells and rocks, and can frequently be collected at the low-water mark during a spring-tide. It sometimes covers the object to which it is attached as a mere crust, at other times it rises up in one or more conical masses. Where there is only one, the fishermen give it the name of the Cow's Paps, from its resemblance to the teat of the cow's udder. The skin is tough, and when examined presents little radiated points, which indicate where the tentacles of the polypes exist. The tentacles are short, obtuse, and ciliated on the margins. The polype-cells are placed just under the skin, at the termination of a series of aquiferous canals which run throughout the polype-mass. These tubes communicate with each other, so that many of the polypes are, as it were, collected together, forming a compound animal. The space between the tubes is occupied by a loose fibrous network, forming lozenge-shaped compartments, with smaller meshes in them. These interstices are filled with gelatinous matter, in which irregular calcareous spiculæ lie embedded. The ova are developed in the polype-tubes, and are about the size of a grain of sand. They are produced in spring and summer, and ultimately discharged from the mouth of the polype.

A second species of *Alcyonium*, *A. glomeratum*, has been described by Dr. A. H. Hassall.

The genus *Sarcodictyon* has been described by Professor Edward Forbes. It differs from *Alcyonium* in the incrusting, creeping, and anastomosing form it assumes. Its polypes also are distant from each other, and placed in uniserial prominent cells. It has eight pinnated tentacula. Only one species has been described, *S. catenata*.

(Johnston, *British Zoophytes.*)

ALCYONIDIUM (from *Alcyonium*, on account of its external resemblance), a genus of animals belonging to the Infundibulate section of the *Polyzoa*, or *Ascidian Zoophytes*. It presents a fleshy variously-lobed mass, containing in it 5-sided cells, which contain ascidian polypes surrounded with a double sheath. The most common species of this genus is the *A. gelatinosum*. It is one of the most common productions of the sea-shore, and few persons can have been at the sea-side without having noticed it. The older botanists described it as a plant. Gerard in his 'Herbal' says:—"This is a very succulent and fungous plant of the thicknesse of one's thumbe; it is of a dark yellowish colour, and buncheth forth on everie side with many unequal tuberosities or knots." He called it the 'Sea Ragged Staffe.' Ray called it a *Fucus;* but Lamouroux, who first classed it amongst plants, has the honour of having discovered that it was studded all over with polypes. We are indebted to Dr. Arthur Farre for a very elaborate account ('Phil. Trans.,' 1839) of this creature. The polype-mass grows naturally in deep water attached to old shells and stones. It is however washed upon most of our coasts after every storm. The mass is clustered or fingered, and rises to the height of from 6 to 12 or 18 inches. It resembles a compact sponge, but is more pellucid and gelatinous. The surface is smooth, but is speckled with dots which indicate the spots where the polypes are contained. The polypes are so closely connected with their cells that it is impossible to separate them without mutilation. The tentacles are 16 in number.

Two other species have been described as frequent on the British coasts, *A. hirsutum* and *A. parasitium*.

(Johnston, *British Zoophytes.*)

ALCYONIUM. [ALCYONIDÆ.]

ALDER. [ALNUS].

ALECTO (one of the Furies of the Greek mythology), a genus of Infundibulate *Polyzoa*, characterised by the creeping and branched character of its polype-mass. There are several species, all of which are found attached to old shells and stones, and are mostly dredged for in deep water.

ALETHO'PTERIS (Sternberg), a genus of Fossil Ferns, mostly from the Coal formation. (*Pecopteris* of Brongniart.)

ALETRIS, a genus of plants belonging to the natural order *Liliaceæ*. One of the species, *A. farinosa*, is the most intense bitter known. It is found in fields and the edges of woods very commonly in the United States, and is used in infusion as a tonic and stomachic. Large doses produce poisonous effects.

ALEURITES, a genus of Euphorbiaceous plants, many of the species of which are now referred to *Croton*. [CROTON.]

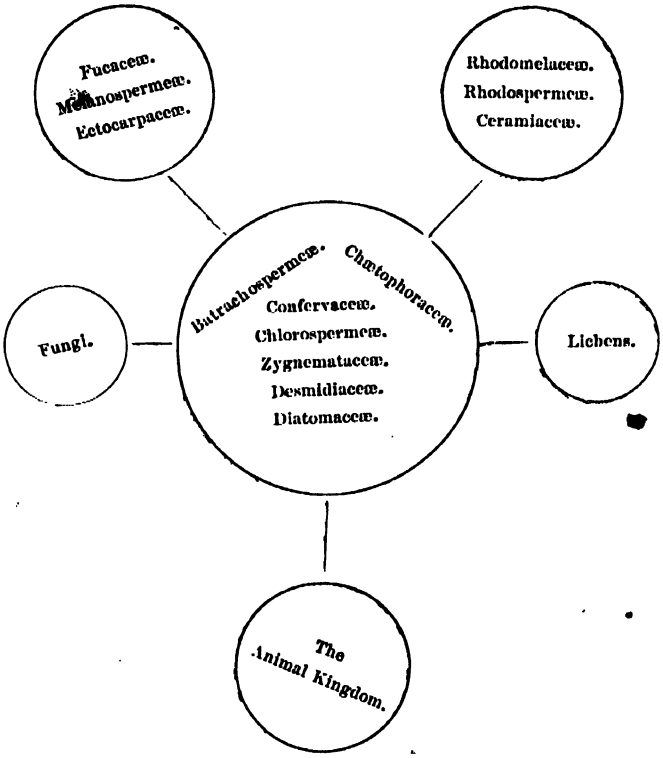
ALEXANDRITE, a name given to specimens of the mineral *Chrysoberyl*, brought from the Ural. [CHRYSOBERYL.]

ALGÆ is the name given by botanists to the tribe of plants which comprehends the Sea-Weeds, Lavers, and fresh-water submersed species of similar habits. In structure they vary through a vast variety of intermediate gradations, from the state of simple microscopic vesicles to branched woody individuals many fathoms in length. Some of them are only visible to the naked eye when they are collected in heaps; of this nature is the green and red slime that we find in damp walks, at the bottom of shaded walls, and in similar situations; others grow together in the beds of the ocean, and when they rise to the surface form floating banks of such extent as to impede the course of ships; of this kind are the *Chorda filum*, or Sea Cat-Gut, of Orkney, meadows of which have been seen in Scalpa Bay; and the Gulf-Weed of navigators, which, according to Humboldt, being carried by the Gulf Stream, forms two banks in the great basin of the Northern Atlantic Ocean, one of which stretches over 11 degrees of latitude, and the other over 4 degrees.

The plants included under this designation are every day becoming better known through the influence which the microscope and better methods of investigation are producing in every department of natural history. Under the term *Algæ* Linnæus included the Lichens and other plants as an order in the class *Cryptogamia*, or *Acrogens*. The Lichens have been long since separated; but the plants that are now ordinarily called *Algæ* present differences quite as wide as any that separate the orders of the class *Exogens*, so that we cannot regard the term *Algæ* as of only ordinal value. Dr. Lindley, in his 'Vegetable Kingdom,' constitutes an alliance which he calls *Algales*, and which he makes to embrace the following natural orders:—

1. *Diatomaceæ*, or Brittleworts.
2. *Confervaceæ*, or Confervas.
3. *Fucaceæ*, or Sea Wracks.
4. *Ceramiaceæ*, or Rose Tangles.
5. *Characeæ*, or Charads.

The first of these orders includes the *Desmideæ*, which are almost entirely microscopic. They are hardly comprehended under the term *Algæ* at all. [DIATOMACEÆ; DESMIDEÆ.] It is only very recently that naturalists have come to the conclusion that they are plants. The Charads, or fifth order, present in many respects a much higher development than the rest, and may be justly regarded as not belonging to *Algæ*. [CHARACEÆ.] The relation of these groups to each other and the animal kingdom may be seen in the following diagram, given by Professor Harvey in his work on the 'British Algæ.'



As Mr. Harvey is the most recent writer on this subject we shall follow him in this article. He divides the *Algæ* into three sub-classes.

1. *Melanospermeæ*, which are marine plants of an olive green, or olive brown colour, having a monœcious or diœcious fructification. The spores are olive-coloured; each enveloped in a pellucid skin, and either simple, or separating into two, four, or eight sporules. They possess *antheridia*, or transparent, orange-coloured, vivacious corpuscles, moving by means of vibratile cilia.

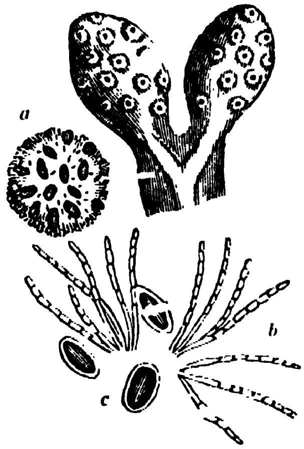
2. *Rhodospermeæ*, which, with one or two exceptions, are marine plants, mostly of a rosy red or purple colour. The fructification is of two kinds: either of spores in external or immersed conceptacles, or densely aggregated together and dispersed throughout masses of the frond; or of tetraspores of a red or purple colour, external, or immersed in the frond, and each enveloped in a pellucid skin which at maturity separates into four sporules. Some possess antheridia which are filled with yellow corpuscles.

3. *Chlorospermeæ*, which are marine or fresh-water plants of a green colour. The fructification is dispersed through all parts of the frond. The spores are green, formed within the cells, and often at maturity having vibratile cilia. They produce also gemmules, or external vesicles, which contain a dense, dark-coloured, granular mass, which finally separates from the frond.

The *Melanospermeæ* include the following orders: — *Fucaceæ*, *Sporochnaceæ*, *Laminariaceæ*, *Dictyotaceæ*, *Chordariaceæ*, *Ectocarpaceæ*.

The *Fucaceæ*, which have for their type the genus *Fucus*, are all of them marine plants. They are of an olive brown or greenish colour, and very fine in their texture. The cellular structure of which all the *Algæ* are composed is in these plants in a very condensed state, assuming a leathery and sometimes even a woody character. The base of their stem or stipes forms a dense shield-like root, whilst their upper part is often expanded into a broad foliaceous appendage. The reproductive organs consist of small black or very dark spores, which are collected into sori or are found scattered on various parts of the frond. These spores are enveloped in a thick gelatinous mucus, which seems to be a provision for the purpose of attaching them more securely to the rocks on which they grow in the midst of the restless element to which they are constantly exposed. They are of very rapid growth, and only a few months serve to cover a surface of naked rock with a forest of various species of *Fuci*. Kelp is manufactured from the species of plants belonging to this section of *Algæ*; the one most commonly collected for this purpose is the *Fucus vesiculosus*. Kelp is not now manufactured to any great extent in this country, but a few years since it was a source of great wealth in the Western Islands and the western shores of Scotland. [KELP.] At one time the quantity made in Scotland and its adjacent isles was not less than 20,000 tons annually, which sold at the average price of 10*l*. per ton.

Of all the species, that which is the most common is the *Fucus vesiculosus*, great quantities of which are cast upon our coasts, and which is known by its strap-shaped, olive-green, forked divisions, having little yellowish oval uneven pods at their points, and by the crackling noise it makes when trodden upon; a circumstance which is owing to its stems having a considerable number of air-bladders, by means of which it floats. The structure of the pods is highly curious. Externally they consist of a hard rind, covered with tumours, each of which has a little hole in its centre. Internally they contain a soft mucous substance, in which lie, next the rind and immediately below its tumours, a number of round balls (*a*). These little balls are composed of jointed threads (*b*) which hold together a great many little oval grains (*c*) enveloped in a sort of jelly. These grains are the spores by means of which the plant is propagated, and when ripe they are discharged through the holes in the tumours above described.



Fucus vesiculosus.

Although, from the simple structure of the *Algæ*, we should not expect that they would elaborate many of those secretions which in higher plants are found subservient to the use of man and other animals as food, yet among many of these a gelatinous matter is secreted, which is nutritious. In Gothland, the *F. vesiculosus* is given as provender to hogs, and hence is called Swine-Tang. Many other animals will also eat this plant as food, in times of scarcity. It is also collected in Jersey, and when dried is used as fuel. The fishermen both of our own and the Dutch coasts use this *Fucus* and the *F. serratus* for packing up their fish; the latter is however preferred, as, from containing less mucus, it is less likely to ferment. The *Fuci* were at one time used considerably in medicine, as well as other forms of *Algæ*, but since the discovery of their active principle, iodine [IODINE, ENG CYC., ARTS AND SC. DIV.], they have been comparatively little used. According to Ecklon, the *Laminaria buccinalis* of the Cape of Good Hope is the sea-weed that produces the greatest quantity of iodine.

The *Sargassum vulgare*, or Tropic Grape, the *Fucus natans* of older writers, is remarkable for the immense quantities in which it occurs in certain portions of the ocean. It only grows within forty degrees of the equator, on each side, although occasionally thrown up by currents on our own shores. In some parts of the ocean it is so constant that it is said to assist pilots in rectifying their longitude. It was the occurrence of immense fields of these weeds that struck the sailors of Columbus with so much awe, and led them to suppose that Providence had determined to frustrate their course, which nearly terminated in the giving up of their great attempt to discover the New World.

Alaria esculenta, when stripped of the thin part, forms a part of the simple fare of the poorer classes of Ireland, Scotland, Iceland, Denmark, and the Faroe Islands.

The *Sporochnaceæ* are a small group, composed of the Scatter-Tuft (*Sporochnus*) and three other genera, which are remarkable for bearing little tufts of fine green filaments on the fronds. They are of an olive or yellowish green colour: they become flaccid on exposure to the air, acquiring a verdigris colour, and possess the property of decomposing other *Algæ* with which they may come in contact.

The *Laminariaceæ*, or Tangles, have a densely fibro-cellular structure, and their spores are collected together in sori on the surface of the frond. These plants are coriaceous or membranaceous in structure, and are little changed by exposure to the air. Some of them are used. *Laminaria esculenta* is an edible species. It grows to the length of 20 feet, and the midrib, stripped of its membranaceous covering, is the part that is eaten. *L. saccharina*, or the Sugar Sea-Belt, is said to be eaten by the Icelanders. In Japan it is also considered a great delicacy. *L. digitata*, or Sea-Wand, is eaten in Scotland, and is cried about the streets of Edinburgh as *Tangle*. Many of the sea-weeds belonging to this and other genera have been found to make excellent manure for grass-lands. Kelp has in many instances been used, and it has perfectly succeeded. It has been tried as a top-dressing, and singly or in combination with other manures on corn, pasture, potatoes, turnips, &c., with the best effect.

To this section belongs the *Chorda filum*, Sea-Whiplash, or Sea-Whipcord, which is often found 30 or 40 feet in length. The frond of this plant is hollow within, interrupted at short distances, an arrangement which appears to be for the purpose of enabling the plant to float in the water, and thus securing the same end as the more highly developed vesicles of *Fucus vesiculosus*.

The *Dictyotaceæ*, or Sea-Networks, are a larger section than the last, and are characterised by the beautifully reticulated texture of the tegument. Their fronds are of various forms, but all of them are ribless.

The *Chordariaceæ* and *Ectocarpaceæ* have their fronds formed of jointed filaments, which are either free or united into a compound body.

The *Ectocarpaceæ* are olivaceous or green marine plants; their fructification is monœcious, the capsules external, and the globules placed between swollen ramuli. It contains the genus *Ectocarpus* and two others.

The *Rhodospermeæ* include the following orders:—*Rhodomelaceæ*, *Laurenciaceæ*, *Corallinaceæ*, *Delesseriaceæ*, *Rhodymeniaceæ*, *Cryptonemiaceæ*, *Ceramiaceæ*. These orders are distinguished by their brilliant and little-fading tints, their leaf-like fronds, and the collection of their spores into sori, or, if scattered, by the spores being arranged on a ternary plan. The *Chondrus crispus*, or Carrageen Moss, belongs to the order *Cryptonemiaceæ*. In Ireland it is used extensively as an article of food, and has lately been sold in London as a substitute for Iceland Moss. It is frequently employed, instead of isinglass, for the manufacture of blanc-mange and jellies. It has a slight bitter flavour, which may be removed by steeping for some time previous to boiling.

Another genus of the same order is *Gelidium*. A species of this genus is said to be the substance collected by the swallows and used in the construction of the edible nests of Java. Strange as it may seem that a taste for birds' nests should exist among any people, yet so strong is this taste in China, that the trade in birds' nests forms a very lucrative and extensive branch of commerce. Burnett, in his 'Outlines of Botany,' observes, "It has been estimated that 242,400 lbs. of birds' nests, worth in China 234,290*l*. and upwards, are annually exported from the Indian Archipelago." The only preparation the birds' nests undergo is that of simple drying, without direct exposure to the sun; after which they are packed in small boxes. They are assorted for the Chinese market into three kinds, according to their qualities; and the common price for birds' nests of the first sort at Canton is no less than 3500 dollars the pecul, or 5*l*. 18s. 1½d. per lb.; for the second, 2800 Spanish dollars the pecul; and for the third, 1600. The collecting these birds' nests, according to Mr. Crawford, is as perilous a toil as our fearful trade of gathering samphire; for he says, "The nests are obtained in deep and damp caves, and are most esteemed if taken before the birds have laid their eggs. The coarsest are those collected after the young have been fledged. The finest nests are the whitest; that is, those taken before they are defiled by the young birds. They are taken twice a year, and if regularly collected, and no unusual injury offered to the caverns, the produce is very equal, and the harvest very little if at all improved by being left unmolested for a year or two. Some of the caverns are extremely difficult of access, and the nests can only be collected by persons accustomed from their youth to the office. In one place the caves are only to be approached by a perpendicular descent of many hundred feet by ladders of bamboo and rattan, over a sea rolling violently against the rocks. When the mouth of the cavern is attained, the perilous office of taking the nests must often be performed by torch-light, by penetrating into the recesses of the rock, where the slightest trip would be instantly fatal to the adventurers, who see nothing below them but the turbulent surf making its way into the chasms of the rock." (Crawford's 'Eastern Archipelago.')

Several other species of *Gelidium* are made use of as food, more especially in the East, where they are added to dishes to render the hot and biting condiments more palatable.

The *Iridea edulis*, Edible Dulse, is a favourite food with many of the *Crustacea*, as lobsters, crabs, &c.: it is also eaten by fishermen, both raw and roasted. It is said to resemble in flavour roasted oysters. The *Halymenia palmata* was at one time used as a masticatory, but its use has been supplanted by tobacco. It is still, however, used as a popular remedy in scorbutic and other cutaneous diseases. "To the Icelanders it is a plant of considerable importance. They prepare it by washing it well in fresh water, and exposing it to dry, when it gives out a white powdery substance, which is sweet and palatable, and covers the whole plant. They then pack it in casks to keep it from the air, and thus preserve it ready to be eaten, either in this state with fish and butter, or, according to the practice of wealthier tables, boiled in milk, and mixed with a little flour of rye. The cattle are also very fond of this sea-weed, and sheep are said to seek it with such avidity as often to be lost, by going too far from the land at low-water." ('Quart. Rev.,' vii. 68.) From this latter circumstance it was called *Fucus ovinus*, or Sheep Dulse. In Kamtchatka it is used for making a fermented beverage, which is easily produced on account of the great quantity of sugar this plant contains.

Amongst the *Rhodymeniaceæ* is the genus *Gracillaria*, the species of which are also used as food, and one of them, *G. lichenoides*, is highly valued in Ceylon and other parts of the East, and bears a great resemblance to *G. compressa*, a species of the British coast, and which Dr. Greville says is little inferior to the first, and has been used in this country both as a pickle and a preserve. The *G. tenax*, the *Fucus tenax* of Turner, is invaluable to the Chinese as the basis of an excellent glue and varnish. "Though a small plant," says Dr. Greville, "the quantity annually imported at Canton from the provinces of Fokein and Tchikiang is stated by Mr. Turner to be about 27,000 lbs. It is sold for 6d. or 8d. per pound, and is used for the purposes to which we apply glue and gum arabic. The Chinese employ it chiefly in the manufacture of lanterns, to strengthen or varnish the paper, and sometimes to thicken or give a gloss to silks or gauze." Mr. Neill thinks it probable that the gummy matter called chin-chou, or hai-tsai, in China and Japan, may be composed of this substance. Windows made of slips of bamboo, and crossed diagonally, have frequently their interstices wholly filled with the transparent glue of hai-tsai.

A celebrated vermifuge on the Continent is prepared from the *Helminthocorton*, a genus which grows in the Mediterranean, and goes by the name of the Coralline of Corsica. It has also been recommended as a remedy in cancer, but is seldom used in this country.

The *Plocamium*, or Hair-Flag (*Delesseriaceæ*), is one of the most elegant plants of this section. It was formerly used much in the construction of artificial landscapes on paper, and its collection and preparation gave employment to many of the poor on our coasts.

The order *Ceramiaceæ* contains six genera, one of which is the *Griffithsia*, a plant named after Mrs. Griffiths, who has done much to advance the knowledge of the order *Algæ* in Great Britain. The most extensive genera in this tribe are *Callithamnion* and *Polysiphonia*. Most of the species belonging to these two genera are natives of the sea, and are found attached to rocks, and to shells, stones, and corallines which are thrown up by the waves. Many of them are also found parasitic upon the larger sea-algæ, as the various species of *Fucus* and others.

The *Chlorospermeæ* include the orders *Siphonaceæ*, *Confervaceæ*, *Ulvaceæ*, *Oscillatoriaceæ*, *Nostocaceæ*, and *Palmellaceæ*.

The order *Siphonaceæ* consists of plants which are found in the sea, in fresh water, or on damp ground, of an herbaceous green colour. The frond is either composed of membranaceous, filiform, continuous, simple, or branched tubes, or formed of a combination of similar tubes, forming a spongy or crustaceous, globular, cylindrical, or flat body; the reproductive organs are vesicles produced on the outer surface of the tubes, filled with a dark green granular mass. This tribe contains four genera: *Codium*, *Bryopsis*, *Vaucheria*, and *Botrydium*. The most interesting genus is *Vaucheria*, on account of the remarkable observations that have been made upon its reproductive granules by Unger and other botanists. [VAUCHERIA.]

Codium, the Sea-Purse, is a hollow, sub-globose, dark green plant, composed of an interwoven mass of tubular continuous filaments, the reproductive vesicles being attached to the filaments near the surface of the frond. There are two British species found on submarine rocks. *Bryopsis* has two British species, which are also marine plants. The frond is membranaceous, filiform, tubular, cylindrical, glistening, branched; the branches are imbricated, or distichous and pinnated, and filled with a fluid containing minute granules. Their numerous branches give them the appearance of feathered mosses—hence their name. *Botrydium* (from Βότρυς), a Grape-Bunch, is nothing more than a spherical vesicular receptacle, filled with a watery fluid: it opens at the apex, and has, descending from the lower part, a bunch of radical fibres. In structure this plant resembles *Codium*, but it is much smaller, the receptacle not being bigger than a grain of mustard, and it grows upon the ground in moist shady situations. Granules are contained in the watery fluid within the plant, and when the weather is dry, the upper part of the receptacle collapses, giving the plant a cup-shape.

The *Confervaceæ* are for the most part green plants, but sometimes pink or brown. The fructification consists of a granular, coloured internal mass, which assumes various forms.

The genus *Conferva*, although still containing numerous species, has been much reduced by the formation of new genera. It has however still an indefinite character, on account of the comparatively little attention which the order *Algæ* has received from botanists. The "filaments are articulated, free, distinct, uniform, simple or branched. Fruit (?), an internal, coloured, granular mass (endochrome). Colour green, rarely purple or orange." The species of *Confervæ* are found wherever there is water. In running streams they attach themselves to the stones at the bottom, and are so abundant frequently in stagnant ponds and pools as to conceal everything else. Some few of them are found in sea-water, and some on dry land. Some of the species have been found developing their peculiar forms under the influence of the ingredients of different mineral-springs; and one, the *Conferva thermalis*, is only found in thermal springs. Under favourable circumstances they sometimes go on developing to an immense extent in lakes or ponds in which they grow. They are generally at first green, but as they ascend to the surface of the water, and are exposed to the air, they become whitish. The rapidity of the growth of these plants is sometimes very extraordinary, and lakes, and even the ocean itself, are covered for several miles with floating masses of *Confervæ* several inches in depth. Of the various species of *Confervæ*, the *C. fracta*, the *C. crispata*, and *C. rivularis* are most abundant in this country. These plants are frequently called Crow-Silks, and in some parts of the country, when dried, they have been used for the purpose of stuffing beds, also as wadding for stuffing garments. Dr. Lightfoot says he has seen at Edinburgh a kind of paper manufactured from the fibres of *Conferva fracta*. *C. ægagropila*, Globe Crow-Silk, or Moor-Ball, is found with its filaments rolled up into the form of a ball, so that it has the appearance of the balls of hair occasionally found in the stomachs of animals. It is an inhabitant of lakes, but is rarely found. It is not fixed to anything, but floats about at the mercy of the waves. The balls vary in diameter from half an inch to four inches.

The genus *Hydrodictyon* has filaments which form a network with regular polygonal meshes, and viviparous articulations. There is but one species, the *H. utriculatum*, Common Water-Net, which is a rare plant, and found only in ditches and pools in the middle and southern parts of England. It is a beautiful plant, forming a tubular net, which floats freely in the water. The meshes of the net-work are pentagonal or hexagonal, and vary in diameter from half a line to half an inch, and the filaments from the width of a human hair to that of the coarsest hog's-bristle.

The genus *Mougeotia*, named after J. B. Mougeot, a German botanist, has articulated simple filaments, which are finally united by transverse tubes. The endochrome is granular, at length forming roundish globules at the point of conjugation. This is one of the genera of confervoid plants whose filaments are said to unite before reproduction takes place. That this conjugation does take place previous to their granules possessing any reproductive power, in many of the species, there can be no doubt. But there are many species of *Confervæ* which belong to the conjugate group of genera, in which the phenomenon of conjugation does not take place previous to reproduction. These exceptions occur more particularly in the genus *Zygnema*. [ZYGNEMA.] Several species of *Mougeotia* are found in Great Britain; the most common is the *M. genuflexa*, which is abundant in pools and ditches, sometimes covering a space 30 or 40 feet in diameter, and being of a yellowish-green or dull yellow colour. The filaments are exceedingly fragile.

The genus *Tyndaridea* has simple filaments, inosculating by transverse tubes. The endochrome is in two roundish masses, which after conjugation unite to form a single globule. The species are found in ponds and ditches, mostly commencing their existence at the bottom of the water, and after a little time rising to the surface, where they form masses varying in size, of a yellowish and yellowish-green colour.

The *Ulvaceæ* include plants which are found in the sea, in fresh-water, or on the damp ground: they are generally of an herbaceous green or fine purple colour, and have a thin, tender, membranaceous, reticulated structure, rarely gelatinous; they are generally furnished with a very minute scutate root, which is either expanded or tubular and continuous; the reproductive organs consist of roundish, mostly quaternate granules, or minute opercular grains, which are imbedded in the delicate membrane of the plant. This order contains about ten genera, of which the five following are British: *Porphyra*, *Ulva*, *Tetraspora*, *Enteromorpha*, and *Bangia*.

Porphyra (from πορφύρεος), the Purple Laver, has a plain frond, exceedingly thin, and of a purple colour. The reproductive organs are of two kinds:—1, Roundish granules arranged in fours, and imbedded in the whole substance of the frond; 2, Masses of smaller ovate granules, which are scattered without order, chiefly towards the margin of the frond. Four species of the Purple Laver are enumerated. The most common is the *Porphyra laciniata*, which has its fronds aggregated and deeply cleft, the segments dilated, and variously cut and waved. This plant is common in the sea from spring to autumn, and grows on rocks and stones, whence it is often torn by the violence of the waves, and thrown on the shore. The frond of this plant abounds in a viscid gelatinous matter, which is said to be very nutritious. On this account this plant, under the name of Laver, is much eaten in many places, especially the south of England. When collected, it is kept in jars with salt, and when brought to the table is served up with lemon juice. Dr. Lightfoot states that in the Western Isles it is gathered in the month of March, and that, when pounded and macerated with a little water, the inhabitants eat it with pepper, vinegar, and butter. It is sometimes stewed with leeks and onions. But although this plant is abundant enough, it is only very partially used as an article of diet.

Ulva the Green Laver, has a membranaceous frond of a green colour with its reproductive granules arranged in fours. There are seven British species of *Ulva*: three growing in the sea, one in fresh water, and three in damp places on the land.

U. latissima, the Broad Green Laver, has a plain, widely-oblong or roundish frond, waved, and of a green colour and tender substance. It is an abundant plant on the rocks and stones of the sea in summer and autumn. In common with *U. Lactuca*, the Lettuce Green Laver, it is gathered and eaten in the same way as the Purple Laver. It is also known under the name of Oyster Green. This plant is popularly supposed to be good for scrofulous habits. It is sometimes applied to the forehead to relieve headache in fevers, and also to procure sleep. *U. bullosa*, the Blistered Green Laver, is the fresh-water species. It has an obovate, saccate frond, which is gelatinous, and at length becomes irregularly expanded, waved, and bullate. It is a very frequent plant in stagnant pools and ditches of fresh water, often covering the whole surface of the water, and giving it the appearance of being in a state of fermentation. Microscopically examined, this is an object of no common beauty; it seems as if composed of little green balls, about as big as the blood-cells in the human blood, having no sort of adhesion with each other, but holding together by a transparent thin jelly. It is by these little green balls, or by the matter they contain, that the *Ulva* is propagated. The common Laver of the shops very nearly resembles it, but is a marine species. The terrestrial species of *Ulva* are found growing on walls, rocks, the roofs of thatched houses, and especially in places exposed to much moisture. *U. thermalis* grows in hot-springs at a temperature of 117° Fahrenheit.

The genus *Tetraspora*, named from the quaternary arrangement of its granules, inhabits fresh water, and includes two British species. The fronds are tubular or inflated, and gelatinous.

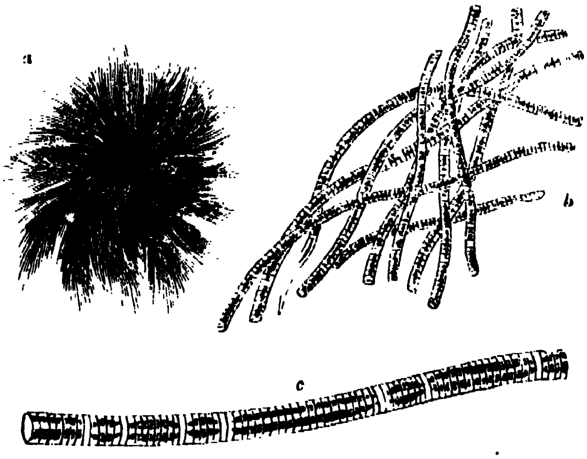
The *Enteromorpha*, Water-Gut, has a tubular, hollow, membranaceous frond, of a green colour and reticulated structure; the reproductive granules are arranged in threes or fours in the reticulations. Seven or eight species of this genus have been described as British. They are all inhabitants of the sea, or of pools and ditches of salt-water, with the exception of *E. intestinalis*, which is also found in fresh-water pools. All the species are long, varying from two or three inches to three feet in length, and when floating in the water very much resemble the intestines of an animal hence their name.

Bangia was named after Hoffman Bang, a Danish naturalist, who wrote a work on the *Confervæ*. It has a flat, capillary, membranaceous frond, of a green, reddish, or purple colour.

The order *Oscillatoriaceæ* is composed of plants which are green or brown in colour, with continuous tubular filaments, seldom branched, though often joined together so as to appear branched. The fructification consists of an internal mass divided by transverse septa, finally separating into roundish or lenticular sporidia. This tribe of plants, like the others, is found wherever there is water, and is more abundant in fresh water than in the sea. There are however many of them found in the sea, and also in mineral-waters. Many of the species, especially of *Oscillatoria*, are endowed with a power of moving so apparently spontaneous, that some naturalists have placed them among animals, as well as the more minute forms of plants belonging to the order *Algæ*. Captain Carmichael, who devoted much attention to this subject, has made the following observations, which were published from among his MSS. by Mr. Harvey: "I have been induced to bestow considerable attention on such of the species as fell under my notice, on account of the singular motion remarked in the filaments by various naturalists; and I do confess that the result is something like conviction that they belong rather to the animal than to the vegetable kingdom. This motion or oscillation has been attributed to various causes—to the rapidity of growth, to the action of the light, or to the agitation of the water in which the specimens were immersed for inspection; but none of these afford a satisfactory explanation. The last may be put to the proof by a very simple contrivance. Let a small portion of the stratum be placed in a watch-glass nearly filled with water, and covered with a circular film of talc, so that its edge may touch the glass; the water will be rendered as fixed as if it was a piece of ice. The glass may now be placed under the microscope, and the oscillation of the filaments viewed without any risk of disturbance from the agitation of the water. By following this course it will be speedily perceived that the motion in question is entirely independent of that cause. The action of light as a cause of motion cannot be disproved, because we cannot view our specimens in the dark; but indirectly there is nothing easier. If a watch-glass charged as above be laid aside for a night, it will be found that by next morning not only a considerable radiation has taken place, but that multitudes of the filaments have entirely escaped from the stratum; both indicating motion independent of light. Rapidity of growth will show itself in a prolongation of the filaments, but will not account for this oscillation to the right and left, and still less for their travelling in the course of a few hours to the distance of ten times their own length from the stratum. This last is a kind of motion unexampled, I believe, in the vegetable kingdom. There is another point in the natural history of the *Oscillatorieæ*, which favours the opinion that they are animalcules. It is the extremely limited term of their existence. The community, if I may so call it, lives for several months; but the individuals die off, and are succeeded by others with a rapidity to which there is no parallel among genuine plants. If a small portion of stratum, say one-fourth of an inch in diameter, be left for three or four days in a watch-glass filled with water, the whole area of the glass will be found covered with a thin transparent pellicle or incipient stratum, derived from the filaments that had successively radiated and died in the course of that short period."

There are several genera in the order *Oscillatoriaceæ*:—*Stigonema* has cylindrical, cartilaginous, branched, inarticulate filaments, including granules ranged in transverse dotted rings. *Scytonema* has branched, flaccid, tough, continuous, tubular filaments, with brown or olive-coloured endochrome, which is transversely striated, and at length separates at the striæ into lenticular sporidia. *Calothrix* has erect tufted or fasciculate filaments destitute of a mucous layer, fixed at the base, somewhat rigid, without oscillation. The tube is continuous, and the endochrome is at length dissolved into lenticular sporidia. Many of the species of *Calothrix* are parasitical on other plants. It is to this genus that the *Conferva nivea* of Dillwyn belongs. It is the *Calothrix nivea* of Agardh. This plant is remarkable for its habitat in springs impregnated with sulphuretted hydrogen. It was first found in the sulphur-springs of Croft in Yorkshire, by Dr. Willan, and has since been found by other observers. Dr. Daubeny found it in many of the sulphur-springs of the Continent, and Dr. Lankester collected specimens at Moffat, Harrowgate, Askern, and other places where there were springs impregnated with sulphuretted hydrogen. The decomposition of this plant, probably mixed with the remains of other organic beings inhabiting the springs, has led to the supposition that the springs in which it was found contained a pseudo-organic matter which has been called by the names of Baregine, zoogene, and glairine. This was the opinion of the late Professor Anglada; but Dr. Lankester, having been able to form glairine by the decomposition of the filaments of *Calothrix nivea*, renders it probable that there are no compounds in mineral-waters, except the salts, which have not been derived from plants or animalcules inhabiting the waters. ('Annals of Nat. Hist.,' 1841; 'Notice of Plants and Animals found in Sulphureous Waters,' by E. Lankester, M.D.) The genus *Lyngbya* has free, flexible, elongated, continuous, decumbent filaments, destitute of a mucous layer; the endochrome densely annulated, and separating at the annuli into lenticular sporidia. This genus was named after H. C. Lyngbye, a Danish botanist, and author of a work on the *Algæ* of Denmark. Some of the species are very common. The *L. muralis* is found almost on every damp wall or walk, forming an intensely green stratum of indefinite extent, which is very conspicuous after a shower of rain. Other species are parasitic upon some of the *Fuci* and are found in the sea.

The genus *Oscillatoria* has rigid, elastic, oscillating, simple, continuous filaments, which are invested by a common mucous matrix. The species are very numerous, but many of them are very difficult to distinguish. They are not all found immersed in water, but always occupy damp places. The *O. tenuissima* is an inhabitant of the warm springs of Bath, occupying broad velvet-like patches of a dark green colour. Its singular appearance, Sir J. E. Smith observes, "arises from the filaments being collected together into little ascending tufts, apparently rooted in the muddy deposit of the water. Each tuft proves, on examination, to consist of simple, uniform, even filaments, crowded together, and quite pellucid and equally destitute of joints and branches; their diameter is not more than an 8-1000th or 10-1000th part of an inch."



Oscillatoria distorta. *a*, natural size; *b*, *c*, magnified.

The order *Nostocaceæ* consists of plants with elliptical or globose cells connected in gelatinous moniliform strings. The filaments are separate, or several are united together in a gelatinous frond. The cells composing the filaments are of two kinds; first, a set of a bright green colour, which constitute the greater part of the filaments, and secondly, solitary cells of different form and size to the rest, destitute of colour, and covered with cilia. They occur at intervals in all the filaments, and are called 'connecting cells,' or 'heterocysts.' They probably represent the antheridia in the higher plants. The

Nostocaceæ are chiefly found in fresh-water streams and damp ditches.

The *Palmellaceæ* are amongst the lowest forms of the *Algæ*. They consist of globose or elliptical cells, which are more or less distinct, and are collected together by means of a string-layer into a frond. The genus *Protococcus* has only one species, the *P. nivalis*. This little plant has gained a large share of attention on account of its being supposed at one time to be the cause of red snow. Now however the animal kingdom has put in a claim for a share in the production of this phenomenon. [Snow, Red.] Most of the species of *Hæmatoccus* are of a red colour, and give an appearance like that of blood to the rocks on which they grow. These appearances have often been regarded with a superstitious eye, and looked upon as warnings or omens from Heaven. One of the species of *Palmella*, the *P. cruenta*, has a dark blood-red colour, and on that account has been called 'gory dew.' It occurs on white-washed walls, especially in damp cellars; and in such situations has sometimes given occasion for alarm, on account of its having the appearance of stains of blood. The other species of *Palmella* have various colours, as yellow, green, and black. They are found in fresh water streams and on rocks on the sea-shore.

(Harvey, *British Marine Algæ;* Hooker, *British Flora;* Agardh, *Species Algarum;* Greville, *Algæ Britannicæ;* Lindley, *Vegetable Kingdom;* Hassall, *Fresh-Water Algæ;* Burnett, *Outlines of Botany.*)

ALGÆ, FOSSIL. The remains of sea-weeds in a fossil state are less common than their probable abundance in the ancient ocean and the generally marine origin of the strata might have led to suppose. This arises perhaps from the cellular texture and destructible nature of the marine plants. Traces however of several genera occur in Silurian, Carboniferous, Liassic, Oolitic, Cretaceous, and later deposits.

ALGAROBA BEAN. [Ceratonia.]

ALHAGI (from the Arabic *Aghul* or *Algul*), a genus of plants belonging to the natural order *Leguminosæ*. The species are undershrubs or herbs with simple leaves and minute stipules. The flowers are red, and disposed in racemes along the peduncles.

A. Maurorum is a native of the deserts of Egypt, Syria, Mesopotamia, and other countries of the East. This plant yields a species of manna which is called Trungibin or Terengabin. It is chiefly gathered in the neighbourhood of Tauris where the plant grows abundantly. The manna is a natural exudation from the leaves and branches of the plant, and is most abundant during hot weather. In Arabia it is supposed that the manna falls from heaven on the plant. It first appears in the form of a small drop as of honey, which goes on increasing in size till it is about as large as a coriander seed. The manna yielded by this plant does not appear to be imported into this country. It is principally made use of at the present day in Persia, and is known by the name of Persian Manna. It is employed as food for cattle. Two other species, *A. Camelorum* and *A. Nipaulensis*, are described by botanists, and cultivated in the greenhouses of this country. They also yield manna.

ALISMA. [Alismaceæ.]

ALISMA'CEÆ, a natural order of plants belonging to the class *Endogens*. It is known from all the other orders of the same division by its genera having the sepals and petals perfectly distinguishable from each other both in colour and situation, and by their carpels being extremely numerous. In many points they approach very nearly to the Crowfoot Tribe (*Ranunculaceæ*), from which the structure of their embryo and their endogenous mode of growth distinguish them.

All the species are aquatic plants, with rather broad-ribbed leaves and white flowers. They appear to be destitute of any active properties, except a slight degree of acridity, which however does not prevent the rhizoma of some of them from being eaten in China.

The order receives its name from the genus *Alisma*, one species of which, *Alisma Plantago*, a common wild plant of Great Britain, in wet ditches and by river sides, has had the unfounded reputation of being a cure for hydrophobia. Its powdered root is given in doses of from half a drachm to a drachm, either infused in wine or mixed with syrup.

Great Water Plantain (*Alisma Plantago*).

ALKANET. [Anchusa.]

ALLAGITE, in Mineralogy, is a variety of the tri-silicate of Manganese.

ALLALITE, in Mineralogy, a variety of *Diopside* or *Pyroxene*. [Pyroxene.]

ALLAMANDA, a genus of plants belonging to the natural order *Apocynaceæ*. It was named after Frederick Allamand, a surgeon who travelled in Guiana, in 1769, and afterwards in Russia. He was a correspondent of Linnæus.

The species of this genus are shrubs yielding a milky juice, with verticillate leaves, and many-flowered peduncles of large yellow flowers. They are worthy of cultivation on account of the beauty of their flowers and foliage. They are all natives of South America, and when cultivated require a strong moist heat to make them flower freely.

An infusion of the leaves of *A. cathartica* is said to act as a powerful purgative, and an overdose to produce poisonous effects.

ALLANITE, in Mineralogy, a synonyme of *Orthite*, which is one of the silicates of cerium mixed with other substances. [Orthite.]

ALLIGATOR, a name originally given by the British Colonists of the Southern States of the North American Union, to a large species of reptile closely resembling the Crocodile of Egypt, but which modern researches have shown to possess characters generically differing from those of that animal. The word is supposed to be a corruption of an old Indian name. According to its modern acceptation among zoologists, the name is no longer confined to the species most commonly found in Carolina, Louisiana, and the other Southern States of the Union; but it is applied generically to all the other American species which agree with it in its most prominent and influential characters, and which have been called Caymans, Jacarés, &c., by the Spaniards, Portuguese, and Indians of South America. The characters which are proper to the Alligators, and by which they are distinguished from the Crocodiles of the Old World, are by no means of such importance with respect to the influence they may be reasonably supposed to have upon the habits and economy of these animals as to warrant the formation of these reptiles into a distinct and separate genus: their manners and habits are precisely those of the true crocodiles, and if they differ in certain minor details of structure, this difference should be considered not as a generic character, but as purely specific.

M. Cuvier thus distinguishes the Alligators from the true Crocodiles: "The alligators have the head less oblong than the crocodiles; its length is to its breadth, measured at the articulation of the jaws, as three to two; the teeth are unequal in length and size; there are at least 19, sometimes even as many as 22, on each side in the lower jaw, and 19 or 20 in the upper. The front teeth of the under jaw pierce through the upper at a certain age, and the fourth from the front, which are the longest of all, enter into corresponding holes of the upper jaw, in which they are concealed when the mouth is closed. The hind legs and feet are round and neither fringed nor pectinated on the sides; the toes are not completely webbed, the connecting membrane only extending to their middle; and finally, the post-orbital holes of the cranium, so conspicuous in the true crocodiles, are very minute in the alligators, or even entirely wanting." The Crocodiles, properly so called, on the contrary, have the head at least twice as long as it is broad; 15 teeth on each side of the lower jaw, and 19 on each side of the upper. The incisor or front teeth, as in the alligators, pierce through the upper jaw, at a certain age, but the fourth or largest of the lower jaw, instead of being received into a corresponding hole of the upper, passes into a notch on each side of it; and finally, the hind feet are bordered by a denticulated fringe, and the toes are completely united by a swimming membrane.

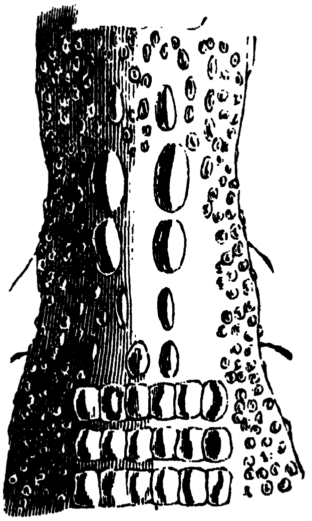
The characters here reported as peculiar to the alligators and crocodiles respectively, are evidently not of sufficient importance to exert any very sensible influence upon their general economy. Of the characters and organic modifications which they possess in common, the principal is the long taper tail, strongly compressed on the sides, and surmounted towards its origin with a double series of keel-shaped plates, forming two upright denticulated crests, which, gradually converging towards the middle of the tail, there unite and form a single row to the extremity. Its great size, and laterally-compressed form, render the tail an organ of the utmost importance to the crocodiles and alligators: it is true that its weight materially impedes their motions on dry land, but it is a most powerful instrument of progression in the water, and influences the aquatic habits of these animals much more than their webbed feet. The latter character, indeed, is comparatively of little weight: the hind feet are only used to assist the progression in slow and gentle motion, but in all sudden and violent actions the tail alone is the active instrument; and even when the animal is surprised on land, as we are assured by Adanson, it becomes a powerful weapon of offence. The compression of the tail is not peculiar among reptiles to crocodiles, though so powerfully influencing their habits; but the second character which is common to the entire genus, namely, the palmated or semi-palmated hind feet, is exhibited by no other genus of reptiles, though all are more or less addicted to an aquatic life. This fact sufficiently demonstrates the small influence which the palmated form of the extremities exerts upon the economy of these animals in general. Still this character is by no means devoid of importance, though in proportion to its utility in aquatic progression it renders the terrestrial motions of the animals extremely slow and awkward; and this effect is still further increased by the length and weight of the tail at one end, and by the anatomical structure of the neck at the other. Each of the cervical vertebræ has on either side a species of false rib, and their meeting at the extremities along the whole neck completely hinders the animal from turning its head to either side, and renders all its movements stiff and constrained. Neither is the pace of the crocodiles on land so swift as to make them objects of fear to ordinary quadrupeds; a man can easily outstrip them, and so sensible are these animals of their own inferiority in this respect, that they immediately retreat to their more congenial element upon the most distant appearance of the human species.

The other general characters of the crocodiles and alligators consist in their long flat heads, thick neck and bodies, protected by regular transverse rows of square bony plates or shields, elevated in the centre into keel-shaped ridges, and disposed, on the back of the neck, into groups of different forms and numbers, according to the species. The mouth is extremely large, extending considerably behind the eyes, and furnished in each jaw with a single row of conical teeth, all of different sizes, and standing apart from one another: these are hollow within, and never vary in number, but are successively pushed out and replaced by others of larger dimensions, as the animals increase in age and size. The tongue is short and fleshy, and attaches to the under jaw throughout its whole extent. It is consequently incapable of protrusion, and from its small size and backward position seldom seen even when the animal opens its mouth, which circumstance occasioned the belief so universally prevalent among the ancients, that the crocodile was altogether deprived of this organ. The eyes are placed on the upper surface of the skull, are much approximated towards one another, and provided each with three distinct lids: the nostrils form a long narrow canal, placed at the extremity of the muzzle; the ears are closed externally by two fleshy valves, and beneath the throat are two small pouches or glands, which open externally and contain a musky substance. Finally, the feet are provided with five toes before, long and separate, and four behind, more or less perfectly united by membranes: of these, the three interior alone on each foot are provided with claws, so that the two outer toes on the fore-feet, and one on the hind, are constantly clawless.

Habits of the Alligator.—It is reported by Pliny, that the Egyptian crocodile retires to a secret cave or hiding-place, on the approach of winter, and spends three or four of the coldest months in a state of lethargy, and without taking any food: this phenomenon, usually called hybernation, is almost universal among reptiles and serpents, at least in temperate and high latitudes, and has been repeatedly observed with regard to the alligators. On the approach of the cold season these animals bury themselves in the mud at the bottom of some stagnant pond, where they remain concealed and inactive till the return of spring. Travellers assure us that they are never to be found in running streams, but that they frequent in preference some stagnant pond or the creeks of large rivers. Here they may be seen in almost countless multitudes, for they are extremely numerous in the remote unfrequented parts of South America, protruding their large flat heads through the leaves of the *Nymphæa*, *Pontederia*, and other aquatic plants which cover the surface of the water, and watching for prey; or sometimes basking in the sun or sleeping on the banks. They never come on shore, except during the hottest part of the day, and always retire to the water on the approach of night, during which time they are extremely active in search of prey. Their food consists principally of fish, and it is conjectured by some physiologists, that the musky fluid, secreted by the glands under the throat, acts as a kind of bait to attract their prey. The alligators are seldom known to attack the human species, unless in defence of their eggs or young; the females of these reptiles are reported to exhibit a much stronger degree of maternal affection for their offspring than usually belongs to their class. They generally lay from fifty to sixty eggs in one place, of about the same size as those of a goose, which they cover up with sand, and leave to be hatched by the heat of the sun; never however removing to any great distance. When the young ones come forth, they are about five or six inches long, and are immediately conducted to the water by the female alligator. Seldom more than half the entire brood live to reach the water. Many are destroyed while in the egg. The vultures waylay and watch the female alligator when she goes ashore to deposit her eggs, which they scratch up and devour as soon as she retires. Numbers of them also fall a prey to the grown males of their own species, and to various descriptions of ravenous fishes which greedily devour them. The Indians eat the flesh of the alligators, notwithstanding its strong musky flavour; and even Europeans, who have succeeded in overcoming their prejudices so far as to partake of it, report it to be both delicate and savoury. A single peculiarity of habit seems to distinguish the alligators from the real crocodiles: the former never leave the fresh water, whilst the latter are known to frequent the mouths of large rivers, and even to pass between different islands, at considerable distances from one another; and so perfectly is this characteristic of the two sub-genera, that the crocodile of the West India Islands differs from all the other American species, and exhibits only those modifications which properly belong to those of the Old World.

It was only at the commencement of the present century that the different species of alligators were properly distinguished from one another, or even that they were suspected to be specifically different from the crocodile of the Nile. This distinction is entirely due to the late Baron Cuvier, and since the publication of the first edition of his work 'Sur les Ossemens Fossiles' little further addition has been made to the subject. He enumerates three species, which he has definitely characterised; and describes a fourth, which he suspects to be distinct, but of which he did not at that time possess a sufficient number of specimens to enable him to determine the question.

1. The Alligator (*Crocodilus Lucius*, Cuvier) properly so called, which inhabits the fresh waters of the Carolinas, the Mississippi, and other southern parts of the United States, and of whose fierceness and voracity Bartram has related such extraordinary accounts. It grows, according to Catesby, to the length of 14 or 15 feet, the head being one-seventh of the entire length, and half as broad at the articulation of the jaws as it is long. It appears to be more fierce and voracious than the South American species, often attacks men and quadrupeds whilst bathing or crossing the rivers, and is even said to prefer the flesh of the negro to all other food; probably because the slave is more exposed to its attacks than his master. The alligators prey chiefly by night; they assemble in vast numbers, besetting the mouth of some retired creek into which they have previously driven the fish, and bellowing so loud that they may be heard at the distance of a mile. To catch the fish they dive under the shoal, and having secured one, rise to the surface, toss it into the air to get rid of the water which they necessarily take in along with it, and catch it again in its descent. When however they succeed in capturing a land animal, which is too large to be swallowed at a single mouthful, they conceal the body beneath the bank till it begins to putrefy, for as their teeth are not formed for cutting or masticating, they are unable to tear the tough flesh in its fresh state; it is then dragged on shore and devoured at leisure. When about to lay, the female digs a deep hole in the sand, and deposits her eggs in layers, separated from one another by intervening strata of leaves and dry grass. It would appear that she lays only one batch of eggs during the same season, though in the hotter parts of South America, if the report of Laborde is to be depended on, the Cayman, or alligator of Surinam and Cayenne, lays at two or even three different periods of the year; but as each batch is said to consist of only twenty or twenty-five eggs, it is probable that the whole does not exceed the number usually assigned to the common alligator. The female of this latter species, it is said, never loses sight of her nest till the young are hatched, and for months afterwards affords them the most unremitting care and protection.



Cervical Plates of Alligator.

This species is frequently found up the Mississippi higher than the Red River. In general, the alligator of North America buries himself under the mud, at the bottom of the swamps and marshes which he inhabits, as soon as the cold weather fairly sets in, and continues in a lethargic sleep till the return of spring. During the very severe frosts, sensation is so completely suspended, that the body of the animal may be cut into slices without dispelling his lethargy; yet it is never actually frozen, and the partial return of a few hours' bright sunshine is at all times sufficient to restore suspended animation. It is particularly in the rivers, lagoons, and swamps of Florida, Georgia, South Carolina, and Louisiana, that the alligator reaches his greatest dimensions. Bartram found immense numbers of alligators and fish in a mineral spring near the Musquito River, in Florida, though the water, at its exit from the earth, was nearly at the boiling point, and strongly impregnated with copper and vitriol.

Besides the characters common to all the American crocodiles, this species exhibits the following modifications which distinguish it from others:—The snout is flattened on its upper surface, and slightly turned upwards at the extremity; the sides of it are nearly parallel, and the nose forms a regular parabolic curve. It was this similarity to the head of a pike that gave to the present species the name of *Crocodilus Lucius*, or the Pike-Headed Crocodile. The internal rim of the orbits is large and protuberant, but without being united by a transverse crest as in the *Crocodilus sclerops*, or Spectacled Alligator. The external openings of the nostrils are separated by a long knob; the skull has two shallow, oblique, oval pits, in the bottom of which are two small holes. On the back of the neck are four principal plates, elevated in the centre into keel-shaped ridges; and in front and rear of these respectively, two smaller ones of similar form. The back exhibits 18 transverse rows of similar plates, the first with only two crests or ridges, then two with four, afterwards three with six, then six with eight, then again two with six, and finally, the last four rows with four crests each. The ridges or crests on the body are of nearly equal size;

those of the tail are much larger, and amount to 38 in all, 19 before the union of the two lateral series, and as many afterwards. The colour is a deep greenish-brown above, and light-yellow on the under surface of the body; the sides regularly marked with alternate bands of both these colours.

2. The Cayman (*Crocodilus palpebrosus*, Cuvier) is at once distinguished from all other species by the bony structure of the eyebrows, which form large knobs of the size of a man's fist; and by the small extent of the membrane connecting the toes of the hind feet, which in prepared specimens can scarcely be recognised. The skull of this species shows not the slightest trace of those post-orbital perforations, which are so conspicuous in the crocodile of the Nile, and more or less developed in all the other species.

This is the common species of Surinam and Guiana: it is there called Cayman, a word most probably of native origin, whilst the following species, which is likewise found in the same countries, though its more appropriate locality would appear to be Brazil and Buenos Ayres, is distinguished by the name of Crocodile. The Cayman does not attain so large a size as the other species, nor will he venture to attack a man on dry land, or even in the water, so long as he keeps his legs and arms in motion. The female deposits her eggs in a single layer, and after covering them slightly with sand, abandons them to the vivifying influence of the tropical sun, without taking any further charge either of them or of the young progeny.

3. The *Crocodilus trigonatus* of Schneider is a species of crocodile, exhibiting all the peculiar characters which properly distinguish the alligators of America, and yet suspected to be of African origin. It is even so closely allied in form and general characters to the Cayman,

that Baron Cuvier has described it as a mere variety of that species. The principal distinction between this and the foregoing species consists in a ridge which rises in front of the orbits, and runs towards the snout, and a small notch in the posterior border of the skull; the second row of cervical plates is larger than the others, and towards its middle are two or three small scales, with irregularly disposed crests; the large ridges assume the form of scalene triangles, which gives the whole animal a rough and bristly appearance; there are 16 transverse bands on the back, the number of plates appearing to vary according to the species, and from 19 to 28 on the tail, 9 or 10 before the junction of the lateral ridges, and from 10 to 17 afterwards. Nothing whatever is known of the manners or habits of this species or variety.

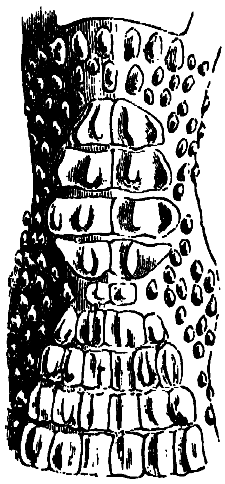
Cervical Plates of *C. Trigonatus.*

4. The Jacaré (*Crocodilus sclerops*, Schneider) appears to be spread over the whole of tropical America, but is more especially numerous in Brazil, where it attains a very large size, and is found in all the rivers and lakes. Its head is more attenuated than in the alligator of North America; the sides converging towards the snout, so as to form very nearly an isosceles triangle; the surface of the bones of the skull has a rough scabrous appearance, as if arising from disease; the orbits of the eyes are surrounded by large prominent rims of bone, and these are connected together by an intermediate ridge, giving the whole very much the appearance of a pair of spectacles; finally, the skull is pierced by two very small holes behind the orbits. The cervical plates are remarkably large; they are arranged in four transverse bands, of which the first two contain four each, and each of the others two. The transverse bands of the back vary according to age, and it would even seem according to the individual; they most commonly consist of two rows, with two plates each, four with six, five with eight, two with six, and four with four. The colour of the animal is greenish-brown above, marbled irregularly with different shades of green, and pale greenish-yellow below. This species grows to the size of from 14 to 18 feet in length; the whole length is from eight to eight and a half times that of the head.



Cervical Plates of the Jacaré (*C. sclerops.*)

The Jacarés, according to Azara, are never known to attack men, or even dogs, in passing the rivers, unless it should happen to be near the place where they have deposited their eggs; and even then, they are never known to prey upon the body, contenting themselves with the fish and water-fowl which they find so plentiful in their own element. During the night they are exceedingly active, and always keep in the water, showing only their heads above the surface, but towards the middle of the day they come ashore to enjoy the heat of the sun; they then sleep profoundly, but always retreat to the water on being disturbed. The eggs are about the size of those of a goose; they are white, and much sought after by the free Indians, who also eat the flesh of the Jacaré itself, though it has a strong musky smell, and scarcely any juice. The female deposits her eggs in the sand in a single layer, and covers them with straw or leaves; few of them, however, escape the quick eye of the vulture, and even many of the young fall a prey to the full-grown males, which at the period of their first appearance, in the hottest part of summer, are particularly fierce and ravenous, the marshes which they inhabit being then dried up, and their food difficult to obtain. This species appears to have pretty nearly the same range towards the south of the continent, that the alligator, or pike-headed crocodile, has to the north. According to Azara, it is never found beyond 32° of south latitude. Many interesting facts regarding the habits of this species are recorded in the narratives of Prince Maximilian, Spix and Martius, and other Brazilian travellers.

ALLIUM, a very extensive genus of bulbous Monocotyledonous plants, belonging to the natural order *Liliaceæ*. The species are all remarkable for having, in a greater or less degree, the odour of garlic, and for the agreeable stimulating effects that accompany it. For this reason some of them have been objects of cultivation from the highest antiquity.

As a genus, *Allium* is known among other *Liliaceæ*, by the flowers growing in round heads or umbels, by the perianth being deeply divided into six spreading lobes, and by having a capsule with three angles, three valves, and three cells, sometimes so deeply lobed, as to have the appearance of six cells. The number of species is very considerable; they are almost exclusively natives of the northern hemisphere, and are principally found wild in the meadows and groves of Europe, in the north of Asia, and the north of Egypt; a small proportion only inhabiting corresponding latitudes in North America. Many of them are handsome flowering plants, but as they are more important on account of their useful properties, we shall confine ourselves to some account of the kinds commonly cultivated in the kitchen-garden.

Allium Cepa, the Common Onion, is too well known to require description. It is not certain of what country it is a native, but it has from time immemorial been cultivated in Egypt. Its varieties are not very numerous, considering that it is almost exclusively increased by seed: the most remarkable are the Blood-Red Onion, which is the most pungent; the Strasburg Onion, which is the hardiest; the Silver-Skinned Onion, which is the smallest, and the most fitted for pickling; and the onions of Portugal and Tripoli, which are the largest and the most delicate. In this country the bulbs do not generally arrive at the large size of those imported from Portugal and Spain; but skilful gardeners have nevertheless succeeded in procuring them fully as fine. Their method has been to take the small onions of a late-sown crop of the previous year, and to plant them in rows in the beginning of April, laying them on the surface of the soil, each surrounded with about a handful of decayed and nearly dry manure. All the time that is usually lost in seed-sowing is thus avoided, and the moment the bulbs push forth new roots, they find themselves in the midst of an abundant store of food, which continues to supply them with nutrition during the whole of the growing season. As they advance in size, the soil round the bulbs is frequently disturbed by the hoe, for the sake of exposing as much as possible the carbonaceous matter of the manure to the action of the atmosphere. This process is only discontinued when the leaves begin to turn yellow; the bulbs are then allowed to ripen as usual.

Allium schœnoprasum, the Chive, is a little tufted plant, with slender, cylindrical, taper-pointed, dark-green leaves; its flowers are arranged in a small compact round head, and are of a purplish or pale violet colour; the bulbs are small, long, and white, and grow in dense, matted tufts. It is a native of the mountainous regions of Europe, from Lapland to Italy; and is found here and there in Great Britain. It is more employed by the French for their cookery than in this country.

Allium fistulosum, the Welsh Onion, is a native of Siberia, and is supposed to have gained its English name from having been imported originally from Germany, with the name Wälsch, or foreign, attached to it. It is a perennial, and cultivated chiefly for the purpose of being sold in the markets when very young, at which time its flavour is delicate; its hardiness enables it when young to brave our spring cold better than the common onion.

Allium Ascalonicum, the Shallot, a native of Asia Minor, is in many respects similar to the chive, from which it is known by its larger leaves, its smaller and more deeply-coloured flowers, and by its stamens having alternately three points on the filaments. It moreover produces bulbs of sufficient size to be fit for use, and accordingly, while the leaves only are employed in the chive, the bulbs are the parts sought for in the shallot. These multiply abundantly, so that every year, when the crop is taken up, there is plenty of small bulbs which can be reserved for planting the succeeding season, while the fine fully-formed ones are selected for the kitchen. To obtain the bulbs in the greatest perfection, they should not be buried in the earth, as is the common practice, but merely placed on the surface of the soil.

Allium sativum, Garlic, has been found wild in Sicily, and some parts of Provence. Its stem is simple, erect, and furnished with flat, narrow, pointed leaves; the flower-heads have usually a number of little bulbs lying among the flowers, which are white or pinkish; the bulbs are remarkable for the development of the greater part of the axillary buds of their scales; these buds grow rapidly, and acquire a bulbous state, and form what are called the cloves of the garlic, which are the parts employed in cooking.

Allium ophioscorodon, Rocambole, or Spanish Shallot, is very slightly different from garlic, being chiefly distinguished by its larger size in all the parts, and by the upper part of its stem being generally twisted spirally just before flowering. It is a native of most parts of the south of Europe.

Allium porrum, the Leek, has, like many other cultivated plants, disappeared in a wild state, so that its origin is unknown. It is a broad-leaved succulent species, not capable of forming a bulb, because the leaves do not perish till the plant itself dies away, but producing instead a cylindrical body composed of the tender, colourless bases of the leaves, which are rolled round each other in a compact manner. As the excellence of the leek depends entirely upon the large size of this part, the attention of the cultivator is exclusively directed to that before all other considerations. It has been found that no method is so successful as to sow the seed early in a light and well-manured soil, and then, when the young leeks have arrived at the thickness of the little finger, or even sooner, to drop them into holes about 2½ or 3 inches wide, and 6 inches deep, in the bottom of which some very fine manure has been deposited.

ALLOCHROITE, in Mineralogy, a variety of Garnet, characterised with other minerals by possessing free silica. [GARNET.]

ALLOMORPHITE, in Mineralogy, a variety of Heavy Spar, which is a sulphate of barytes.

ALLOPHANE, a mineral belonging to the group of Clays which contain a large proportion of water. It occurs reniform, botryoidal, globular, and massive. No cleavage. Colour blue, green, brown. Fracture conchoidal. Hardness 3·0 nearly. Lustre vitreous, transparent, translucent. Specific gravity 1·852 to 1·859. It is found at Saalfeld in Thuringia, at Schneeberg in Saxony, and other places. Its analysis, by Stromeyer, gives:—Silica, 21·922; alumina, 32·202; lime, 0·730; sulphate of lime, 0·517; carbonate of copper, 3·058; hydrate of iron, 0·270; water, 41·301.

ALLSPICE. [EUGENIA.]

ALLUVIUM, a name given to those accumulations of sand, earth, and loose stones or gravel brought down by rivers, which, when spread out to any extent, form what is called Alluvial Land. The word is derived from the Latin verb *alluere*, signifying 'to wash upon,' as the sea does upon the coasts, or a river upon its banks, and is chiefly used as a term in geology. Many geologists restrict the expression to such water-worn materials as have been deposited either recently or within the historical era, and which do not include the remains of extinct species of organised bodies: but as there are similar accumulations of transported materials, belonging to almost every geological period in the history of the earth, it is an unwarranted restriction of the term to confine its use to the recent period only. There is, no doubt, this distinction between modern alluvia and those of ancient periods, that in the latter, besides the remains of extinct species of animals and plants, there is more frequently a consolidation into stone. To these last accumulations of water-worn materials some geologists apply the name *Diluvium*, which is objectionable, because it expresses, not a particular state of the materials, but a theory of their formation; that is, that they were produced by a deluge,—some indeed go so far as to assert that they were accumulations from the Mosaic flood. The word Alluvium might be conveniently used as a general term, and we might say Ancient Alluvium and Modern Alluvium, as the French geologists say *Terrains de Transport—Anciens* and *Modernes*. We might go farther, and say Secondary and Tertiary Alluvium, and the Alluvia of particular groups of strata.

In treating of this subject we have to consider three operations: 1, The disintegration and decay of the superior crust of the earth by the action of meteoric agents, of tides, currents, and streams of running water; 2, The transportation of the loosened materials by streams and currents; and 3, The deposition of the matter at the bottom of rivers, lakes, estuaries, and the ocean. The surface of the earth is subject to unceasing changes from the operation of three great classes of agents, namely, the meteoric, the aqueous, and the igneous. Under the first of these classes are comprehended, the air of the atmosphere, the vicissitudes of heat and cold, moisture and rain, light, electricity, and the wind: under the second class, running water of every kind on the surface of the land, the tides, waves, and currents of the sea as they strike against its shores: the third class comprehends volcanoes and earthquakes, which will be discussed under another head. It is the second class with which we have chiefly to do at present, and we shall only briefly touch upon the first as subservient to the subject with which we are occupied.

All rocks, and indeed almost all mineral substances, have a greater or less tendency to combine with the oxygen of the atmosphere, especially when under favourable circumstances of heat and moisture, and probably also of electricity and light: carbonic acid and water also are absorbed by rocks in considerable quantity; and the effect of these combinations, whether chemical or mechanical, is to loosen the cohesion between the particles of the stone, and induce a tendency to disintegration. This separation of the parts is very much accelerated by those sudden expansions and contractions which are occasioned by vicissitudes of temperature, and especially during frost, when the imbibed moisture is converted into ice. This slow and silent work of waste is unremittingly going on wherever rocks are exposed to the weather. No species of stone is exempt; and even granite, which in general is so little subject to change as to be proverbially a symbol of endurance, and is selected for our bridges and other great works of architecture, under particular circumstances of constitution and exposure, is remarkably disposed to disintegration. "The granite of some parts of Finland," says Mr. Strangways, "is so liable to decomposition, that a great boulder of it may often be seen with a hole cut in it large enough to admit a cart and horse; and the stone, though at a small distance it seems calculated to last for ages, is cut down and shaped away with the same ease, and much in the same manner, as a hay-rick." The same agents sometimes give more marked proofs of their destructive power, when lightning shivers a pinnacle of rock, or when a mass of water, enclosed in a cleft and converted into ice, rends, by its great expansive force, vasts blocks asunder. The effect of these several indefatigable agents, all working together, with gravity in their favour, is a system of universal decay and degradation, which may be traced over the whole surface of the land, from the mountain-top to the sea-shore. The wind, though it may sometimes detach particles, is chiefly instrumental in transporting to a distance matter already separated. Every drop of rain that falls, as soon as it touches the earth becomes an instrument of destruction, and the minute fragments which every shower washes away are hurried along the streams into a river, and are either deposited at a lower level, or are transported to the sea: thus, a solid body which once formed a part of a mountain-top among the Andes, after being swept along for thousands of miles through the bed of a river into the waters of the Atlantic, may, by ocean-currents, be deposited at the bottom of the Gulf of Mexico, while the fragment with which it was once united may be carried far into the depths of the Pacific.

To this assertion of the constant waste of the land, and the conclusions which are drawn from it, it has been objected, that we can hardly discover any change in the shapes and altitudes of mountains, that the forms of many lands have continued unaltered since the earliest records, and that even productions of human art exposed to the action of the weather for many centuries have undergone no perceptible decay. No doubt the process is slow, if compared with the progress of events in which the human race has had concern, but no one will deny that rivers are loaded during every flood with solid matter; and, as the matter so suspended can only be derived from the land, it necessarily follows that a continuance of the process must in time wear down the loftiest mountains, where the rocks are not protected by a covering of turf from the action of the destructive agents. Of the rapidity of this waste we have no means of judging, and any attempt to express our conjectures by figures would be little better than an idle occupation. It is almost within our own time that any accurate measurements of heights have been made: and as two estimates of the same mountain, made with all the accuracy of which our instruments are capable, often give a difference of several feet, we are not even now able to leave behind us data by which posterity may mark the progress of this species of geological change; for the removal of such a mass of matter as should diminish the height of a mountain by three or four feet, by ordinary agents, may require thousands of years for its accomplishment. If Mont Blanc, by our most accurate measurements, be now 15,744 feet above the level of the sea, and if the geologist, many centuries hence, by newly-discovered methods not liable to error, should find it only 15,740, it would be impossible for him to know whether the difference was to be set down to geological change, or to the imperfection of the instruments of his ancestors.

In geological speculations we must lay aside all considerations as to time: we have only to do with that element when our inquiries relate to man; and if we are to be guided by analogy in our reasonings, we must be satisfied that a space of time of vast duration must have been requisite to produce any great amount of geological change. We see even in many chemical processes, that long-continued action gives birth to substances which could not otherwise be obtained,—as, for example, crystals of felspar are formed if the heat be maintained for some weeks, but not otherwise; and long-continued action in the great laboratory of Nature has no doubt been an equally powerful instrument.

Although we can, in strictness, only say that certain geological events must have preceded others, we are not warranted in withholding any length of time for the accomplishment of the change, merely because we are unable to form a conception of an indefinite period: it would be as irrational as if we were to withhold our assent to some of the established truths in astronomy, merely because we are incapable of forming an idea of indefinite space. It has been eloquently said by Playfair, that "It affords no presumption against the reality of the progress of decay that, in respect of man, it is too slow to be immediately perceived. The utmost portion of it to which our experience can extend is evanescent in comparison with the whole, and must be regarded as the momentary increment of a vast progression, circumscribed by no other limits than the duration of the world. Time performs the office of integrating the infinitesimal parts of which this progression is made up; it collects into one sum, and produces from them an amount greater than any that can be assigned." But slow and silent as the work of these agents of destruction is, we have only to direct our view towards those parts of the earth where the machinery of Nature is to be found on its grandest scale, to be sensible of the prodigious effects which their unceasing operation must produce in the long lapse of ages.

The force of water, when directed against any obstacle in its course, is very considerable, even by its own weight alone, especially if it be flowing over a highly-inclined surface; but its destructive power is greatly augmented if it be loaded with sand and gravel. In floods, very considerable blocks are carried by the stream to great distances; for it must be remembered that these are much more easily moved in water than on land, in consequence of the law in hydrostatics, that a solid body fully immersed in water weighs so much less than it does in air by a sum equal to the weight of the mass of water which it displaces. If the water flows with a velocity of 3 inches per second, its force, when free from suspended matter, is sufficient to tear up fine clay; 6 inches per second, fine sand; 12 inches per second, fine gravel; and 3 feet per second, will tear up beds of loose stones of the size of an egg. The flood occasioned by the bursting of the barrier of a lake in the valley of Bagnes near Martigny, in the Vallais, moved at first with the tremendous velocity of 33 feet per second, afterwards diminished to 18, and 11; and at the end of its course, when the water reached the Lake of Geneva, it was still running at the rate of 6 feet per second. From the barrier to this point the fall is 4462 feet; the distance is 45 miles; and the mass of water passed over this large space in 5½ hours. It swept along houses, bridges, and trees; masses of rock equal in dimensions to houses, which it tore out of an ancient alluvial soil, were carried a quarter of a mile down the valley. A flood which happened in the north of Scotland in 1829 afforded numerous examples of the power of running water to transport large blocks of stone. In the river Nairn, a fragment of sandstone rock, 14 feet long, by 3 feet wide, and 1 foot thick, was carried above 200 yards down the river. The river Don forced a mass of 400 or 500 tons of stones, many of them 200 or 300 pounds weight, up an inclined plane, rising 6 feet in 8 or 10 yards, and left them in a rectangular heap, about 3 feet deep, on a flat ground. The small rivulet called the College, in Northumberland, swollen by a flood in August, 1827, carried several masses of stone, weighing from a half to three-quarters of a ton, two miles down its course; a large block, weighing nearly two tons, was transported to the distance of a quarter of a mile.

Thus it appears that the instruments of waste employed by Nature are far more powerful in their effects than is generally supposed. It is also evident that such powers, unremittingly exerted, must, after a long period, cause changes in the configuration of the earth's surface, and we shall now proceed to point out some of the effects which are produced by the working of this powerful machinery.

The cause of the formation of valleys is a subject of great controversy among geologists. Some ascribe their formation to extraordinary floods, waves, or deluges, which in their sudden passage scooped out the land; others, to the gradual effect of those natural agents of whose existence and power we have had experience. It may fairly be presumed that, when the continents were raised out of the sea, their surfaces did not present a uniform plain, but were broken by numerous ridges and inequalities, and that the ridges themselves were traversed by numerous fissures, one of the effects of the power by which they were raised. The first rains that fell, and the first springs which burst forth, would necessarily collect in the lowest levels, and thus the direction of the great trunk of a river would be determined; and it might also happen that other clefts—depressions at a higher level—would communicate with this main channel. But that every such great depression would have a direct communication with the sea, and that such a combination of subordinate valleys as compose a river-system could have been formed by the breaking up of the earth's crust, either by elevation or subsidence, can hardly, we think, be maintained by any one. A river-course, or system, may be not inaptly compared to a picture of a great tree, whose branches gradually diminish in size, but increase in number, as they recede from the stem. The great trunk of the river is divided into many branches, which spring from it at various distances from one another; and these again are subdivided into an infinity of smaller ramifications, each diminishing in size as it increases in distance from the main trunk—a regular communication being kept up between every point and the line of greatest depression; "forming together a system of valleys communicating with one another, and having such a nice adjustment of their declivities, that none of them join the principal valley either on too high or too low a level." Some idea may be formed of the extent to which the surface of the land has thus been furrowed by means of the subordinate streams that feed a great river, from what Riede says of the tributaries of the Isar, which, flowing from the Tyrolese Alps, and passing by Munich, joins the Danube some miles above Passau. This river is fed on its right bank by 433 streams, on its left by 800; the former joining the main bed by 59 channels, the latter by 44. But the Isar is only one of the 34 great branches of the Danube, and holds only a fourth rank among them; and even the Danube is a river of the third magnitude in the physical history of the earth.

We have direct proofs of the power of water to wear a channel in the hardest rocks in almost every country, and even in a remarkably short time. A stream of lava, poured out from Ætna in 1603, flowed across the bed of the Simeto, the largest river in Sicily, which flows along the base of the mountain and falls into the sea near Catania. The stream has now cut a passage through the hard rock, which is only a little less compact than basalt, to the depth of from 40 to 50 feet, and from 50 to several hundred feet wide.

The Nerbudda, a river of Hindustan, has worn a channel in a basaltic rock to the depth of 100 feet. Professor Sedgwick and Sir Roderick Murchison state, that in the enormous masses of horizontal coarse conglomerate, found in many of the valleys of the Eastern Alps, rivers have often scooped out gorges to the depth of 600 or 700 feet; and that in the valley of the Inn, near Innspruck, and in that of the Drave, between Klagenfurt and Marburg, there are splendid examples of these phenomena.

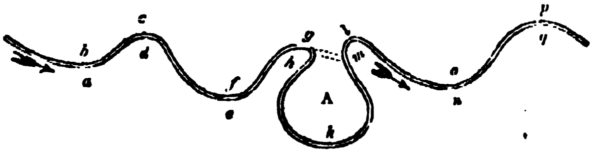
The rock over which the water of the Niagara is precipitated at its celebrated Falls is undergoing a daily waste; so that the cataract has receded nearly 50 yards in the last 40 years. The river below the Falls runs in a channel above 150 feet deep, and 160 yards wide, for a distance of 7 miles, where it emerges into a plain; and this channel has evidently been formed by the same operation as that which is now in progress. Sir Charles Lyell computes, from this and other data, that the Falls have been 30,000 years in wearing this channel. The waste is accelerated by the action of the water at the Falls on an under-bed of soft clay, which being washed away leaves the superincumbent limestone strata unsupported, when they fall down in huge masses. A similar effect is produced, even in mountains of considerable elevation, when the superficial water, or underground springs, obtain access to an inferior bed of soft materials, and gradually wash it away. This took place in 1806 at the Rossberg, near the Lake of Zug in Switzerland, a mountain more than 5000 feet above the level of the sea. The stony masses which were undermined were inclined at an angle of 45°; and thus slid down, covering the valley below with an enormous heap of blocks of stone and earth, and overwhelming several villages, in which above 800 persons perished.

There are many valleys and narrow defiles, which, on account of deep lakes that occur in them, the barriers by which they are inclosed, and the levels of the adjoining country, could not have been formed by the action of the waters now passing through them, however much we may suppose them to have been swollen by floods. In such cases, elevations and subsidences of the land, brought about by those subterranean agents which give rise to earthquakes, must be looked to as the most rational explanation. But there is perhaps not one of these which has not been subsequently modified in a considerable degree by the action of running water operating during a long period.

The wearing and transporting powers of rivers depend upon the volume of water, the quantity and size of the solid matter suspended, and the velocity with which it moves. A river generally runs with greatest rapidity in the higher parts of its course, where indeed it often consists of a succession of torrents and cataracts for many miles, but it has not yet acquired its full destructive force, because the mass of water is still comparatively small, nor has it yet become loaded with solid matter. In the lower part of its course, long before it joins the sea, it has usually reached a level country, and there its velocity becomes greatly retarded. The Senegal in Africa does not, according to Adanson, fall more than 2½ feet from Podor to the sea, a distance of 60 leagues. The destructive force is thus lessened by the diminished velocity, and by the consequent inability of the stream to drag its heavy artillery along with it. It is, therefore, in the middle part of its course that a river commits the greatest waste—after it has acquired a considerable volume, has become loaded with solid matter, and, from the inclination of the ground, still possesses power to wield its more mighty weapons of destruction.

The increase of the volume of water in rivers during the flood-seasons is often prodigious. The bed of the Mississippi, at Natchez, about 300 miles above New Orleans, measuring along the course of the river, scarcely exceeds a mile in breadth when the water is low; whereas in the flood-season the mass of water is nearly 30 miles wide. The Orinoco, at St.-Thomas's, 200 miles from its embouchure, is about 3½ miles wide in the dry season; but when flooded, its waters, according to Dupens, stretch out to the enormous breadth of 70 miles.

The loss of destructive power, by diminished velocity in the level country, is sometimes compensated, in a considerable degree, by the effects produced by the weight of the great volume of water impinging upon certain parts. This will be better understood by the annexed diagram.



When the river, in its oblique course at the entrance of the plain, strikes against the bank *a*, it speedily forms a steep or vertical cliff which turns off the water in its downward course into an opposite direction. The river now falls with its whole force against the point *c*, which, in its turn, becomes precipitous, and deflects the water towards the point *e*; and in this manner the process is repeated, at short intervals, producing a series of salient and re-entering angles.

The diagram represents a river after the process of erosion has considerably advanced; at first the course would be much less tortuous. If the country be composed of rock, both banks are usually steep; but if the ground consist of looser materials, the spaces between the precipitous parts of the banks—that is, between the salient angles consist of flat, fertile, alluvial land, with a gravelly bottom, the gradual creation of the stream. Sometimes the course of the river is so tortuous that two points, *h* and *m*, may be within a few hundred yards of each other, and yet, *following* the line of the stream, they may be some miles asunder. In this case, the narrow neck of land is acted upon doubly; for the force of the water is directed against it on each side. In time this isthmus is breached, and the river either flows entirely through the new channel, or, dividing, forms the land A into an island.

Such tortuous courses, when they are cut through solid rock, as in the case of the Moselle, whose banks are sometimes 600 feet high, are among the strongest proofs of the destructive power of running water, for no sudden deluge, however powerful, could have scooped out such a trough; and that a cleft of such a nature should be occasioned by any disruption of the earth's crust, is not less improbable. More sudden and therefore more striking instances of the waste of the land occur where a river flows through a lake, and by its wasting action causes a breaking-down of the barrier. We have already alluded to the bursting of a lake in the valley of Bagnes in Switzerland. That flood was produced by the melting of ice, which, falling in successive seasons from neighbouring glaciers, had formed so continuous a mass as to dam up the water of a stream which flowed in the bottom of the valley. If the barrier of a lake consist of strata of rock, supported by beds of clay or sand, and if, by any change of circumstances, the running water get access to this inferior bed, and gradually wash it away, the superincumbent rock, thus undermined, suddenly breaks down, and devastation and ruin overwhelm the country below.

The distance to which the detached fragments are carried depends upon the volume of water, and the nature of the ground over which it flows. The torrents from the south-western Alps, rushing over a steep uninterrupted slope, transport large blocks to the sea; but a river that runs through a long stretch of level country deposits the grosser matter in the upper part of its course, and carries to its mouth only that which is more easily held in suspension. The larger stones, after being detached from their parent rock, have therefore to undergo an intermediate process of abrasion, by being rubbed against each other in the bed of the stream before their particles are finally committed to the deep. If a river pass through a lake in its course, the solid matter will be deposited in that trough until it has filled it up; and if the lake be very large, even the lighter particles will have time to fall, and the water will flow out clear from the other extremity. The Lake of Geneva affords a remarkable instance of this process; for the Rhône, where it enters, is extremely turbid; but at Geneva, where it leaves the lake, it is beautifully transparent. At the upper end there is a tract of alluvial land nearly 8 miles in length, which has been gradually formed by the deposits from the river; and some measure of its progress is obtained by the change in the situation of the town of Port Vallais, which was once at the water's edge, but in the course of about 800 years has been left a mile and a half inland. Other torrents, on both sides of the lake, likewise pour in large quantities of solid matter; and thus, although from its great depth a long period must elapse if the present order of nature remains undisturbed, the Leman Lake will be converted into green meadows, and cattle will graze where there are now 160 fathoms of water. Nor is this an extravagant expectation, or more than has taken place elsewhere in past times. The vast fertile valley between the Vosges Mountains and those of the Black Forest, through which the Rhine flows for above 100 miles, between Strasburg and Worms, without falling more than two feet in a mile, is in great part covered with alluvium, and is filled to an unknown depth under the soil with sand and gravel similar to that now transported by the Rhône. There is every reason to believe that this valley was at one time the site of a lake far larger than that of Geneva, and probably quite as deep.

The Rhine, in the higher part of its course, is filling up the Lake of Constance, where a considerable tract of alluvial land has been formed; and, after issuing pure from the lower end, it appears from the observations of Hammer to have carried on the work of destruction so powerfully in the comparatively short distance between the Lake of Constance and the bottom of the falls at Schaffhausen, as to have supplied materials sufficient to fill up several lakes between Schaffhausen and Strasburg, besides the great lake below Strasburg already spoken of. There are numerous instances of this gradual filling up of lakes, especially in the courses of the greater rivers, as in the Danube between Ulm and Neuburg above Vienna, and most eminently so in the case of the St.-Lawrence. Simond states that the river Lint, in Switzerland, is perpetually filling up its old channel, and overflowing into a new one, in consequence of the mass of rubbish and stones brought down from the Glarus Mountains; and that the level of the Lake of Wallenstadt had been actually raised 10 feet in the previous 60 years by this accumulation. If the river does not meet with lakes in its course, and flows over a great extent of country having a slight degree of inclination, the transported matter very often so accumulates as to raise the bed of the stream itself. One of the most striking instances of this kind is afforded by the Po, the common receptacle of the waters of the numberless torrents which rush down on both sides of it, loaded with spoils from the Alps and Northern Apennines. The effect of this has been that the river has frequently shifted its course; and, to prevent the damage that ensues from such events, the inhabitants of Lombardy have protected their lands by embankments, which confine the river to its channel. This, however, is a work of incessant labour, and deceptive security, for the accumulation of matter in the bed goes on with unremitting constancy; and, to prevent the water from overflowing, the matter must be taken from the bottom and thrown upon the banks, sometimes as much as a foot in a season. The effect of this has been, that in the lower parts of its course the Po runs on the top of a high mound, which even overtops the houses in Ferrara.

In a mountainous country where the land rises rapidly from the shore, the rivers descending over a steep bed sweep all the contents into the sea. If the neighbouring sea be deep, and the tides be strong, an estuary or inlet is formed at the mouth of the river—that is, the sea forms a deep indentation into the land, of a triangular shape, forming what Rennell and other geographers have fancifully called a 'negative delta.' If, on the other hand, a low shelving shore, and the absence of strong tidal currents favour the gradual and tranquil deposit of the solid matter brought down by the river, an extensive level of alluvial land is formed. In this case the main river, at a distant point inland, often divides itself into two streams, which, gradually diverging until they reach the sea, inclose a triangular space of land having the form of the fourth letter of the Greek alphabet, Δ, and hence called a *delta*. The mass of water does not, however, long continue divided into two streams only; the process of separation is repeated several times, and thus the delta is traversed by several channels, and the great river empties itself into the sea by many mouths, as may be seen by the inspection of the Nile and Ganges in any map of Egypt or Hindustan on a tolerably large scale. In this way a delta is formed at the mouths of the Rhine, Rhône, Po, Danube, Wolga, Nile, Indus, Ganges, Orinoco, and many others. The magnitude of the delta, generally, although not always, corresponds to the volume of the waters by which it has been created. The head of that of the Rhine is about 90 miles distant from the general line of sea-coast of Holland; and although the name of the main river is almost lost by the subdivision of its waters and the junction of other rivers, we include within the Rhine delta the whole of the low-land from the neighbourhood of Calais to the north-eastern shores of the Zuyder Zee, which makes the base of the triangle nearly 200 miles. The head of the delta of the Ganges is 220 miles from the sea, its base is 200 miles long, including the space occupied by the two great arms of the Ganges which bound it on either side. The tract in the lower part of this delta, called the Sunderbunds, a wilderness infested by tigers and crocodiles, is, according to Rennell, equal in extent to the principality of Wales. The whole of a deposit within a delta, as well as much above and on each side of it, is therefore an encroachment of the land upon the sea, and in many rivers this growth of the land is in a steady progress of advancement; as, for example, the city of Ravenna, formerly a seaport of the Adriatic, is now 4 miles inland. There are causes, however, which often prevent the farther increase of a delta after it has advanced a certain length: such seems to be the case with the delta of the Nile, which does not advance with the rapidity that might be expected from the quantity of matter brought down by the river. [Nile, in Geog. Div.]

Great as is the amount of new land thus formed, it is insignificant in comparison with the quantity of solid matter carried down by rivers, and deposited in the depths of the sea. It is impossible to form any estimate of this upon which reliance can be placed, because no accurate observations have been made to supply the data. To come to anything like a satisfactory conclusion, it would be necessary to have a vertical section of the river at a given point, obtained by numerous soundings, so as to get the profile of the bed, and by observations at different seasons to get the mean height; we must also have the results of experiments throughout the year, to ascertain the mean velocity, and the volume of solid matter contained in a given bulk of the water. The quantity of mud and sand poured by the Ganges into the Bay of Bengal is so great, in the flood-season, that the sea recovers its transparency only at the distance of 60 miles from the coast. Sir Charles Lyell, in his 'Principles of Geology,' makes a calculation (founded upon the computations of Major Rennell) as to the mean quantity of water discharged by the Ganges into the sea, by which he shows that, supposing the water to contain one hundredth part of solid matter, a mass equal in bulk to the greatest of the Pyramids of Egypt is brought down by the Ganges every day. The sea is discoloured for many leagues from the mouths of the Orinoco, and the solid contents, swept by ocean-currents through the Gulf of Paria, after being partly deposited on the shores of Guiana and the island of Trinidad, are carried into the Caribbean Sea and Gulf of Mexico. By the observations of Colonel Sabine, it appears that the muddy waters of the river Amazonas may be distinguished 300 miles from its mouth. The great basin of the Amazonas, which is drained by that mightiest of rivers and its vast and countless tributaries, embraces an area, according to Humboldt, only one-sixth less than the whole of Europe, and through this the main stream flows for nearly 3400 miles. The river, at the point where its waters unite with those of the Atlantic, is, according to the same illustrious traveller, 40 miles broad.

If a river loaded with sand encounter a marine current at its mouth, the effect frequently is to throw up a great sand-bank or bar, often to the detriment of the navigation in the adjoining sea, and sometimes to the entire destruction of a harbour. If such sand-banks be thrown up opposite to the delta of a great river, they accelerate its formation, for the matter brought down, in place of being carried far out to sea, is deposited in the intermediate space, and the sand-bank in time becomes united to the delta.

An extensive waste of the land is in constant progress along every line of coast which presents an abrupt face to the sea. The amount and rapidity of that waste depend upon a variety of circumstances:—the nature of the rocks of which the cliffs are composed, according as they are capable of long resistance, or are easily acted upon by the weather and the sea; the force of the tides and currents; the greater or less frequency of storms;—all these accelerate or retard the destructive force of the ocean. In this case also, as well as in the action of running water on the land, the force is greatly augmented when the water is charged with solid matter. The violent surge of a tempest dashing against a cliff detaches large blocks, and sweeps them away; but the next returning wave hurls them back again against the cliff, and thus a powerful artillery is supplied by the land for its own destruction. When we look upon a map of the world, and see the irregular form and indented line of coast of every continent and island, we have before us the most irresistible proof of the powerful force of the waves, and that the line of the shore must have been formed, in a great degree, by the action of the sea.

The east and south coasts of Great Britain, from the nature of the rocks of which they are composed, and from the violent storms to which they are exposed, are extremely subject to decay. The Shetland and Orkney Islands are laid open to the whole violence of the waves of the Atlantic, and the ocean-current runs in the Pentland Frith, in ordinary spring-tides, at the rate of 10½ miles an hour, and about 13 miles during storms. The steep cliffs on the shores of the Shetland Islands are hollowed out into caves, so that the sea enters in some places to the depth of 250 feet, lofty arches are worn in projecting rocks, and almost every promontory ends in a cluster of pillars, obelisks, and towers, the last fragments of extensive continuous strata. In stormy winters, vast blocks are moved from their seat, overturned, dashed into the sea, or carried considerable distances up acclivities. In this case, even rocks of the hardest composition have been unable to withstand the force with which they have been assailed. Islands have been wholly destroyed, and the remains of others rise like the ruins of a Palmyra in the desert of the ocean. Representations of these have been given by Dr. Hibbert in his description of the Shetland Islands, and the following is a copy of one of the most striking.

In the year 1795 a village on the coast of Kincardineshire was swept away by a storm in one night, and the sea penetrated 150 yards inland, where it has maintained its ground ever since. Almost the whole coast of Yorkshire, from the Tees to the Humber, is in a state of constant decay, especially between Flamborough Head and the Spurn Point, the rate of encroachment at Owthorpe being at present about four yards in a year. An inn at Sherringham, on the Norfolk coast, built in 1805, 70 yards from the sea, in 1829 was separated only by a small garden from the edge of the cliff. There is now a depth of water sufficient to float a frigate at one point in the harbour of that place, where, only half a century ago, there stood a cliff 50 feet high, with houses upon it. The whole site of ancient Cromer now forms a part of the German Ocean. Dunwich, once a flourishing and populous town, and the most considerable sea-port on the coast of Suffolk, has been gradually swept away, so that there now only remain about twenty houses. The church of Reculver, on the coast of Kent, was nearly a mile inland in the reign of Henry VIII.; it is now little more than 60 yards from the water's edge.

The whole coast of Sussex has been incessantly encroached upon by the sea from time immemorial; tracts of 400 acres have been carried away at one time; and the old town of Brighton, which stood between the site of the present cliff and the sea in the reign of Elizabeth, has been wholly destroyed. The projecting foreland of Beachy Head is falling away rapidly: in the winter of 1852 many large portions gave way and fell into the sea, among which were some of a picturesque form, known as the Charleses, which were much visited by tourists. By the undermining of the sea on the coast of Dorsetshire, in 1792, a portion of land 600 yards from east to west, and a mile and a quarter from north to south, sunk 50 feet in 24 hours. The island of Heligoland, off the entrance of the river Elbe, has been reduced to the fourth part of its size within the last 500 years, and since 1770 has been divided into two parts, the channel between them being navigable by large ships. Nowhere has the sea made greater inroads than on the coast of Schleswig. The island of Nordstrand, in the earlier part of the 13th century, was separated from the main-land by a narrow stream, and was 50 miles long and 35 broad, populous and highly cultivated. In the year 1240 a great part of it was destroyed, and at the end of the 16th century it was reduced to an area of 20 miles in circumference. The industrious inhabitants endeavoured to save their territory by the erection of lofty dikes; but in October, 1634, a great storm devastated the whole island, destroyed 1340 people, and 50,000 head of cattle; and three small islets, which have since considerably diminished, were all that remained of the once fertile and populous Nordstrand.

It would be superfluous to give, in this place, farther instances of the like nature: those we have already mentioned have all occurred within the historical era; others, however, still more remarkable in extent, date from a much earlier period of the earth's history, and the evidence of their occurrence is supplied by the identity in composition of the opposite portions of the separated lands. There is every reason to believe that England once formed a part of France: the cliffs on the opposite sides of the channel are identical with those at the Straits of Dover; and between Folkestone and Boulogne a submarine chain of hills is, in some places, only 14 feet below the surface at low water. From the German Ocean to the Straits the water becomes gradually more shallow, diminishing, in a distance of 200 leagues, from 120 to 18 fathoms; and in the same manner, from the Straits to the mouth of the English Channel, there is a gradual increase of the depth of the water, so that at the Straits there is a ridge with a fall to the west and to the east. In the wearing of the sides, and consequent widening of the Straits, which is now going on, we see only an advanced stage of a work of destruction which has been many thousand years in operation. That Sicily was at one time united to Italy was a tradition in the time of Virgil ('Æneid,' iii. 414):—

> 'Th' Italian shore
> And fair Sicilia's coast were one before
> An earthquake caused the flaw: the roaring tides
> The passage broke that land from land divides;
> And where the lands retired the rushing ocean rides."
> Dryden's *Trans.*

All modern observations on the structure of the opposite shores, the bottom of the intervening sea, and the violence with which it is often agitated, give every degree of credibility to the tradition. But as Sicily is in that part so frequently convulsed by volcanic fires, it is very probable that subterranean movements have greatly contributed to the formation of the Straits of Messina. In like manner, there is every reason to believe that the island of Ceylon was at one time united to the continent of Hindustan. [ADAM'S BRIDGE, in GEOG. DIV.] Humboldt is of opinion that the Caribbean Sea was once mediterranean, inclosed by a circuit of land, of which St.-Domingo, Jamaica, and Cuba, are the principal remains; and the whole form of the land from the promontory of Yucatan, through the above-named islands to Trinidad, and the coast of Cumana, with its deeply-indented shores, the numerous islets and shoals, give countenance to the conjecture, and justifies the belief that we see in the West India Islands the monuments of the irresistible force of the waves of the Atlantic, co-operating with subterranean agency, through an indefinite succession of ages.

To what, it may be asked, does all this lead? If such a constant destruction of the land be a part of the system of Nature, it necessarily follows, that, if her laws continue to endure, the whole of our present continents must in time disappear under the surface of the sea. Undoubtedly to that, and to no other conclusion must we arrive; but such a transference of the land which now rises above the surface of the sea is in perfect accordance with what geology tells us has been the economy of Nature in times past. All the stratified masses of which the crust of the earth is composed, however high their position may now be, must at one time have been at the bottom of the sea; and the materials of which they are composed must have constituted the component parts of other rocks, which, in a former condition of the earth's surface, must have been acted upon and abraded by similar agents. In every great group of strata we find beds composed of large water-worn fragments, materials supplied, most probably, by rivers which had a rapid descent to the sea; but as such watercourses form but a small proportion to those which traverse low and level countries, and carry only the finer particles to the sea, so we find that the beds of conglomerates bear only a small proportion to those strata the materials of which are in a comminuted state—an additional fact in support of the doctrine, that the formation of strata in past times took place under circumstances analogous to those which are now in progress; that is, that the laws of the material world have continued unaltered. But renovation as well as decay is a part of the economy of Nature; and the same subterranean forces which raised our present continents, may, in after ages, repeat the process, and other Alps and other Andes may be produced from the materials which are now washed from our shores, and are accumulating in the unfathomable depths of the ocean. We can in no way conclude these observations so well as by quoting the following eloquent passage from the 'Illustrations of the Huttonian Theory:'—"How often these vicissitudes of decay and renovation have been repeated, it is not for us to determine: they constitute a series, of which we neither see the beginning nor the end—a circumstance that accords with what is known concerning other parts of the economy of the world. In the planetary motions, where geometry has carried the eye so far both into the future and the past, we discover no mark either of the commencement or the termination of the present order. It is unreasonable, indeed, to suppose that such marks should anywhere exist. The Author of nature has not given laws to the universe, which, like the institutions of men, carry in themselves the elements of their own destruction. He has not permitted, in His works, any symptom of infancy or of old age, or any sign by which we may estimate either their future or their past duration. He may put an end, as He no doubt gave a beginning, to the present system, at some determinate period; but we may safely conclude that this great catastrophe will not be brought about by any of the laws now existing, and that it is not indicated by anything which we perceive."

ALMANDINE, in Mineralogy, the precious Garnet. It is the mineral which is most commonly employed in jewellery under the common name of garnet. It is a silicate of alumina and magnesia. [GARNET.]

Almandine-Ruby is a name given to a variety of Spinell which is an aluminate of magnesia. [SPINELL.]

ALMOND. [AMYGDALUS.]

ALNUS, a genus of plants belonging to the natural order *Betulaceæ*. It was formerly united with the birch in the same genus, but modern botanists have separated it, because its fruit is wingless and its stamens only four.

Several species are described in botanical works, most of which are found in America, between the mountains of New Granada and Hudson's Bay: a small part belongs to Europe, and northern and middle Asia. Of these, the only species that need be noticed here are, the Common Alder, the Turkey Alder, and the Heart-Leaved Alder.

Alnus glutinosa, the Common Alder, is an inhabitant of swamps and meadows in all Europe, the north of Africa and Asia, and North America. Its favourite station is by the side of rivulets, or in the elevated parts of marshy land where the soil is drained; it does not thrive so well if placed in absolutely stagnant water. Next to the charcoal from Black Dogwood (*Rhamnus frangula*), that supplied by the Common Alder is of the best quality; and this tree is in consequence extensively cultivated in plantations for use in the manufactories of gunpowder. Its juice contains a great abundance of tannin, which renders the bark valuable for tanning, and the young shoots for dyeing various colours when mixed with other ingredients; the veiny knots of its wood are cut into veneer by cabinet-makers for ornamental purposes; and its stems, hollowed out, are among the best materials, next to metal, for water-pipes and underground purposes.

Common Alder (*Alnus glutinosa*).

Its foliage being large, and of a deep handsome green, the alder is rather an ornamental tree; and when old it frequently becomes a picturesque object, if unbroken or uninjured by the hatchet of the woodman.

Several varieties of the Common Alder are met with in collections, and among them one, called the Cut-Leaved, which is extremely ornamental when young: there is also another, with very much-lobed leaves, called the Hawthorn-Leaved, in which almost all trace of the usual appearance of the alder has disappeared.

Alnus incana, the Turkey Alder, or Upland Alder, is distinguished from the preceding by its more erect mode of growth, and by its leaves being destitute of clamminess, but covered instead with copious white down on the under side. It is found all over continental Europe, from Sweden to the north of Italy, and east beyond the Caucasus, as far even as Kamtchatka. Like the Common Alder, it shows itself in a number of varieties, among which several are of dwarfish stature; but its general character is to grow more rapidly and to acquire a larger size than the Common Alder. What makes it particularly valuable is, that it will grow on light land where there are neither rivulets nor ditches; an important property, as it can scarcely be doubted, from its appearance, that it possesses whatever useful qualities are found in the Common Alder. Botanists seem to suppose that the Turkey Alder is their *A. oblongata*, but this is a manifest error.

A. cordifolia, the Heart-Leaved Alder, resembles but little in appearance either of the preceding. It forms a rather large and very handsome round-headed tree, with broad, deep-green, shining leaves, deeply heartshaped at the base. It grows with rapidity, and is one of the most interesting ornamental trees that have of late years been introduced into cultivation. Though a native of the kingdom of Naples, and a most distinct species, its very existence was unknown till within a few years. It is a perfectly hardy plant, notwithstanding its southern station.

All the Alders are increased with great facility by layers; they will also strike readily enough from cuttings, but the latter are longer in becoming handsome plants. Common Alder is obtained by the nurseryman from seed; which should, if possible, be sown in very light, rich, damp soil, in the autumn, soon after it is ripe. If kept till the spring, even if preserved in sand, it loses in a great degree its power of vegetating; and if not kept in sand, it will scarcely ever grow at all.

ALOE, a genus of succulent plants belonging to the natural order *Liliaceæ*. It comprehends a very considerable number of species which differ from each other exceedingly in the size, form, and surface of their leaves, in stature, and in the colour, size, and structure of their flowers. The greater part of them are mere objects of curiosity, and are only seen in collections of succulent plants; but among them are species of much value, on account of their yielding the well-known medicinal drug called Aloes.

From what particular species the resinous substance called Aloes is procured, and whether the different samples known under the name of Hepatic Aloes, Socotrine Aloes, and Horse Aloes are yielded by different species, or are only different qualities of the same species, are points not settled.

All that appears certain is that plants nearly related to *Aloe perfoliata* of Linnæus, which some consider distinct species, while others pronounce them mere varieties of each other, are what the drug is prepared from. In all probability, all the species of the genus having an arborescent stem and thick succulent leaves will yield the substance equally well.

That which has the reputation of producing the best aloes is *A. Socotrina*, a plant having, when old, a round stem 3 or 4 feet high; leaves of a sword form, 1½ to 2 feet long, sharp-edged, sawed, hard, and pungent at the apex, often collected in clusters at the top of the stem; and red flowers tipped with green, borne in clusters on tall stalks which rise erect from among the leaves. This is a native of the Cape of Good Hope, and the island of Socotra, but it is now commonly cultivated in the West Indies. The processes of preparing the drug are various. Sometimes the leaves are cut off at their base and placed in iron vessels to drain, until they have discharged all their juice, which is then inspissated; in other places, the leaves are cut into slices and boiled for ten minutes, after which the water in which they have been boiled is evaporated; occasionally pressure is resorted to for the purpose of procuring the greatest quantity of juice.

Socotrine Aloes seem to be the purest kind obtained by draining only; Hepatic or Barbadoes Aloes, which are obtained from the *Aloe vulgaris*, are less pure, and may be obtained by boiling or slight pressure; while Horse Aloes are undoubtedly a coarse preparation of the dregs of the last-mentioned. [ALOES, in ARTS AND SC. DIV.]

No plants can be more easy to cultivate artificially than the Aloe Tribe. They are incapable of parting rapidly with water, and therefore require to be planted in a soil that is very slightly retentive of moisture, so that they may not be gorged with it by their roots; for this reason, they are potted in a compost consisting of little more than lime rubbish mixed with a small quantity of ordinary soil, and carefully drained.

They require a green-house which is capable of being maintained at a temperature of not less than 40° in the depth of winter, at which time they should have no water whatever; in the summer they want no fire-heat, but may be watered regularly, the supply being always in proportion to their rate of growth and to the temperature of the air; that is to say, when in full growth and in a high temperature, they may have abundance of water, and when growing slowly in a low temperature they should have but very little.

ALOPECU'RUS, a genus of plants belonging to the natural order *Graminaceæ*. It is distinguished from all other British grasses by its flowers, which grow in close cylindrical heads, consisting of two glumes of equal size and a keeled compressed figure, inclosing a single palea, from the base of which arises an arista or beard. It contains many species.

Alopecurus pratensis, the Meadow Foxtail Grass, is a valuable plant to the farmer. It is so much larger than any other British species of *Alopecurus* as to be easily recognised; and from *Phleum pratense*, which it resembles, it may be immediately known by its not having two paleæ, and by its beard proceeding from its palea and not from its glumes. It grows commonly in meadows, where it forms rather a coarse but an abundant and early herbage, of which cattle are very fond. In such situations it is invaluable, but it becomes worthless if sown on light dry soil.

Meadow Foxtail Grass (*Alopecurus pratensis*).

A. agrestis, Slender or Field Foxtail Grass, has a fibrous root, and blossoms in July or August. Although a troublesome weed amongst wheat, it is useful for sowing on light sandy soils on the sea-coast. In such situations it grows better than even the common rye-grasses.

ALOYSIA, a genus of plants belonging to the natural order *Verbenaceæ*. *A. citriodora* is the Sweet-Scented Vervain of our gardens. [VERBENA.]

ALPINIA, a genus of plants belonging to the natural order *Zingiberaceæ*. The species have thick tuberous horizontal roots. The stems are numerous and perennial, with lanceolate leaves, having a slit ligulate sheath. The flowers are in panicles, or loose racemes or spikes. The tube of the corolla is short, the inner limb 1-lipped. The filament of the stamens linear. The fruit is capsular and 3-celled, with winged seeds.

A. Galanga is a native of Sumatra, and is cultivated in the Indian Archipelago. Its roots are pungent, acrid, and aromatic, and are often substituted for ginger. They are sold by druggists under the name of *Galanga major*. A plant related to, if not identical with, the *A. exaltata* of Meyer, the *Renealmia exaltata* of Linnæus, is called *Corowatti* in British Guyana, and is described by Dr. Hancock as a bitter pungent plant, and when taken acting as a diaphoretic and diuretic, and in large doses as emetic. [GALANGA.]

ALTERED STRATA. In addition to the consolidation and division by cracks, joints, and fissures, to which all rocks have been subjected, in unequal degrees, there are special cases of uncommon induration, internal re-arrangement of particles, and even the production of new mineral ingredients, which happen in the strata near to rocks of igneous origin, and along certain great fractures and flexures. Heat is usually appealed to for these effects, and justly; but in addition to mere pervading warmth, Von Buch supposes vaporisation of some ingredients (as magnesia, which converts limestone to dolomite), and the solution of others in hot water, to be necessary to explain the various contents of mineral veins.

ALTERNATION OF GENERATIONS, an expression introduced into natural history by Professor Steenstrup, a Danish naturalist, to designate the difference of form observable between the parents and immediate offspring in the lower animals, as in the *Acalephæ* [ACALEPHÆ], *Salpæ* [SALPACEÆ], and some others. [GENERATIONS, ALTERNATE.]

ALTHÆA, a genus of plants belonging to the natural order *Malvaceæ*. It is known by its double calyx, the outer whorl of which has six to nine sepals, whilst the inner has five. *A. officinalis* is the Marsh-Mallow, a plant the use of whose mucilaginous roots and leaves, in all cases in which emollient or demulcent substances are required, is of great antiquity. It is a common European plant, and is often found in marshes, especially near the sea, in great abundance. It is a perennial, with a carrot-shaped white fleshy root, as thick as the thumb, and a foot or more long. The stems are two or three feet high, covered all over with a soft down, which also is found on the leaves, to which it gives a hoary aspect. The leaves are soft, stalked, often a little heart-shaped, divided into three or five shallow serrated lobes. The flowers are of a pale rose colour, and appear in very short clusters from the bosom of the leaves; their calyx is 5-toothed, and surrounded with eight or ten or even more bracts. The corolla and other parts are like those of the Common Mallow. The demulcent lozenges sold in the shops under the name of Pâte de Guimauve, are made of Marsh-Mallow.

Marsh-Mallow (*Althæa officinalis*).

Althæa rosea, the Hollyhock, is another species. It is found wild in China, and is now extremely common in our gardens. Linnæus considered it a distinct genus, which he called *Alcea*.

ALUM-ROOT, the root of *Geranium maculatum*. It contains alum, and is a powerful astringent. [GERANIUM.]

ALUM-SLATE, a rock from which, as its name implies, alum is prepared. It is found in Germany, Sweden, &c.; and in Yorkshire a stratum occurs, which, according to Mr. Winter (Nicholson's 'Journal,' No. 25, p. 241), is 28 miles in length, extending from 10 miles to the southward of Whitby to 18 miles to the northward; the cliffs are in general precipitous, and their height is from 100 to 750 feet. The colour of this slate is bluish-gray: its hardness varies; at the top part of the stratum it may be crumbled between the fingers, whereas at a considerable depth it is as hard as roofing-slate. The specific gravity is about 2·48. By exposure to the air it effloresces, and acquires the taste of alum. Alum-slate has not been accurately analysed; it contains silica, alumina, and, before efflorescence, probably pyrites or bisulphuret of iron.

At Hurlett, near Paisley, and Campsie, near Glasgow, alum is manufactured from what appears to be slate-clay impregnated with bisulphuret of iron; it is obtained from old coal-pits, and having been long exposed to air and moisture, sulphate of iron and sulphate of alumina are formed, and crystallise so as completely to destroy the texture of the slate.

This double sulphate of iron and alumina occurs in the form of soft delicate fibres, easily separable from each other; it is nearly colourless, of a silky lustre, and resembles asbestos in appearance. It is readily soluble in water; the solution yields crystals of sulphate of iron; and when potash-salts are added to the remaining solution of sulphate of alumina, crystals of alum are immediately formed; and this is the process of alum-making already noticed.

ALUM-STONE, a mineral which occurs in a secondary rock at La Tolfa in Italy, and is there used in the preparation of alum; it is found in small masses and veins, and according to Cordier it exists in most burning volcanoes. It is said to be met with also in Tuscany and Hungary.

This mineral is either massive or crystallised; the former is usually grayish-white, and sometimes red. It is translucent, easily frangible, scratches calcareous spar, but is scratched by fluor spar. When heated by the blowpipe it decrepitates, and by continuing the heat emits a sulphureous smell.

The crystals are generally situated in the cavities of the massive substance; they are small, shining, sometimes externally brownish; their form is an obtuse rhomboid, variously modified.

Both varieties have been analysed—the massive by Vauquelin, and the crystallised by Cordier; the results are—

Massive.		Crystallised.	
Sulphuric acid	25·00	Sulphuric acid	35·495
Alumina	43·92	Alumina	39·654
Potash	3·08	Potash	10·021
Silica	24·00	Water, a trace of oxide of iron and loss	14·830
Water	4.00		
	100·00		100·000

ALUMINITE, in Mineralogy, a variety of native Sulphate of Alumina, also called *Websterite*. It is found in reniform masses and in botryoidal concretions in Halle in Prussia, Epernay in France, and at

Newhaven in Sussex. It has a white or yellowish-white colour. It is soft and friable, and has an earthy fracture. It is occasionally translucent, but more frequently opaque. It has a specific gravity of 1·7. It is a hydrous sub-sulphate of alumina, and has the following composition:—

Sulphuric Acid	23·27
Alumina	29·87
Water	46·86
	100·00

ALUMO-CALCITE, a mineral belonging to the group of Clays containing a large quantity of water. It occurs in the clefts of ironstone veins at Eybenstock, in the Erzgebirge. It is massive, and has a white colour inclining to blue. It has a white streak, a conchoidal fracture, and is so soft that it may be crushed between the fingers. It adheres strongly to the tongue. The specific gravity is 2·714. Its analysis by Kersten gives—

Silica	86·60
Alumina	2·25
Lime	6.25
Water	4·90
	100·00

ALUNITE, in Mineralogy, a name for the Alum-Stone. [ALUM-STONE.]

ALVEOLI'TES (Lamarck), a genus of Fossil *Polypiaria*, from the Cretaceous and Tertiary Strata.

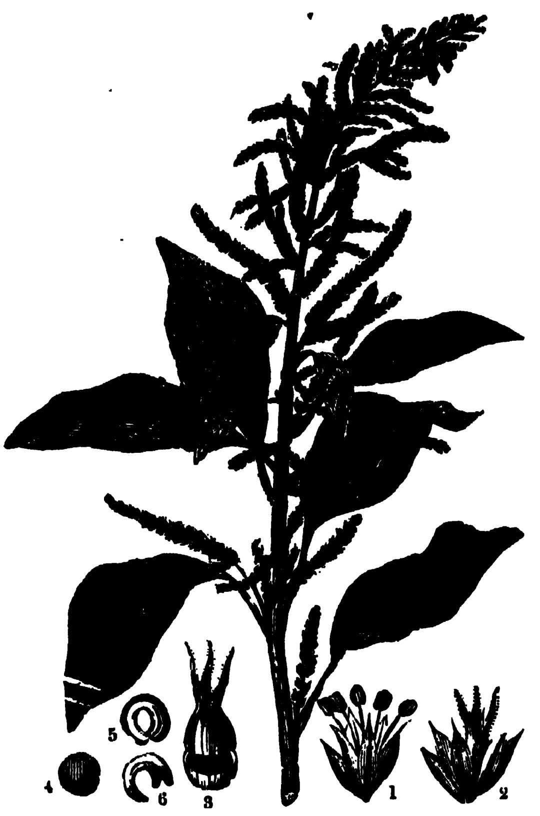
AMADO'U, the name of an inflammable substance occasionally used as tinder. It is prepared from the dried plant of the *Boletus igniarius*, steeped in a strong solution of saltpetre, and cut into thin slices. This plant grows horizontally from the sides of the cherry, the ash, and other trees. When it first makes its appearance it is a little round wart-like body, the size of a pea of a yellow colour, and of a soft yielding substance; it gradually increases in size and hardness till it becomes of a darkish-brown, and is as large as an apple. It afterwards takes a horizontal direction, forms a border and becomes covered with numerous closely-packed tubes on its under surface, which are exceedingly minute. When the plant is full grown the tubes are of a reddish-brown colour, and of a hard woody texture; and the upper surface is of various colours disposed in gray, brown, or clouded concentric elevated circles. The plant is perennial, and increases yearly in size.

Boletus igniarius.

AMARANTA'CEÆ, Amaranths, a natural order of Apetalous Dicotyledonous plants, remarkable for the dry coloured scales of which all their bracts and floral envelopes are composed—a character by which they are principally known from *Chenopodiaceæ*. Their essential distinction is briefly this: calyx, dry, coloured, not falling away; petals, wanting; stamens, five or more; ovarium, quite simple, superior; fruit, an utricle, containing a single seed, which has an embryo curved round a central farinaceous albumen; leaves, destitute of stipules.

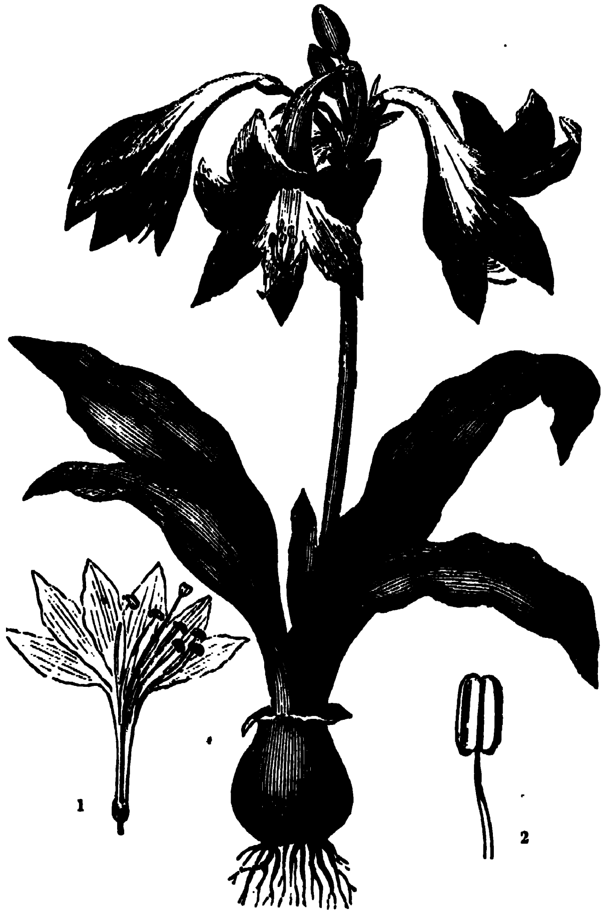
The species are found chiefly in tropical countries, where they are often troublesome weeds. The Cock's-Comb, the Globe-Amaranth, the Prince's-Feather, the Love-Lies-Bleeding, of our gardens, belong to this order.

Many of the species are used in the countries where they grow as pot-herbs, and indeed none of them present any unwholesome properties. The seeds of *Amaranthus frumentaceus* and *A. Anardhana* are gathered as corn crops in India. A large number of the species have a reputation for possessing medicinal properties, but, as is the case with the majority of such remedies, they seldom bear out the encomiums bestowed upon them by the ignorant. (Lindley, 'Vegetable Kingdom.')



Amaranthus polygamus.
1. A calyx and bract with stamens. 2. The same with the pistil.
3. The pistil opening. 4. A seed.
5. A seed cut down, showing the embryo. 6. The embryo. All magnified.

AMARYLLIDA'CEÆ, Amaryllids, the Narcissus Tribe, a natural order of Monocotyledonous plants, to which the Daffodil, the Belladonna



Amaryllis reticulata, diminished in size.
1. The flower cut open. 2. A stamen the natural size.

Lily and Guernsey Lily, the showy Brunsvigias and Blood-Flowers (*Hæmanthus*) of the Cape of Good Hope, and the American Aloe belong. They are characterised by having six stamens, a highly-coloured flower, and an inferior ovary. The beauty of their blossoms serve as a cloak to their poisonous properties, and shows how little the external appearances of plants are to be trusted in judging of their virtues. To form an opinion only from their aspect, these would be pronounced the most harmless of plants, while in fact their bulbs are dangerous poisons. The juice of that of *Hæmanthus toxicarius* is inspissated by the Hottentots, who smear their arrow-heads with it; other kinds are not less fatal, and even the common daffodil and snowdrop contain within their bulbs an acrid irritating principle which renders them emetic. Like many other poisonous families, this occasionally secretes a kind of fœcula, or flour, which, when separated from the juice that is naturally mixed with it, becomes a wholesome article of food. The arrow-root of Chili is yielded by an *Alströmeria*, which belongs to *Amaryllidaceæ*.

The species, which are chiefly scattered over Brazil, Africa, and tropical Asia, are nearly all bulbous; a few only acquire a high degree of development, and lose their bulbous character, as the *Doryanthes*, *Agave*, and *Littæa*. [Agave.]

AMAZON-STONE, in Mineralogy, a green variety of Felspar. [Felspar.]

AMBER, a carbonaceous mineral which occurs in beds of lignite, in Greenland, Prussia, France, Switzerland, and some other countries. The greater portion of it comes from the southern coasts of the Baltic Sea, where it is thrown up between Königsberg and Memel. (Berzelius, 'Traité de Chimie,' vi. 589.)

It is also stated ('Annales de Chimie,' xvi. 215) that it is obtained by mining at a distance of 200 feet from the sea, and at a depth of about 100 feet, and is found in small cavities. It is occasionally met with (Aikin's 'Dict. of Chemistry,' i. 57) in the gravel beds near London, in which case it is merely an alluvial deposit. Amber occurs generally in small pieces, which are sometimes colourless, frequently light-yellow or deep-brown, and very commonly translucent; two large masses have, however, been found, one of them weighing upwards of thirteen pounds, and the other more than eighteen.

Amber is rather harder than common resins, which it resembles in several properties: it is susceptible of a good polish, and when rubbed becomes electrical; indeed the word *electricity* is derived from *ἤλεκτρον*, the Greek name for amber. Its density varies from 1·065 to 1·070. When bruised it exhales a slight aromatic odour; and when heated to 448° Fahrenheit it melts, inflames, burns with a bright flame, and emits a smell which is not disagreeable.

The subject of the origin of amber is one which has been much discussed. According to Berzelius ('Chimie,' vi. 589), it was originally a resin dissolved in a volatile oil or natural balsam. The proofs of this opinion are, he conceives, numerous. Thus, it has often the impression of the branches and bark upon which it has flowed and solidified; it often contains insects, some of which are so delicately formed, that they could not have occurred except in a very fluid mass. Dr. Brewster ('Edinburgh Phil. Journal,' iv. 332) concludes, from an examination of the optical properties of amber, that it is an indurated vegetable juice.

Amber consists of a mixture of a volatile oil, two resins soluble in alcohol and in ether, succinic acid, and a bituminous body that resists the action of all solvents, and which is the principal part of amber.

Water does not act upon this substance; it does not even dissolve any of the succinic acid. Alcohol takes up a soft, yellow, limpid resin. Cold concentrated sulphuric acid dissolves amber; the solution has a brown colour, and when water is added to it, the greater part of the amber is precipitated. Nitric acid converts it into a resinous substance, and dissolves it totally.

When amber, in the state of fine powder, is boiled in a solution of potash, a great quantity of succinic acid is dissolved.

According to Drapiez, the composition of amber is as follows:—

Carbon	80·59
Hydrogen	7·31
Oxygen	6·73
Ashes	3·27
Loss	2·10
	100·00

The ashes consist of lime, silica, and alumina. This analysis can only be considered as an approximation.

Amber is employed for ornamental purposes, in the manufacture of necklaces, &c. It is used also for preparing amber-varnish, for obtaining a peculiar oil used in medicine, and it yields succinic acid emyloyed in chemical investigations.

AMBERGRIS, a substance of animal origin, found principally in warm climates, floating on the sea, or thrown on the coasts. The best comes from Madagascar, Surinam, and Java. It has been found in the intestinal canal of the *Physeter macrocephalus*, mixed with the remains of several marine animals which have served it for food. On this account it has been supposed to be a morbid product, analogous to biliary calculi.

Ambergris of good quality is solid, opaque, of a bright gray colour which is darkest externally, and intermixed with yellow or reddish striæ. When it is heated or rubbed, it exhales an odour which is agreeable to most persons. It is sufficiently soft to be flattened between the fingers. Its fracture is fine-grained, with traces of lamellar structure. The heat of the hand is sufficient to soften it. Its specific gravity varies from 0·908 to 0·920.

When ambergris is heated with boiling alcohol of the specific gravity 0·833, until it is saturated, a peculiar substance, called *Ambrein*, is obtained as the solution cools, grouped in mammillated, small, colourless crystals. The solution, by evaporation, yields a further portion of ambrein, which may be rendered pure, by being redissolved in alcohol, and then crystallised.

Ambrein, thus obtained, is brilliant, white, and insipid; it has an agreeable odour, which appears, however, to be adventitious, because it is diminished by repeated crystallisations; by fusion or a long-continued gentle heat it acquires a resinous odour. Nitric acid converts it into a peculiar acid, called *Ambreic Acid*. The caustic alkalies do not form soap with it.

According to Juch and Bouillon-Lagrange, benzoic acid exists in distilled ambergris; by the analysis of John, ambergris appears to be composed of ambrein 0·85, an extractive matter soluble in alcohol, and probably containing benzoic acid, 0·025; watery extract with benzoic acid and common salt, 0·015; with 0·11 not accounted for.

Ambergris is used as a perfume; and as the alcoholic solution is the most odorous preparation of it, it is generally employed in that form.

AMBLIGONITE, a mineral, consisting of phosphate of alumina and lithia. It has a greenish-white colour, and occurs both massive and in rhombic prisms. It is found at Chursdorf, near Penig, in Saxony, and at Avendal in Norway. The cleavage is parallel to the sides of the prism. It has an uneven fracture, and in thin laminæ is translucent or transparent. The following is the analysis of Berzelius:—

Phosphoric Acid	54·12
Alumina	38·96
Lithia	6·92
	100·00

AMBLYSE'MIUS (Agassiz), a Fossil Fish, from the Oolite of Northamptonshire.

AMBLYU'RUS (Agassiz), a genus of Fossil Fishes, from the Lias of Somersetshire.

AMBURIA, a genus of plants belonging to the natural order *Chenopodiaceæ*, several of the species of which yield volatile oils that are employed as medicines in the countries where they grow. *A. anthelmintica* is a native of North America, and its oil is extracted and used as an anthelmintic under the name of Worm-Seed Oil.

AMELANCHIER (the Savoy name of the Medlar), a genus of plants belonging to the sub-order *Pomeæ* (*Pomaceæ*, Lindley), of the order *Rosaceæ*. It has a 5-cleft calyx with lanceolate petals, and an ovary of 10 cells, with a solitary ovule in each. The mature fruit is 3-5-celled, with one seed in each cell. The species are small trees, with simple serrated deciduous leaves, and racemes of white flowers.

A. vulgaris, the common species, is a native of rugged places throughout Europe. It is the *Avonia rotundifolia* of Persoon.

A. Botryapium, the Grape-Pear or Canadian Medlar, is a very common plant in Canada; it is also a native of Newfoundland, Virginia, and the higher parts of Columbia. It is a shrub 6 or 8 feet in height, with a purple fruit.

A. ovalis is also a shrub 6 or 8 feet high, and is a native of North America, throughout Canada from Lake Huron to the Saskatchewan and Mackenzie rivers, and as far as the Rocky Mountains. Sir John Richardson says that it "abounds on the sandy plains of the Saskatchewan. Its wood, named by the Crees *Meesass-quat-ahtick*, is prized for making arrows and pipe-stems, and is thence termed by the Canadian voyageurs 'Bois de Flêche.' Its berries, about the size of a pea, are the finest fruit in the country, and are used by the Crees under the name of *Meesasscootoom-meena* both in a fresh and dried state. They make a pleasant addition to pemmican, and excellent puddings very little inferior to plum-pudding."

Another North American species is known by the name of *A. sanguinea*. Its fruit is of a blood-red colour.

(Don, *Dichlamydeous Plants.*)

AMENTA'CEÆ, a name sometimes given to a group of plants, chiefly forest-trees, found in the north of Europe, Asia, and America; the flowers of which are arranged in a dense cylindrical deciduous spike, called by botanists an *Amentum*. Such are the poplar, the birch, the hazel, the willow, the oak, and many others. But as these genera are in fact constructed in very different manners, *Amentaceæ* are more correctly separated, by modern botanists, into several different orders. [Corylaceæ; Salicaceæ; Betulaceæ, &c.]

AMETHYST. This name has been applied to two precious stones of essentially different natures. The *Oriental Amethyst* is a rare variety of *Adamantine Spar* [Adamantine Spar] or *Corundum*. The *Occidental*, or *Common Amethyst*, now to be described, is a variety of quartz or rock crystal, which is met with in many parts of the world, as India, Siberia, Sweden, Germany, Spain, &c. It occurs in various forms, as massive, in rounded pieces, and crystallised. The primary form of the crystal, like that of quartz, is a slightly obtuse rhomboid, but it is usually found in the secondary form of a 6-sided prism, terminated at one or both ends by a 6-sided pyramid; sometimes, though rarely, the prism is wanting, and the pyramids being then united base to base, the secondary crystal is a dodecahedron with triangular faces.

The amethyst is principally distinguished from common quartz by its colour, which is occasionally of every shade of violet, or rather purplish-violet, and this in the perfect amethyst is pretty equal throughout the crystal: very commonly the summits only of the crystal are amethystine, the lower part being nearly colourless, or tinged with green. By long-continued heat the colour is destroyed and the crystals become white and opalescent. Sometimes the crystals are aggregated or fasciculated; in the Palatinate they are found lining geodes of agate, and in Silesia capillary crystals occur mixed with micaceous iron ore.

The crystals of the amethyst vary from diaphanous to translucent, and they exhibit various degrees of splendour, both externally and internally. The fracture is commonly conchoidal, and the fragments are of indeterminate form. Like quartz, the amethyst is sufficiently hard to give fire with steel and to scratch glass; and has also been found, like it, with cavities containing water; it is infusible by the common blow-pipe. According to Rose, it consists of—

Silica	97·50
Alumina	·25
Oxide of Iron and Manganese	·50
	98·25

AMMANIA (in honour of John Amman, a distinguished botanist), a genus of plants belonging to the natural order *Lythraceæ*. The species are aquatic plants, with smooth opposite entire leaves, 4-cornered stems, and small pink or red flowers. They are natives of both the New and Old Worlds, and very generally distributed. One species, *A. vesicatoria*, has a strong peculiar smell, and the leaves are very acrid. They are used by the native doctors of India for the purpose of raising blisters, which they do in the course of half an hour.

AMMODYTES, a genus of fishes belonging to the division of *Apodal Malacopterygii* and family *Anguillidæ*. The body is very long and the head lanceolate. On the back is a dorsal fin extending nearly its whole length. The anal fin is also long; and the caudal, which is forked, is separated from both the dorsal and anal. Two species occur on the coasts of the British Islands, the *Ammodytes tobianus* and the *Ammodytes lancea*. The former is the larger, and is distinguished by the greater size of the head, and by the dorsal fin, which commences in a line with the extremities of the pectorals, whilst in the *A. lancea* it commences in a line with the middle of the pectorals. The Sand-Eel, by which name the first species is popularly known, attains a length of between 12 and 15 inches. When alive the back is of a dark bluish-green, and the sides and belly bright silvery-white. It frequents sandy shores in great numbers, but is capricious in its visits, more so than its congener. At the ebbing of the tide it buries itself with great dexterity and rapidity in the wet sands to the depth of from 4 to 6 inches, whence it is extracted by means of various instruments, such as peculiarly formed gripes and sickles with blunt edges, made for the purpose. It is much esteemed by fishermen as a bait, and is also sought after on many parts of the coast as an article of food, being very delicate eating when fresh, and excellent when dried in the sun and grilled.

The Sand-Launce, *Ammodytes lancea*, is a smaller species, and usually of a more brownish hue, with a tinge of red about the head. It is more abundant than the Sand-Eel, and has always been distinguished from it by the fishermen, though for a long time confounded with it by naturalists. The distinctions between the two species were first pointed out by M. Lesauvage of Caen. Both appear to be generally distributed through Northern and Western Europe. In Scotland the Sand-Eel is known by the name of the Horner, and in the Isle of Man the two species are distinguished from each other as the Gray Gibbon and Red Gibbon.

(Yarrell, *British Fishes*, vol. ii.; Parnell, *Fishes of the Frith of Forth.*)

AMMONITES, a fossil genus of Cephalopodous *Mollusca*, allied to the recent genus *Nautilus*. The species are known by the old Latin name *Cornu Ammonis*. These *Cornua Ammonis*, *Cornes d'Ammon* of the French, were so called from a fancied resemblance to the horns with which the head of Jupiter Ammon was sculptured. In the earlier times their origin was variously accounted for. Some thought them petrifactions of real rams' horns, taking the name above-mentioned in a strict and downright matter-of-fact sense; others thought they were the curled tails of certain animals; some took them for petrified marine worms rolled up; others saw in them coiled serpents, whence they were called Snake-Stones. The legends of the saints invested them with a sacred interest.

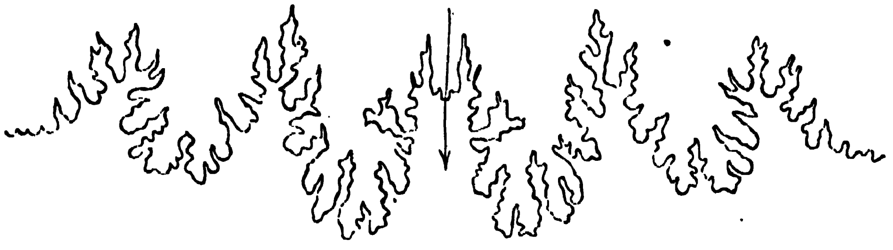
> Of thousand snakes, each one
> Was changed into a coil of stone,
> When holy Hilda pray'd.

And the prayer, we are told, was not only followed by petrifaction, but by decapitation. We believe that there is a similar tradition of St. Keyna, who, when she found herself in a wood at Keynsham, between Bath and Bristol, surrounded by serpents, changed them by the fervour of her devotions into headless stones. Nor were these opinions confined to the mere vulgar. Wormius described Ammonites as petrified adders. Langius considered them to be either the vertebræ of serpents or convoluted marine insects. These notions were not lost on the dealers; and there are few fossil collections which do not even now possess what was called 'a perfect *Cornu Ammonis*,' that is, an Ammonite with a carved serpent's head ingeniously fitted on to the fossil shell by way of aperture. Our limits will not permit us to dwell on this fabulous part of the history of Ammonites further than to observe that other learned men, Torellus Sarayna, Fracastorius, and others, considered them as *Lusus Naturæ*, formed by the plastic power of the earth. The ancients held them in high estimation as very sacred and of the highest value to the dreamer. Thus Pliny ('Hist. Mund.,' xxxvi. 10), "Hammonis cornu inter sacratissimas Æthiopiæ gemmas, aureo colore, arietini cornus effigiem reddens, promittitur prædivina somnia repraesentare;" and even to the present time the Indians are said to ascribe extraordinary properties to them.

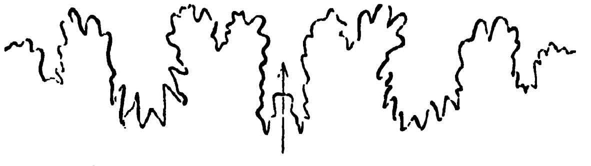
To the zoologist Ammonites are objects of great interest, and to the geologist they are of the utmost consequence. "It is easy," says Mr. Phillips, in his 'Guide to Geology' (8vo. 1834), "to see how important, in questions concerning the relative antiquity of stratified rocks, is a knowledge of Ammonites, since whole sections of them are characteristic of certain systems of rocks." (sec. 82.) Dr. Buckland ('Bridgewater Treatise,' p. 333), thus comprehensively describes the range of these extinct cephalopodous mollusks: "The family of Ammonites extends through the entire series of the fossiliferous formations, from the transition strata to the chalk inclusive."

According to Mr. Owen's system, the Ammonites form the fourth genus of his second family (*Ammonitidæ*) of his first order *Tetrabranchiata*, of the class *Cephalopoda*. In the opinion of all naturalists this great group of fossils requires to be subdivided. The *Goniatites* [GONIATITES] of the Palæozoic rocks have been effectually separated; the *Ceratites* of the triassic strata may be also withdrawn, but still the number of genuine *Ammonites* which remain is too enormous to be treated except in sections more or less founded on structural affinities. Without discussing what may be the best principles for such a classification, we may refer to that of Von Buch, as most generally accepted by geologists. This is mainly founded on a consideration of the sutures, or sinuous lines at the surface of the shell, formed by the edges of the diaphragmal plates which separate the chambers.

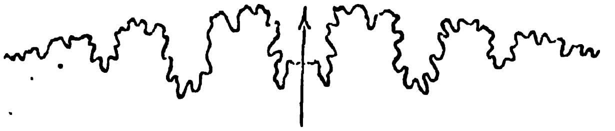
To illustrate this view of the subject we subjoin a few examples of characteristic Ammonitic sutures.



Ammonites sublævis (Sowerby). From Kelloway rock.



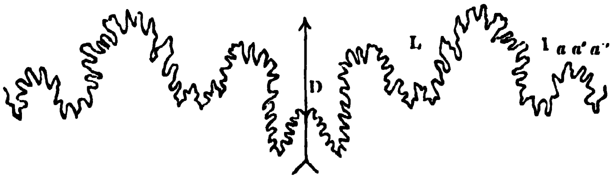
Ammonites Walcottii (Sowerby). From the Lias.



Ammonites venustus (Phillips). From Speeton Clay.

The following are Von Buch's groups, with their prevalent geological distribution :—

Arietes.—The back is usually broad, and carinated (often a furrow on each side of the keel) ; the ribs are simple and strong. The sutural line formed upon the following general model :—



The group of *Arietes,* including *A. Bucklandi, A. Conybeari,* &c., belongs almost wholly to the Lias formation.

Falciferi.—The back is narrow, acuminated to a sharp keel (no furrow on its sides) ; the ribs are elegantly and sigmoidally bent. The sutures differ from those of *Arietes,* the dorsal sinus D being much less deep, with diverging and not parallel sides ; the sinus L is very much deeper, and there are three or four smaller ones, *a a′ a″*, near the inner edge of the whorls. The latter whorls usually embrace the preceding ones.

These *Ammonites* are numerous in the Upper Lias and Lower Oolite formations. *A. Strangwaysii* of Sowerby is an example. (*Ammonites Walcottii* does not belong to this division.)

Amalthei.—The back is generally acute and keeled, the keel generally crenated ; the ribs generally a little sigmoidal ; the latter whorls embracing the preceding ones. The sutures are in general form much like those of the last division, but more richly laciniated and foliaceous.

This group belongs to the Upper Lias and Oolitic formations. *Ammonites amaltheus* of Schlottheim (*A. Stokesii,* Sowerby) is an example from the Lias.

Capricorni.—The back broad, without a keel. The ribs simple, straight, strong, and crossing the back. Inner whorls exposed. The sutures often approach to those of the *Arietes* in respect of the sinus D ; but the posterior edge of D, L, and l range on the same line, and the undulations are all lower and less foliaceous than in the *Falciferi* and *Amalthei.* *Ammonites planicostatus* (Sowerby) is an example. The species are common in the Lias.

Planulati.—The back and sides rounded ; no keel ; the inner volutions exposed. The ribs are often divided over the dorsal region. The sutures are remarkably laciniated and complicated ; the sinus (L) extremely deep, and generally trifurcate.

The species occur commonly in the Lias and Oolitic formations. *Ammonites communis* (Sowerby) is an example from the Lias ; *A. plicatilis* (Sowerby) from the Coralline Oolite.

Dorsati.—The back is broad and not keeled ; the whorls often quadrate : the ribs are simple on the sides, but divided over the back, and generally bear a tubercle at the point of division. *Ammonites Davœi* (Sowerby) is an example from the Lias.

Coronarii.—The back without a keel, usually broader than the sides ; the ribs are straight and simple on the sides, but divided into two, three, or more, as they cross the back, and the point of division is usually sharply tuberculate. The sutures resemble those of the *Planulati.* The species occur in the Oolites, as *A. Humphresianus* (Sow.) ; *A. Gowerianus* (Sow.) ; and in the Lias, as *A. Bechei* (Sow.).

Macrocephali.—The back is without keel, and round and broad, and the umbilicus deep. The ribs are straight on the umbilical face and simple, but sometimes arched, and generally divided across the back. The sutures resemble those of the *Planulati,* but are somewhat differently proportioned to the dorsal and umbilical surfaces. The species occur in the Oolite and Chalk. The *Ammonites sublævis* (Sow.), is a good example, from the Kelloways Rock.

Armati.—The back without a keel, often broader than the sides ; ribs tuberculated on the sides. The inner whorls exposed. The sutures have the dorsal sinus (D) large and deep, the lateral sinus (L) widely removed from it and very deep, and somewhat trifurcate. Occurs in the Lias and Oolite, and more plentifully in the Chalk. *Ammonites Bakeriæ* of Sowerby is an example.

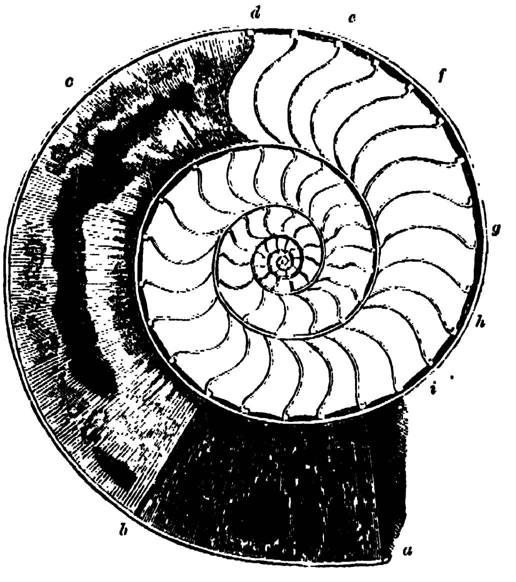
Ornati.—The back flat or even hollow, narrow, and not keeled ; the broad sides joining it at a right angle, marked in general by a row of small tubercles or the numerous fine ribs which cross the back and toward the inner edge unite in parcels to form acute or knotted ridges. (The old shells are often plain.) The sutures have the dorsal sinus (D) shallow, the lateral (L) deep. The species are almost confined to the Oxford Clay and Kelloways Rock : as *A. Calloviensis* (Sow.) ; *A. Duncani* (Sow). ; *A. gemmatus* (Phil.), &c. (Von Buch rightly separated from these the *Dentati* in his original memoir, though they have been injudiciously reunited again.)

Dentati.—To this group we refer *Ammonites splendens, A. lautus, A. dentatus,* &c. of the Gault. The back is flat or concave, and margined by tubercles, or prominent ends of strong ribs, often united near the inner edge into tuberculated ridges, but not crossing the back. The sutures resemble in general form the preceding.

Flexuosi.—The back narrow, with borders tuberculated or serrated by the terminations of the ribs, and in a young state with a tuberculated keel. The ribs are ridged or tubercled near the inner edge. This group is quoted from the upper Oolitic and Chalk formations, and *A. asper* and *A. flexuosus* are examples.

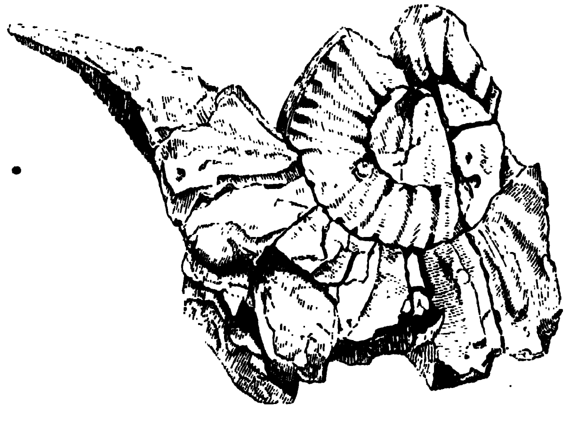
The classification above sketched is very far from perfect. It is difficult to define the groups, when we pass from the typical to the ordinary species, and there are many forms which refuse to be included in the formulæ. Still it is an admirable sketch, and when the *Ammonitidæ* are fully developed, according to the principles thus exemplified by Von Buch, we shall have them recognised, not as a genus with subdivisions, but as a family including many genera. (D'Orbigny's 'Palæontologie Française;' 'Annales des Sci. Nat.,' 1841, N.S., xvi. p. 113, also (1829) xvii. 267 ; xviii. 417 ; xxix. 5.)

Having given this sketch, it will be necessary to meet the question whether the *Ammonites* were external or internal shells. Cuvier and Lamarck thought that they were internal. The former says ('Règne Animal,' last edition), "The smallness of the last chamber might induce us to believe that, like the Spirula, they were internal shells." Mr. Owen, in his arrangement above quoted, says, "Animal unknown, presumed to resemble the Nautilus; shell external . . . . The last chamber the largest and lodging the animal;" and probably this was the actual state of things. Dr. Buckland, in his 'Bridgewater Treatise,' says, "The smallness of the outer chamber or place of lodgment for the animal is advanced by Cuvier in favour of his opinion that Ammonites, like the Spirula, were internal shells. This reason is probably founded on observations made upon imperfect specimens. The outer chamber of Ammonites is very seldom preserved in a perfect state ; but when this happens, it is found to bear at least as large a proportion to the chambered part of the shell as the outer cell of the *Nautilus Pompilius* bears to the chambered interior of that shell. It often occupies more than half, and, in some cases, the whole circumference of the outer whorl. This open chamber is not thin and feeble, like the long anterior chamber of the Spirula, which is placed within the body of the animal producing this shell, but is nearly of equal thickness with the sides of the close chambers of the Ammonite."



Ammonites obtusus. *a, b, c, d,* outer chamber.

It should be remembered that the specimen is apparently imperfect at the aperture. The siphon or tube of communication may be traced from *d,* where it opens into the last or outer chamber, along the edge



Ammonites rostratus.

of the section, *e, f, g, h, i*, to the very nucleus of the shell. The waved transverse lines represent the partitions of the chambers.

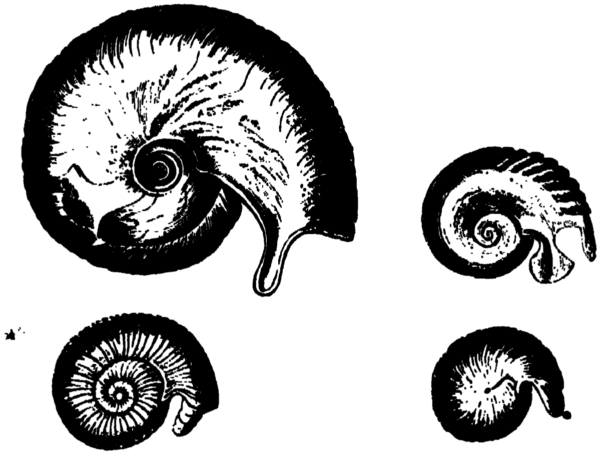
The large proportion of the outer chamber is very strongly marked in specimens of *Ammonites rostratus*, that have the aperture perfect or nearly so.

"Moreover," continues Dr. Buckland, "the margin of the mature Ammonite is in some species reflected in a kind of scroll, like the thickened margin of the shell of the garden snail" (*bourrelet* of the French), "giving to this part a strength which would apparently be needless to an internal shell. The presence of spines also in certain species (as in *Ammonites armatus, A. Sowerbii*) affords a strong argument against the theory of their having been internal shells. These spines, which have an obvious use for protection, if placed externally, would seem to have been useless, and perhaps noxious, in an internal position, and are without example in any internal structure with which we are acquainted."

Sir Henry de la Beche has proved from the mineral condition of the outer chamber of Ammonites from the Lias at Lyme Regis, that the entire body was contained in it, these animals having been suddenly destroyed, and buried in the earthy sediment of which the Lias is composed, before their bodies had either undergone decay or been devoured by the then existing crustaceans.

Dr. Buckland very happily illustrates the different arrangements by means of which a union of lightness and strength is secured to the shell, both from the external contormation and the mode in which the transverse plates are disposed; and as our limits will not allow us to enter minutely into the subject, we must refer the reader to the 'Bridgewater Treatise' for the interesting details, which show that a more perfect instrument for affording universal resistance to external pressure—an instrument in which the greatest possible degree of lightness combined with the greatest strength was required—could scarcely be imagined; and must confine ourselves to the doctor's summary:—"As the animal increased in bulk, and advanced along the outer chamber of the shell, the spaces left behind it were successively converted into air-chambers, simultaneously increasing the power of the float. This float being regulated by a pipe passing through the whole series of the chambers" (see the cut of *Ammonites obtusus*), "formed a hydraulic instrument of extraordinary delicacy, by which the animal could at pleasure control its ascent to the surface or descent to the bottom of the sea. To creatures that sometimes floated, a thick and heavy shell would have been inapplicable; and as a thin shell inclosing air would be exposed to various and often intense degrees of pressure at the bottom, we find a series of provisions to afford resistance to such pressure in the mechanical construction both of the external shell and of the internal transverse plates which formed the air-chambers. First, the shell is made up of a tube coiled round itself, and externally convex. Secondly, it is fortified by a series of ribs and vaultings disposed in the form of arches and domes on the convex surface of this tube, and still further adding to its strength. Thirdly, the transverse plates that form the air-chambers supply also a continuous succession of supports, extending their ramifications, with many mechanical advantages, beneath those portions of the shell which, being weakest, were most in need of them."

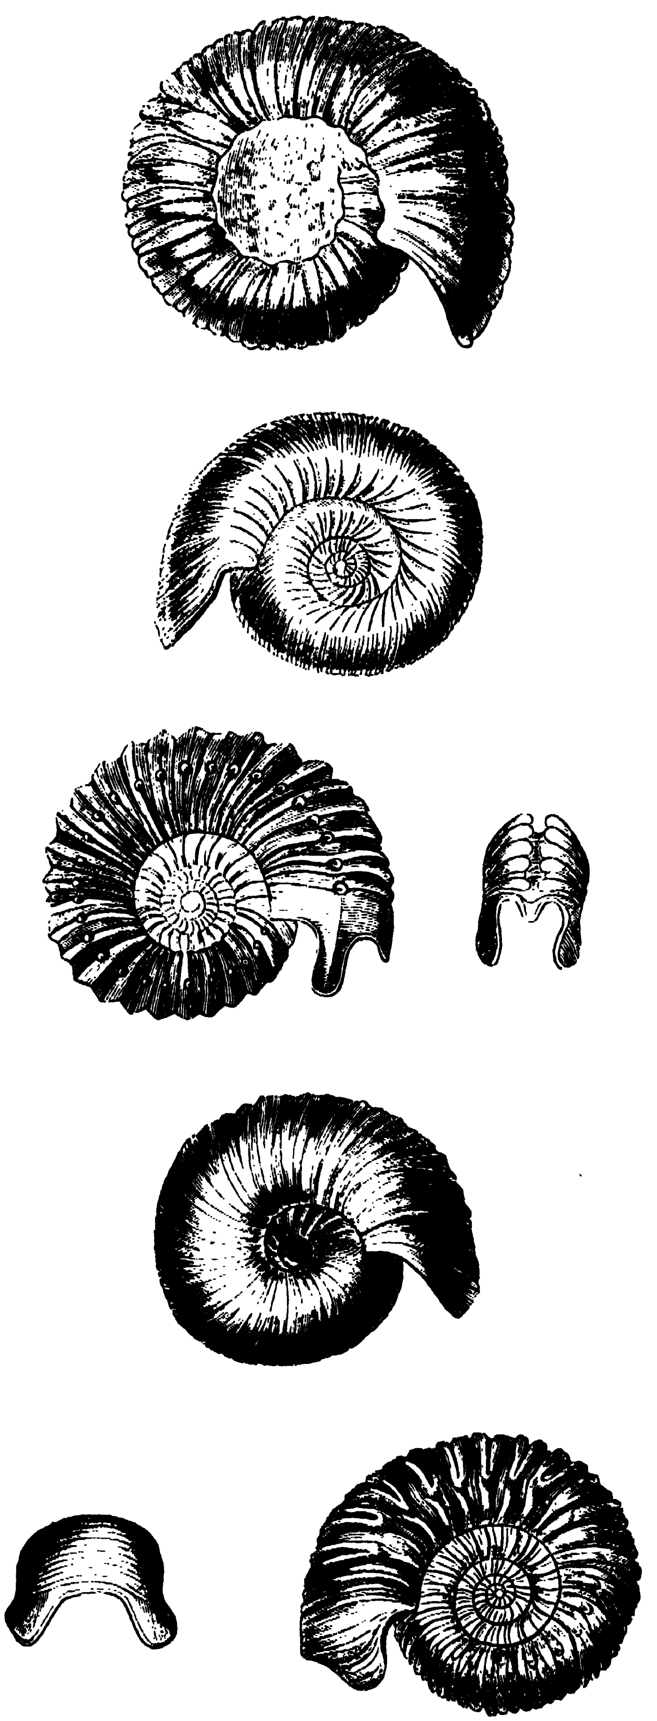
Ammonites with perfect mouths.



Reinecke,[*] Von Buch,[†] Zieten,[‡] and De Haan[§] are among those who have written treatises on this interesting genus, or have illustrated it.

The species of Ammonites are very numerous, and although the arrangement of Von Buch is at present the best, it is probable that when more is known of the form of the aperture, it will serve as a leading character.

Ammonites with perfect mouths.—(*Continued.*)



---

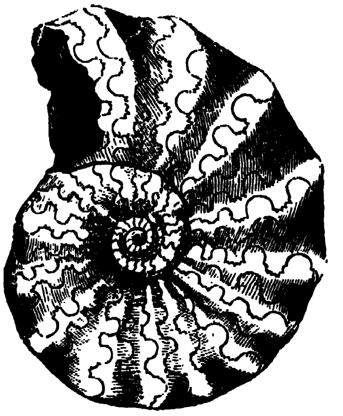
[*] Maris protogæi Nautilos et Argonautos, vulgo *Cornua Ammonis*, in agro Coburgico et vicino reperiundos, descripsit et delineavit, etc., D. I. C. M. Reinecke. Coburgi, 1818, 8vo.

[†] Ueber die Ammoniten in den älteren Gebirgs-Schichten. Gelesen in der Akademie der Wissenschaften, am 1 April, 1830. 4to. Recueil de Planches de Pétrifications remarquables, par Leopold de Buch. Berlin, 1831, folio.

[‡] Die Versteinerungen Würtembergs, &c. Stuttgart, 1830, and following years, folio.

[§] Specimen Philosophicum Inaugurale, exhibens Monographiam Ammonitearum et Goniatitearum, etc. 1825. Lugduni Batav.

The accompanying cuts, which are copied from De Blainville, will not only give the reader some idea of the shape of the aperture, but also of the external appearance of the shell, while the following, from Dr. Buckland's 'Bridgewater Treatise,' will convey a notion of the concamerations in some of the species. An internal view of a very simple form of those and of the siphon or pipe will be seen in the cut of *Ammonites obtusus.*



Ammonites nodosus.

Geological Distribution.—Professor Phillips, in his 'Guide to Geology,' published in 1834, since which time numerous additions have been made, thus distributes the Ammonites among the different formations.

SUB-GENERA OF AMMONITES.

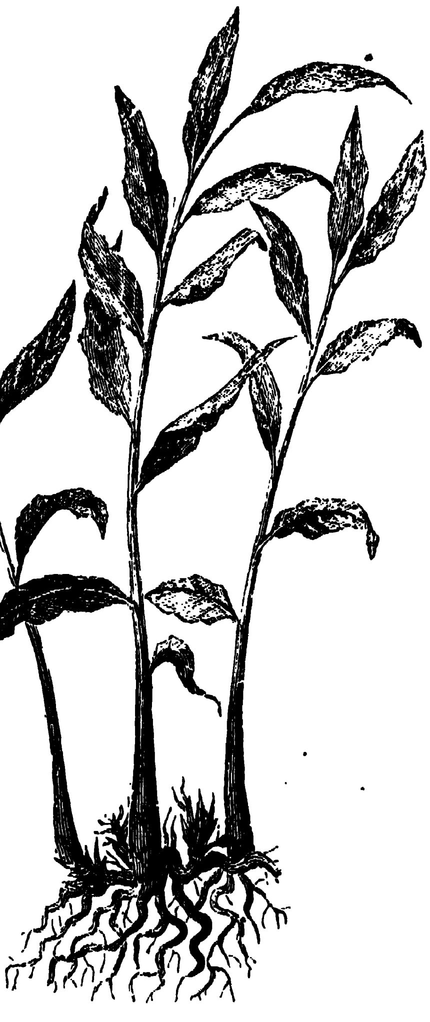
Total, 223 species.

Geographical Distribution.—As the Ammonites were evidently principal agents for keeping within bounds the mollusks, &c., the crustaceans, and perhaps fishes of the periods prior to the Chalk Formation, and belonging to the latter epoch, we should expect to find them widely distributed. Accordingly, they occur in Europe, Asia, and America in strata apparently of the same date. In some instances, the genera and even the species are identical. Dr. Gerard found in the Himalaya Mountains, at an elevation of 16,000 feet, *Ammonites Walcottii* and *Ammonites communis,* fossils that are found in the Lias of Lyme Regis. M. Ménard met with one in the Maritime Alps at an elevation of 1500 toises. Their numbers must have been great. M. Dufresne informed Lamarck that the road from Auxerre to Avalon in Burgundy was absolutely paved with them. The individual agency too of some of these carnivorous instruments for preserving the balance of marine animal power must have been of no small importance. Lamarck says that he has seen Ammonites of two feet (French) in diameter. Mr. James Sowerby and Dr. Mantell record Ammonites in the Chalk with a diameter of three feet; and Dr. Buckland states that Sir T. Harvey and Mr. Keith measured Ammonites in the Chalk near Margate which exceeded four feet in diameter; and this in cases where the diameter could have been in a very small degree enlarged by pressure.

AMOIBITE, in Mineralogy, a variety of Arsenical Nickel, containing from 40 to 50 per cent. of nickel and 14 per cent. of sulphur.

AMO'MUM, a genus of plants belonging to the natural order *Zingiberaceæ.* It consists of species having white flowers collected in close heads, which arise from the base of the leaves, and only just raise themselves above the ground; the lower lip of the flower is very broad and large compared with the others, and the other has a two-lobed crest. The seeds are contained in a loose skin, and are inclosed in a rather tough capsule, which is separated into three cells by as many membranous partitions, and finally opens into three valves. The leaves are of a broadly lanceolate or oval figure tapering to the point, and enwrapping the stem like a sort of sheath.

A. Cardamomum has a root-stock creeping under the surface of the soil like that of the Ginger, but it is smaller. The stems rise obliquely to the height of from two to four feet. The leaves are alternate. Flowers in spikes, seated in lanceolate acute villous scarious ash-coloured bracts. The tube of the corolla slender. The anther double, with a large three-lobed concave crest. The fruit a capsule containing roundish angular dotted brown seeds. This plant is a native of the mountainous parts of Java and Sumatra, and is commonly cultivated in the gardens of India. The seeds are aromatic, and are used by the Malays instead of the true Cardamoms, which are the produce of the *Elettaria Cardamomum.* [ELETTARIA.] Sir J. E. Smith states that this plant is the *Amomum verum* of the older botanists.



Amomum Cardamomum.

A. angustifolium is a sharp-leaved species, and a native of marshy ground, in Madagascar. It is cultivated in the Mauritius. It has a deep blood-red calyx, and the outer segment of the corolla is red. The whole plant is aromatic, and the fruit constitutes the *Cardamomum majus* of the older writers.

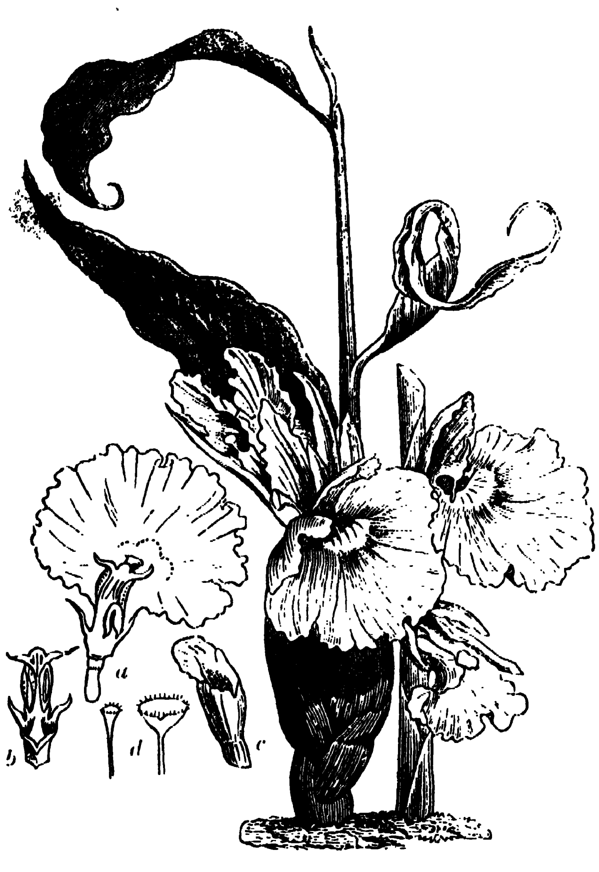
A. aromaticum is a native of the valleys on the eastern frontiers of Bengal. The fruit has similar qualities to those of the true Cardamoms, for which they are often sold to the druggists of India.

A. Grana-Paradisi has a perennial root-stalk, giving off erect slender stems, 3 feet high. The leaves are numerous and crowded. The capsule is large, 1½ inch long, and half-an-inch in diameter. It has a very strong aromatic odour and flavour. The seeds have the same properties as the Cardamoms. The plant is a native of Guinea, near Sierra Leone. The fruits are known by the name of Grains of Paradise, and Melligetta or Malaguetta Pepper.

A. grandiflorum, of Smith, is also a native of Sierra Leone. It has large flowers, and yields seeds, which differ from those of Grains of Paradise in being gray or lead-coloured, much less polished, and possessing a totally different flavour, resembling that of camphor. They may be used for the same purposes as the Cardamoms.

The Cardamoms of commerce are the capsules, which are gathered as the seeds ripen, are dried in the sun, and are then fit for sale. The small capsules, or Lesser Cardamoms, are the most valuable. [CARDAMOMS, in ARTS AND SC. DIV.]

(Lindley, *Flora Medica.*)



Amomum grandiflorum.

a. The lip and a back view of the anther. *c.* Calyx.
b. A front view of the anther. *d.* Stigma.

AMPELI'DEÆ, one of the names of the Vine Tribe. [VITACEÆ.]

AMPHERI'STUS, a Fossil Fish, from the Isle of Sheppy. (König, *Icon. Fossil.*)

AMPHI'BIA (from the Greek word *ἀμφίβιος*, which signifies 'having a double life'), the name of an order of the class of *Reptiles*. In common conversation we are accustomed to call all mammals, such as seals, otters, beavers, &c., amphibious, whose organisation disposes them to resort indifferently either to the land or water for procuring food, and other purposes, or whose habits are at once terrestrial and aquatic; thus we usually denominate the Common Campagnol (*Arvicola amphibia*), and the White-Bellied Shrew (*Sorex fodiens*), the Water-Rat, and Water-Shrew respectively, and consider them in every respect as amphibious animals. But in this sense of the word every land-animal is more or less amphibious, for all resort occasionally to the water, and, with the single exception of man, all appear to have an instinctive power of swimming. Previous to the time of Linnæus, the earlier naturalists attached no more definite meaning to the word than that which was sanctioned by popular custom, and which, it will be observed, is more properly expressed by the term aquatic. The great Swedish philosopher, however, rejected this vague and improper signification, and applied the term generally to the third class of his system of zoology, which comprised not only all the animals since more properly denominated *Reptiles*, such as the tortoises, lizards, serpents, and frogs, but likewise the Cartilaginous Fishes. Linnæus was evidently ignorant of the true characters and natural limits of this class of animals. The term *Amphibia* was certainly very applicable to many of the genera and species which it embraced, but with regard to the great majority of them it was an absolute misnomer. The shark and the ray are as incapable of existing out of the water as many of the common lizards are of living in it, and consequently neither the group which Linnæus proposed to establish, nor the name by which he designated it, has been adopted by more recent zoologists. The Cartilaginous Fishes have been referred to the other aquatic tribes, with which their habits and organic conformation naturally connect them, and the remainder of the class, which stands in Gmelin's celebrated edition of the 'Systema Naturæ' under the name of *Amphibia*, is admitted into modern systems under the more appropriate designation of *Reptiles*.

Taken in its strict and literal sense, the term amphibious would apply only to such animals as have the power of living indifferently at the same time, either upon land or in water. To fulfil this condition it is necessary that a truly amphibious animal should be provided with the means of breathing in either of these elements, that is, that it should simultaneously possess both lungs and gills. Now there are four genera of batrachian reptiles which actually do possess this extraordinary double apparatus for extracting the principle which supports animal life indifferently from either element; and these, as Baron Cuvier has justly observed, comprise in reality the only known vertebrated animals which are truly amphibious. They are the *Axolotls*, the *Menobranchi*, and the *Sirens*, all of which inhabit the rivers and lakes of America, and the *Proteus*, which is found in subterraneous streams connecting certain lakes in Carniola and Hungary. These, then, are the only strictly amphibious reptiles; but if the term is taken in a little more extended sense, it may, without impropriety, be applied to the entire order of *Reptiles* which M. Brongniart, and after him most modern naturalists, denominate *Batrachians*, because all these animals, without exception, breathe by means of gills in their tadpole state, and only acquire lungs when they assume the more mature and perfect form of reptiles. In this sense the term is now employed by English naturalists.

Some, indeed, as Mr. Bell, Dr. Grant, and other writers, separate the *Amphibia* from the *Reptiles*, as a distinct class.

The *Amphibia* differ essentially from the other three orders of Reptiles: *Chelonians* (Tortoises), *Saurians* (Lizards), and *Ophidians* (Serpents). They have no ribs, or rudiments of ribs only. Their skin is naked, being without scales. They have feet. The male has no external organs distinctive of sex. In the Frog Tribe the ova are fecundated on their exclusion from the body of the female: they are shelless and generally laid in the water. The young, which are called *Tadpoles*, when first hatched, breathe by means of branchiæ, or gills, very much after the manner of fishes, being in their early stage of growth quite unlike their parents, and, in that state, forming a natural passage to the last-named class of animals. These branchiæ disappear in the higher *Amphibians*, and one order has therefore been named the *Caducibranchiate Amphibia*, which have been divided into—first, the *Anourous* or *Tailless Batrachians*, having no tails except in their young state, including the Frogs and Toads; and second, the *Urodèles* or *Tailed Batrachians*, such as the Salamanders.

Under the *Perennibranchiate Amphibia* are included the *Proteus*, *Siren*, *Menobranchus*, and *Axolotl*.

The following arrangement of the *Amphibia* or *Batrachians* has been published by Messrs. Dumeril and Bibron, in their elaborate 'Erpétologie Générale': –

Characters
- Body, varied in form; skin naked; most frequently without either carapace or scales.
- Head, with two occipital condyles, not carried upon a narrower neck.
- Feet, variable, as regards their presence, their number, their proportion; toes most frequently without claws.
- Sternum, most frequently distinct, never united to the ribs, which are short or null.
- Male organs of generation not projecting. Eggs with soft not calcareous shells. Young, subject to metamorphosis.

Limbs		Suborders.		Groups.			Families.
Null.	Body serpentiform	*Peromèles*		*Ophiosomes*			1. *Cæcilioïdes.*
Four or two.	No tail,	*Anoures*, with a tongue	Distinct	*Phaneroglosses*: with the upper jaw	Toothed; ends of toes	Little or not dilated	2. *Raniformes.*
						Very dilated	3. *Hylæformes.*
					Without teeth		4. *Bufoniformes.*

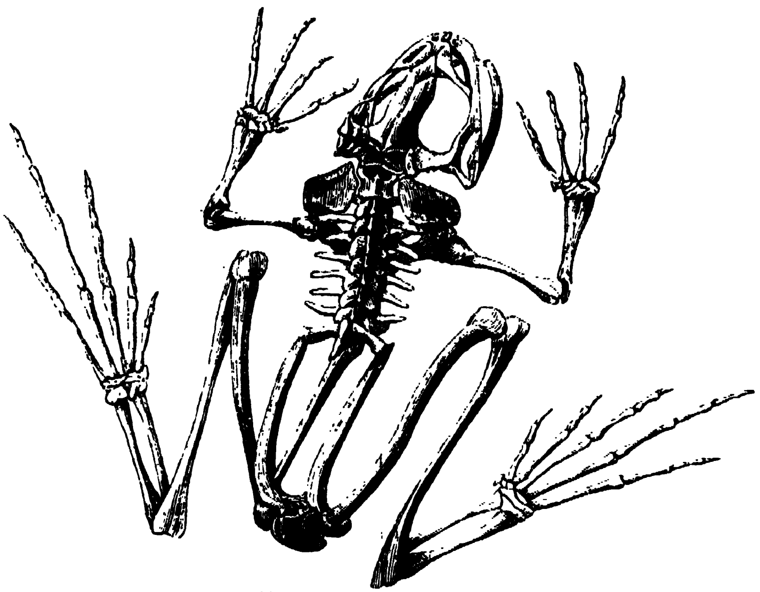
In this article we shall speak of the organisation and natural history of the *Amphibia* in two groups: first, the *Anourous* or *Tailless Amphibia*, and secondly, the *Urodèles* or *Tailed Amphibia*.

ANOUROUS OR TAILLESS AMPHIBIA.

Skeleton.—The skull, in the Reptiles generally, is made up of the same parts nearly as that of the mammiferous animals, though the proportions are different. But the lower *Amphibia*, which approach the fishes in this particular, have not the internal cavity corresponding so completely with the surface of the encephalon as the other Reptiles. The skull is very much flattened; and small as the cerebral cavity is, it is by no means filled with the brain. It is narrower and more elongated in the species which pass their whole lives in the water than it is in the *Anourous Amphibia*, or True Frogs.

The vertebral column commences at the posterior part of the head, and, unlike the rest of the Reptiles, the *Batrachians*, like the rays, the sharks, and the mammiferous animals, possess two condyles situated on the sides of the vertebral hole. In the Tadpole the vertebræ are of the same calibre throughout, but a difference takes place when the limbs are developed. At this period, the vertebral canal diminishes gradually in length, the spinal marrow contracts, and no trace of the canal is left in the elongated coccyx. It is in the *Tailless Amphibia* that the vertebral column is shortest, for the Frogs have only ten and the Pipas but eight vertebræ.

As a general rule, the anterior extremities are shorter than the posterior limbs; but in some of the Frogs especially, the lower extremities are twice or thrice as long as the anterior feet, as might be expected in animals whose progression is principally effected by leaps. Ribs there are none; but the sternum is highly developed and a large portion is very often cartilaginous. It receives anteriorly, or in its mesial portion, the two clavicles and two coracoids which fit on to the scapula. The whole makes a sort of band which sustains the anterior extremities, and an elongated disk which forms a support for the throat, and assists in the offices of deglutition and respiration. Another disk extending backwards, being for the insertion of the recti muscles, protects the abdominal viscera in some species. The pelvis is well developed in the Frogs, especially in the Pipa, and though apparently deprived of all traces of a tail after undergoing their last transformation, there remains, internally, a true coccygeal piece, most frequently even moveable and elongated, but without anything like vertebral form.



Skeleton of the Common Frog.

The bone of the humerus or arm is single, and is long in proportion to the bones of the fore-arm, which are united throughout their length, their duality being manifested by a simple furrow or depression. These bones are distinct in the reptiles generally, and the radius is generally rather the longest; the ulna is prolonged backwards into a kind of olecranon, and sometimes this apophysis is distinct, and becomes a sort of sesamoïd-bone in the thick part of the tendon of the extensor muscles. The Pipas, the Tortoises, and the greater part of the Saurians have this conformation. The bones of the carpus, or wrist, exhibit nothing extraordinary in their structure; nor do those of the fingers, which are without nails or claws, require particular notice.

The bones of the well-developed pelvis present considerable differences in the various genera of *Anourous Amphibia.* Thus in the Frogs (*Rana*) and the Tree-Frogs (*Hyla*), the ossa ilii are very much elongated, articulated in a moveable manner on the sacrum, and very much approximated below towards the cotyloid cavity; so that the two heads of the thigh-bones seem to be placed in contact, a conformation which much influences the action of the posterior limbs upon the trunk in the execution of the motions of swimming and leaping. In the *Pipa*, or Surinam Toad, the ossa ilii are very much widened at the point of junction with the sacrum, which is, itself, dilated, forming a strong union by means of a true symphysis. The femur, or thigh-bone, is very much elongated, and slightly curved in the form of the letter S in the Frogs (*Rana*), and in the Tree-Frogs (*Hyla*); it is a little shorter in the Toads (*Bufo*), and is flattened in the *Pipa.* The bones of the leg (tibia and fibula) are, in the Reptiles, generally distinct; but in the *Anourous Amphibia, Rana, Hyla*, and *Pipa*, for instance, they are so soldered together as to form but a single articulation with the femur and tarsus, and to present the appearance of a single very-much-elongated bone, which some have erroneously considered as a supernumerary bone, or second femur. The knee-joint and articulating bones are so disposed that the feet have always a direction outwards. In the Reptiles generally, the posterior feet are more developed than the anterior limbs; and this modification is particularly observable in the *Anourous Amphibia*, which have the tarsus so much elongated as to induce some to consider the first bones composing it to be a fibula or tibia. The bones of the metatarsus correspond to the number of toes.

The Teeth.—As these are very important organs in the whole of the *Amphibia*, we shall now present an abstract of this subject from Professor Owen's celebrated work entitled 'Odontography.' He remarks that the variations which the dental system presents in the *Amphibia* are more conspicuous in the number, situation, and structure of the teeth, than in their form or mode of attachment. Certain Batrachians, he observes, are edentulous, the genus *Hylaplesia* among the Tree-Frogs, for example, and the *Bufonidæ*, or Toad Family, with the exception of some species of *Bombinator.* The teeth when present are described by him as generally numerous, simple, of small and equal size, and close-set, either in a single row or aggregated, like the teeth of a rasp, and he points out a characteristic condition of the dental system in fishes, namely, the absence of teeth on the superior maxillary bone, as being continued in those genera of Perennibranchiate Batrachians which stand lowest in the class of Reptiles; not only the superior maxillary teeth, but the bones themselves are absent, he observes, in *Siren, Menobranchus*, and *Proteus.* In the *Siren*, he describes the lower margin of the intermaxillary bones, and the sloping anterior and upper margin of the lower jaw, as trenchant, and each encased in a sheath of firm, albuminous, minutely fibrous tissue, harder than horn. The bones thus armed slide upon each other, he tells us, like the blades of a pair of curved scissors, when the mouth is closed, and are well adapted for dividing the bodies of small fish, aquatic larvæ, worms, &c. The horny substitute for teeth in the lower jaw is supported by the bony element corresponding with the premandibular of the *Lepidosiren.* [PROTOPTERUS.] A second bony piece applied to the inner surface of the branch of the jaw (representing the splenial or opercular element in the jaw of the crocodile) is beset with numerous minute pointed teeth, set in short oblique rows, and directed obliquely backwards. The palatal surface of the mouth is described as presenting on each side two flat, thin, and moderately broad bones, forming an apparently single, oblique, oval plate, which converges to meet its fellow at the anterior part of the palate, so as conjointly to constitute a broad rasp-like surface in the form of a chevron. The Professor regards the anterior long plate on each side as the representative of the divided vomer, and it supports 6 or 7 oblique rows of small pointed retroverted teeth; the smaller posterior plate, which he thinks may probably be the homologue of the pterygoïd, is beset with 4 rows of similar teeth; and thus we have 10 or 11 rows on each side of the chevron of the palate. The greatest number of denticles (11 or 12) is in the middle rows; in the anterior and posterior rows they are fewer; all are of similar size and form, corresponding with those of the lower jaw opposed to them. "The condition of the dental system in this, the lowest of the class of reptiles," says Mr. Owen, "is not without interest, independently of the absence of the superior maxillary teeth, and of the presence of the palatal and inferior maxillary *dents en carde.*" If, for example, the dense sheath of the trenchant anterior parts of the upper and lower jaws had been completely calcified and converted into hard dentine, the correspondence between the *Siren* and the *Lepidosiren* would have been very striking in this part of their structure; but the maxillary sheaths of the *Siren* being composed of horn, and being moreover easily detached from the subjacent bones, much more closely resemble the deciduous mandibles of the Tadpoles of the higher Batrachians. (Part ii., pp. 188, 189.)

In the *Axolotl* also the ichthyic character of the rasp-like teeth are aggregated in numerous rows upon the palatal region of the mouth, and upon the splenial or opercular element of the lower jaw; but here, Mr. Owen observes, the superior maxillary bones are developed, and support teeth. The premandibular and the intermaxillary bones, he adds, instead of presenting the larval condition of the horny sheath, have their alveolar border armed with a single row of small, equal, fine, and sharp-pointed denticles, which are continued above along the maxillaries; thus, he observes, establishing the commencement of the ordinary Batrachian condition of the marginal teeth of the buccal cavity. As in the *Siren*, the dentigerous bones of the palate consist of two plates on each side; the anterior pair, or vomers, converge and meet at their anterior extremities, and the minute denticles which they support are arranged quincuncially. The posterior pair of bones continued backwards, according to the usual disposition of the pterygoïds, abut against the tympanic or quadrate bones; and the denticles are confined to the anterior part of their oral surface, resembling, in their arrangement and anchylosed attachment, those of the palatal series, of which they are the posterior termination.

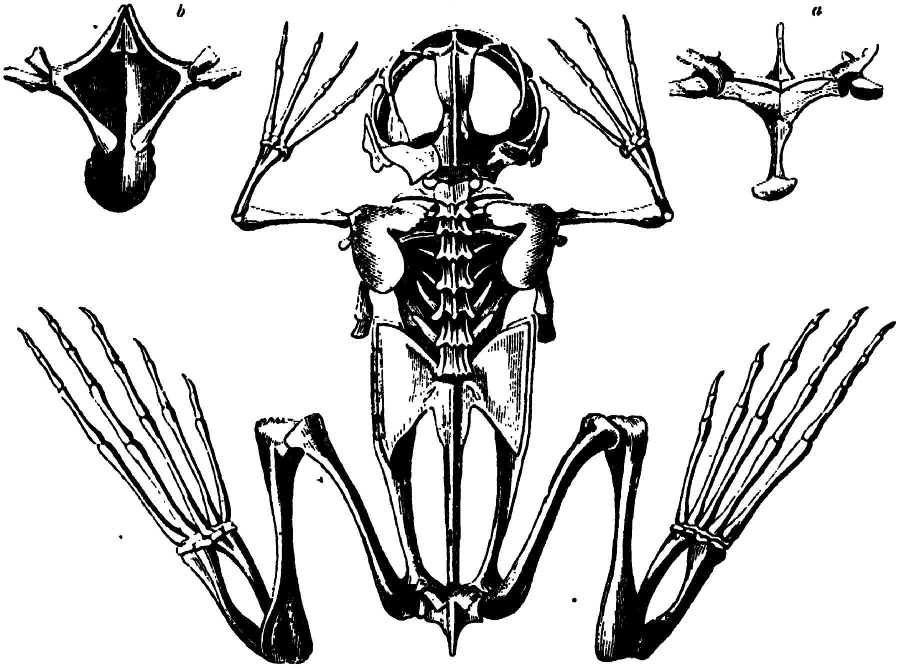
The superior maxillaries and their teeth are, it appears, wanting in *Menobranchus* [NECTURUS]; but in this form an advance to a higher type of dentition is perceptible by the arrangement of the teeth in a single row, both upon the roof and at the margins of the mouth. The intermaxillary bones are produced backwards, and the single row of small pointed teeth which they support is opposed to a similar series upon the premandibular bones below. The palatal teeth form a single row on each of the broad bones which correspond with those described by Cuvier as the divided vomer in the higher Batrachians, and extend backwards upon the pterygoïds, which support a few teeth.

The three preceding genera are perennibranchiate, and though the *Proteus*, like them, always retains its external gills, it offers a further advance to the dentition of the higher Batrachians, and to that of the *Amphiuma* especially. Each intermaxillary bone carries on its alveolar border a row of 8 or 10 minute, fine, sharp-pointed teeth, and each premandibular bone is armed with a greater number of similar but larger teeth, arranged also in single series. The palatine bones (two vomers of Cuvier) support a row of denticles, similar to the intermaxillary crescentic series, and parallel with them; but Mr. Owen points out that the horns of the palatal dental crescent are continued much farther back, terminating, as in *Menobranchus*, on the anterior part of the pterygoïd bones. Twenty-four teeth are contained in each half of the "crescentic or chevron-shaped series," as the arrangement is appropriately designated by the Professor, who adds that the superior maxillary bones are represented in this form by mere cartilaginous rudiments.

The *Amphiuma*, like the *Proteus*, presents the Batrachian disposition of the teeth in a single close set series along the alveolar border of both upper and lower jaws. "The upper series extends along well-developed maxillary and intermaxillary bones, and in the extent of the maxillary and palatal series, especially in *Amphiuma tridactylum*, the indication of a highly interesting character in regard to the affinities of an extinct race of gigantic Batrachians with biconcave vertebræ is discernible."

In the *Amphiuma* the palatal teeth run in a single close-set row along the lateral margins of the vomer, forming an acute angle at its anterior portion, whence the series is extended backwards on either side nearly longitudinally, and parallel with the maxillary teeth. "All the teeth are conical, pointed, slightly curved backwards and inwards; their points glisten with a yellow metallic lustre," whence Dr. Mitchell's name *Chrysodonta*. The number of teeth in *Amphiuma means* is considerably less than in *Amphiuma tridactylum*.

"The *Menopome* exhibits," says Professor Owen, "the same essentially Batrachian condition of the teeth as the *Amphiuma*; but in their disposition, and in the disposition and form of the vomer, it makes a near approach to the Caducibranchiate group, and allies itself most closely with the gigantic Newt of Japan (*Sieboldia*, Bonap.), and with that equally gigantic extinct species of Newt so noted in palæontology as the *Homo Diluvii Testis* of Scheuchzer. In the persistence of the branchial apertures, and the more complex structure of the os hyoïdes, the *Menopome* however manifests its generic distinctness from the *Sieboldia*. The single close-set series of small, equal, conical, and slightly-recurved teeth describes a semicircle on both the upper and lower jaws: the row of similar but smaller teeth on the anterior expanded border of the divided vomer runs parallel with and at a short distance behind the median part of the maxillary series. The premandibular teeth are received into the narrow interspace between the two rows in the upper jaw when the mouth is closed. The teeth of the *Menopome*, as of the *Amphiuma*, are anchylosed by their base and part of its outer side to a slightly elevated external alveolar ridge.



Skeleton of *Dactylethra Lalandii*.

The figures on each side show the difference of the sternum in the Common Frog, and in the *Dactylethra*; *a* represents the sternum of the former; *b* that of the latter.

"*Sieboldia*.—The Perennibranchiate or Fish-like *Amphibia*, 'doubtful reptiles' as they have been termed, lead by so easy a series of transitions to the Caducibranchiate group, in which all external trace of the branchial apparatus is lost, that the artificial nature of such a division of the order is evident, and some naturalists have even hesitated whether to separate, generically, the last of the Perennibranchians from the species *Sieboldia gigantea*, with which the description of the dental system in the higher division of the Batrachians is here commenced. As regards the teeth, the difference between the great aquatic Salamander of the volcanic mountains of Japan and that of the Alleghanies is very slight, and merely specific; the form, disposition, and attachment of the teeth are the same in *Sieboldia* as in *Menopome*; they differ slightly in the relative size, those of the Japanese Newt having the advantage in this respect, with a somewhat deeper implantation of their anchylosed base, and the alveolar parapet of the intermaxillary bones is higher and is slightly incurved. ' There are 14 teeth in each intermaxillary, 72 in each superior maxillary, and 64 teeth in each vomer of the *Sieboldia gigantea*."

All the *Caducibranchiate Amphibia* with tails, as the Newts and Land Salamanders, have teeth on the inferior maxillary and vomerine bones, as well as on the intermaxillaries and superior maxillaries.

The Frogs have no teeth on the lower jaw, though in some species (*Ceratophrys* for example) the alveolar edge of the lower jaw-bone is finely notched or dentated. The *Bufonidæ*, as a general rule, are toothless, but in the *Bombinatores* the subgenus *Hyladactylus* has teeth upon the vomer, and *Sclerophrys* has teeth on both the intermaxillary and maxillary bones.

Muscular System, particularly as relating to Locomotion.—The muscles destined to give activity to the framework, examples of which are given below, are, like those of all the Reptiles, remarkable for their irritability. There are not wanting zoologists who have seen Toads, Salamanders, Tortoises, and Serpents, deprived of their heads and skins, but kept moist, display muscular motion for whole weeks. In the *Anourous Amphibia*, the Frogs especially, the muscles of the abdomen are more developed than in the other Reptiles, offering in this particular some analogy to the abdominal structure of the Mammifers. But it is in the disposition of the muscles of the thigh and leg in the Frogs and others of this group, that the greatest singularity is manifested. These, whether taken conjointly or singly, present the greatest analogy with the muscular arrangement of the same parts in Man. We find the rounded, elongated, conical thigh, the knee extending itself in the same direction with the thigh-bone, and a well-fashioned calf to the leg, formed by the belly of the gastrocnemii muscles. It is impossible to watch the horizontal motions of a frog in the water, as it is impelled by these muscles and its webbed feet, without being struck with the complete resemblance in this portion of its frame to human conformation, and the almost perfect identity of the movements of its lower extremities with those of a man making the same efforts in the same situation.

We have seen that the ribs are absent in the *Anourous Amphibia*, and the functions of respiration, as well as those of deglutition, being carried on by means of particular muscles, as we shall presently have to notice, those bones would have been mere incumbrances. In the Frogs, the muscles are not attached to the skin, which envelops the whole muscular arrangement in a sort of insulated, insensible, moveable bag: in the *Urodèles*, on the contrary, the integuments serve as the point of insertion to almost all the active organs of motion.

The locomotion of the *Anourous Amphibia* on land consists in walking, running, and leaping, in its various modifications; the latter being the motion most prevalent. The greater part of them are excellent swimmers; and when they betake themselves to this exercise, the body is extended horizontally, and the animal is propelled by the mechanism of the lower extremities alone—a mechanism admirably adapted to this mode of progression, as well as to the other varieties of movement which the necessities of the animal require. By the aid of these well-developed lower limbs, and the prodigious power of their muscular and bony levers, a Frog can raise itself in the air to twenty times its own height, and traverse, at a single bound, a space more than fifty times the length of its own body.

Digestive Organs.—The *Anourous Amphibia*, in their adult state, are, like the greater part of the existing Reptiles, carnivorous, and swallow their living prey without mastication. The mouth in many of them is very wide; so wide, indeed, in some (the large Frogs and Pipas, for instance), as to admit of their swallowing vertebrated animals; but insects, annelides, and small mollusks form the chief of their food. They have no true fleshy lips, nor indeed have any of the Reptiles; but the fresh-water tortoises are furnished with folds of skin as a covering for their cutting jaws, and perhaps as a more complete apparatus for shutting the mouth. The same conformation is observable in the greater number of the Tadpoles of the Batrachians, the larger portion of which, in their adult state, have the lower jaw received under a soft skin which covers and edges the mandible. The branches of the lower maxillary bone are rarely soldered at the symphysis, and sometimes, as in the genera *Rana* and *Hyla*, there is, at the point of junction, a mere cartilage which admits of a certain amount of motion. In the Frogs and the *Urodèles*, the number of pieces composing each of the branches amounts to three. One of these pieces corresponds with the symphysis, and is armed with teeth; the second serves for articulation, and the third is situated backwards, and prolonged below. On the palate of many of these *Amphibia* are certain processes which may be termed teeth; but these are pointed, and not tubercular, as the old error of naming some of the teeth of fossil fishes *Bufonites* might lead us to suppose. These palatal teeth form a part of the bones to which they are attached, as in the case of fishes.

The tongue performs a leading part in the capture and deglutition of the prey. In the greater portion of this group the structure of this organ is altogether anomalous, and its insertion is equally at variance with the mode adopted in the other vertebrated animals. It is very soft, fleshy almost throughout, and is not supported at its base by an os hyoïdes. Its attachment is the reverse of that generally seen, for it is fixed in the concavity which is formed by the approach of the two branches of the lower jaw towards the symphysis. In a state of repose, and when the mouth is shut, this tongue, which has its root, so to speak, in the interior edge of the anterior part of the lower jaw, has its free extremity in the back part of the mouth and before the aperture of the air-passages; but when the animal puts it forth, it is considerably elongated and thrown sharply out of the mouth, as if by an effort of expulsion. The end reaches to a considerable distance, as, turning on the pivot of its anterior fixture, it is reversed in such a manner that the surface which was below when the tongue was in the mouth, and in a state of repose, is, when it is thrown out, above; and when the tongue is returned into the mouth, the surface, which was an instant before above, resumes its original position, and is again beneath. The organ is armed with a tenacious viscous secretion; and when it touches the prey, the latter adheres so firmly to it, that it is carried back with the tongue into the mouth. There it is, in most cases, compressed, involved again in a glutinous sort of saliva, and almost instantly submitted to the act of deglutition. The motion of throwing out and returning the tongue is often performed with a rapidity which the eye can hardly follow. If any one will observe a toad in a melon-frame, he will see the ants or other insects which come within shot of its tongue disappear; but his vision must be very acute and prompt to detect the action of the tongue. The muscles, whose office it is to move the bones, cartilages, and other parts of the mouth, act more especially upon the lower jaw, upon the bone of the mandible, and upon the tongue, which, after being shot forth as we have endeavoured to describe, is returned and swallowed, as it were, with the captured prey, and the act of deglutition is continued till the food is lodged in the stomach.

The pharynx in mammiferous animals consists of that backward cavity of the throat, into which the lower orifices of the nostrils, the orifice of the mouth, the canal of the ear, the larynx, and the œsophagus open; but in the reptiles there cannot be said to be any true pharynx; for the nostrils, as well as the glottis, open into the mouth, the œsophagus commences immediately behind the nostrils, and the muscles that act more especially upon these parts and upon the tongue are those that begin the act of deglutition: we shall presently see that these same muscles are also put in requisition to force the air necessary for respiration into the glottis and trachea, in order to supply the cavity of the lungs. The stomach of the *Anourous Amphibia* does not require any particular notice; but the maxim that the more carnivorous an animal is, the shorter and the less flexuous is its intestinal canal, is well illustrated in that tribe. The Tadpole, which lives upon vegetables, possesses an extremely long digestive tube; but in its perfect state, and when its appetite has become altogether carnivorous, the intestines become very much shortened, losing four-fifths of the length which distinguished them when the animal was in its early stage of existence. The vent is rounded and wrinkled. The liver generally consists of three lobes, and the gall-bladder adheres to and is hidden in the concavity of the liver, very high up. The spleen in the Frog and Toad is rounded, not of large dimensions, and situated in the mesial region, under the intermediate lobe of the liver. There is also a pancreas, and the chyliferous veins may be distinctly traced. The digestive organs vary considerably in the Tadpole. In this early stage they have a mouth furnished with lips, and horny cutting processes, that act as jaws in the division of the vegetable food which forms their principal nourishment, and their intestinal canal is coiled spirally within their large rounded abdomen. The metamorphosis is complete, internally as well as externally, when this armed little mouth is changed into the widely-opening gape, which reaches beyond the eyes, and the animal swallows its living prey entire. In this their last stage they can endure a long abstinence. They grow slowly, and they live to a considerable age. The skin which edges their jaws is soft, and forms a sort of gum or external lip; their under-jaw is received into a kind of rim or groove, which runs along the upper-jaw, and its two branches are slightly moveable towards the symphysis: this junction of the jaws is as complete as the shutting of a well-fitted lid of a snuff-box.

Circulating System.—The circulation in the *Anourous Amphibia* varies with the different metamorphoses which the animal undergoes. In the early or tadpole stage the whole of the blood is driven by the heart into the branchial vessels, the circulation at that period being the same as it is in fishes. The apparently single auricle (for according to the observations of Dr. Davy and of Messrs. Saint Ange and Wébert, it is in fact separated into two divisions), or rather the partition which exists at the point where the oxygenated blood arrives through the pulmonary veins, can hardly be said to be distinct, and the venous blood, which is poured into it by the large vena cava, penetrates finally into the single ventricle, which, by contracting, pushes the blood into the single arterial trunk, furnished at its base, near the valvules, with a sort of bulb, or contractile swelling. This artery, which contains the black or venous blood, is divided into two trunks, one directed to the right, the other to the left; and these are then subdivided into two, three, or four branches, according to the number of the branchial leaflets: on their arrival there, they inosculate with the venous trunks, and by that time the blood has assumed its arterial quality and colour. These arterial veins unite successively, so as to form, by means of two principal trunks, the origin of one great artery, or aorta descendens, which is, at the point of its formation, placed near the head, to which it gives off many branches, and continues to descend down the vertebral column.

But when the time of metamorphosis arrives, and when the animal which had been breathing by means of gills is to respire through the medium of lungs, an entire and necessary change takes place. In proportion as the branchiæ of the Tadpole are destroyed and absorbed, the calibre of the venous arteries, which were distributed to them, diminishes gradually, till they are at last entirely obliterated. The first of these vessels then develops itself, and receives on each side the whole of the blood, giving off three principal trunks—one for the head, corresponding to the carotid artery; one for the anterior limbs, or a branchial artery; and one, the longest of all, for the cellular lung, which is of considerable volume. The rest of the principal trunk follows the mesial line, and unites with its congener, so as to form a true aorta for the supply of the viscera and lower extremities, which acquire their large dimensions at this period.

Respiratory System and Vocal Organs.—The absence of the ribs prevents any application of costal influence upon the respiratory organs of the *Anourous Amphibia*, as is the case with the mammiferous animals; but though their form, as well as the medium in which they live, is so totally different in the early and late part of their life, the principle of action on these organs is nearly the same. The young may be said to swallow water, or at least receive it into the cavity of the mouth, before they force it into the branchial vessels; and though the mode of breathing is so entirely changed in after-life, the operation consists in the perfect animal of a succession of deglutitions of air.

When the *Amphibia* leave the egg, their branchiæ appear externally like little coloured fringes on each side of the neck, and so they remain in the *Urodèles*, as long as their lungs are not sufficiently developed to serve for complete respiration. But in the Frogs and the *Anourous Amphibia* the first stage of the animal's life endures but a short time. It soon assumes the Tadpole form, with an enormous belly and head, in one undistinguished outline, and a long tail. At this period the branchiæ, or gills, are hidden, being contained in a cavity, and then the water enters the mouth by the orifice of the nostrils, which are supplied with valves. When in the cavity of the mouth, which is well closed on all sides, with the exception of the throat, where are placed the branchial slits, the water, acted upon by the muscles which cover them, traverses these spaces, and bathes the branchiæ before its exit through the branchial holes. The blood which is pushed into these branchiæ is then distributed, as it is in the fishes, and passes, as we have seen, from the arterial venous vessels into the arteries which unite to form the aorta.

On acquiring their perfect form, and when the obliteration of certain points, and the development of the others, have adapted the *Anourous Amphibia* for breathing air, by means of its two large lungs, the muscles employed in deglutition are the great agents for carrying on the respiration. The anterior nostrils, as we have before stated, open nearly straight, by means of simple apertures in front of the palate; the tongue is applied as a kind of stopper upon the back nostrils, and the trachea is terminated by a glottis opening into the mouth. The air thus imprisoned is forced or pumped at each gulp through the glottis, to be distributed over the lungs.

In the museum of the Royal College of Surgeons are several preparations, illustrative of the aëration of the blood, by means of branchiæ, in the early stage of *Rana paradoxa*, and also of the mode of respiration in the adult forms of the same group of animals.

The activity of respiration is increased in proportion to the elevation of the temperature of the surrounding air. M. Delaroche found that

Frogs exposed to a temperature of 27 degrees Centigrade (80° Fahr.), absorbed four times as much oxygen as those submitted to a temperature of 6 or 7 degrees (42° to 47° Fahr.) only.

The organs of the voice in the *Anourous Amphibia* are only put in action, generally speaking, at the season of reproduction, and then principally by the males: their croakings and cries seem intended to make the one sex sensible of the presence of the other. The trachea is indeed very short in the Frog; but it is longer in the male than it is in the female, and the rima glottidis is also longer in the former. But in some Frogs the males are distinguished by peculiar membranous bags. Thus, the Green Frog has two cheek-pouches, which are inflated by the animal in the breeding season, by means of two apertures close to the rima glottidis; and the chordæ vocales are very large and distinct in many species. The glottis bears, apparently, considerable analogy to the upper larynx in birds; but in the birds the voice receives its modification only from the edges of the glottis, which shuts the trachea at the point where it opens into the mouth; the sounds being produced by the lower larynx, which is formed at the point of junction of the two branches which constitute the origin of the trachea. When the air-passages of the reptiles emit sounds, they are produced by the single larynx and the glottis: from the absence of moveable lips, and the velum palati, or their inconsiderable development, those sounds cannot be much modified. Nevertheless, the vocal powers of these animals vary very much, according to the varying mechanism manifested in each. The cries of the different species of *Rana*, from the well-known croaking of the Common Frog to the bellowing of the Bull-Frog; the shrill trebles of the species of *Hyla*, of the males especially; the flute-like and metallic sounds occasionally given out, and the sort of seemingly ventriloquous grumbling which some species of Toads exert, are vocal sounds emitted above the larynx—a sort of falsetto or *voce di testa*—from the buccal cavity, or some of the accessory sacs.

Connected with the phenomena of breathing, it should be stated that the naked skin of the Frogs, and indeed of the Batrachians generally, has the power of acting upon the air in such a way as to fulfil, in a great degree, the functions of the lungs, and that aërated water may be made subservient to this cutaneous respiration. The experiments made on frogs which have been kept in vessels, and under water charged with air renewed from time to time, and on toads which have been kept alive for months in nets sunk under running water, at a low temperature, without any direct access to atmospheric air, prove this. These powers, the faculty of enduring long abstinence, their hybernation, and the age (as great as 36 years) to which the *Anourous Amphibia* are said to attain, naturally lead us to the consideration, of the stories told of the discovery of toads, 'antediluvian toads' as they were once called, inclosed in solid rocks and in the heart of trees, where they had been supposed to have existed for centuries, deprived of the possibility of access to either food or air, though when found they were alive and vigorous. Nor do these stories rest solely on the doubtful hearsay evidence of uneducated persons. Thus Smellie, in his 'Philosophy of Natural History,' alludes to the account in the 'Memoirs of the Academy of Sciences' for the year 1719, of a toad found alive and healthy in the heart of an old elm; and of another discovered in the year 1731, near Nantz, in the heart of an old oak, without any visible entrance to its habitation. From the size of the tree it was concluded that the animal must have been confined in that situation at least 80 or 100 years. He adds, that in the many examples of toads found in solid rocks, exact impressions of their bodies, corresponding to their respective sizes, were uniformly left in the stones or trees from which they were dislodged; and he asserts that it was said that there existed, when he wrote, a marble chimney-piece at Chatsworth with a print of a toad in it; and that there was a traditionary account of the place and manner in which it was found.

That frogs, toads, snakes, and lizards "occasionally issue from stones that are broken in a quarry, or in sinking wells, and sometimes even from strata of coal, at the bottom of a coal-mine," may be readily admitted; but, as Dr. Buckland well observes, in a paper recording some experiments on this subject—and to these we shall presently allude—"the evidence is never perfect to show that the reptiles were entirely inclosed in a solid rock; no examination is ever made until the reptile is first discovered by the breaking of the mass in which it was contained, and then it is too late to ascertain, without carefully replacing every fragment (and in no case that I have seen reported has this ever been done), whether or not there was any hole or crevice by which the animal may have entered the cavity from which it was extracted. Without previous examination, it is almost impossible to prove that there was no such communication. In the case of rocks near the surface of the earth, and in stone quarries, reptiles find ready admission to holes and fissures. We have a notorious example of this kind in the lizard found alive in a chalk-pit, and brought alive to the late Dr. Clarke." The same author remarks, that the first effort of the young toad, as soon as it has left its tadpole state, and emerged from the water, is to seek shelter in holes and crevices of rocks and trees. "An individual, which when young may have thus entered a cavity by some very narrow aperture, would find abundance of food by catching insects, which like itself seek shelter within such cavities, and may have soon increased so much in bulk as to render it impossible to go out again through the narrow aperture at which it entered. A small hole of this kind is very likely to be overlooked by common workmen, who are the only people whose operations on wood and stone disclose cavities in the interior of such substances."

Without, then, attempting to throw discredit upon the observations published upon this curious subject by authors whose character for veracity is unquestionable,—those of Guettard, in 1771 ('Mémoire sur différentes Parties des Sciences et des Arts,' tom. iv.); of Edwards, 1824 ('De l'Influence des Agens Physiques sur la Vie'); and of Mr. Thomas, in Silliman's Journal, in addition to those above alluded to for example—we may conclude with Dr. Buckland, in his remarks on the last publication, that the several authentic and well-attested cases to be found in such memoirs, "amount to no more than a repetition of the facts so often stated and admitted to be true, namely, that reptiles occur in cavities of stone, and at the depth of many feet in soil and earth; but they state not anything to disprove the possibility of a small aperture by which these cavities may have had communication with the external surface, and insects have been admitted. The attention of the discoverer is always directed more to the toad than to the minutiæ of the state of the cavity in which it was contained."

Dr. Buckland made some experiments on this subject which he commenced in November, 1825. He caused 12 circular cells to be prepared in a large block of coarse Oolitic Limestone, from Heddington quarry, near Oxford. Each cell was about 1 foot deep, and 5 inches in diameter, and had a groove or shoulder at its upper margin, fitted to receive a circular plate of glass, and a circular slate to protect the glass; the margin of this double cover was closed round, and rendered impenetrable to air and water, by a luting of soft clay. Another block of compact silicious sandstone (Pennant Grit, of the Bristol coal-formation) was made to contain 12 smaller cells, each 6 inches deep and 5 inches in diameter, and each under the same double cover as the first-mentioned cells. A live toad was placed in each of these 24 cells on the 26th November, 1825, and the double cover of glass and slate was placed over each of them, and cemented down by a luting of clay. Dr. Daubeny and Mr. Dillwyn, who were present, ascertained and noted the weight of each toad (they had all been imprisoned together in a cucumber frame, some of them for two months previously), as it was immured. The largest weighed 1185 grains; the smallest 115 grains; and they were distributed equally, small and large, among the Limestone and Sandstone cells. The blocks were buried in the earth of Dr. Buckland's garden, 3 feet deep. On the 10th of December, 1826, these blocks, which had remained unopened from the period of their inhumation, were examined. Every toad in the smaller cells of the Sandstone block was dead, and so much decayed, that they must have been dead for some months. The greater part of those in the larger cells of the oolitic block were alive. No. 1, which weighed when placed in its cell 924 grains, was reduced to 698 grains. No. 5, whose weight at the same period was 1185 grains, had increased, it is asserted to 1265 grains. Dr. Buckland observes, that the glass cover over this toad's cell was slightly cracked, so that minute insects might have entered; but none were discovered therein. In another cell, the glass of which was broken, and its tenant dead, there was a large assemblage of minute insects; and a similar assemblage was observed also on the outside of the glass of a third cell. In the cell, No. 9, a toad which weighed at its entrance 988 grains, had increased to 1116 grains. The glass cover of this cell was entire, but the luting that secured it was not attentively examined; and Dr. Buckland observes, that it is probable that there was some aperture by which small insects found admission. No. 11 had decreased from 936 to 652 grains.

The result of Dr. Buckland's experiments was, that all the toads, both large and small, inclosed in Sandstone, and the small toads in the Limestone, were dead at the end of 13 months, a fate which befel all the large ones also, before the expiration of the second year: these last were examined several times during the second year, through the glass covers of their cells, but without removing them to admit air; they appeared always awake, with open eyes, and never in a state of torpor; but at each successive examination they became more and more meagre, till at last they were found dead. The two toads which when first examined had increased in weight, and were at the end of the first year carefully closed up again, were not exempt from the common annihilation, but were emaciated and dead before the expiration of the second year.

When Dr. Buckland inclosed these toads in stone, he at the same time placed four other toads, of moderate size, in three holes cut for that purpose, on the north side of the trunk of an apple-tree. Two were placed in the largest cell, and each of the others in a single cell, the cells being nearly circular, about 5 inches deep and 3 inches in diameter. These were carefully closed with plugs of wood, so as to exclude access of insects, and were apparently air-tight. Every one of the toads thus 'pegged' in the knotty entrails of the tree was found dead and decayed at the end of the first year.

Four toads were, at the time the others were shut up, each placed in a small basin of plaster of Paris, 4 inches deep and 5 inches in diameter, having a cover of the same material luted over them: these were buried at the same time and in the same place with the blocks of stone, and on being examined at the same time with them, in

December, 1826, two of the toads were dead; the other two alive, but greatly emaciated.

Dr. Buckland concludes from the experiments generally, that toads cannot live a year excluded totally from atmospheric air; and from the experiments made in the larger cells in the Oolite, that there is a probability that those animals cannot survive two years entirely excluded from food. ('Zoological Journal,' vol. v. p. 314.)

Absorption of Air and Water, Exhalation, and Transpiration.—A rapid process of absorption and evaporation of fluids, by the pores of the skin, gives to the *Anourous Amphibia* the power of resisting heat. If a frog be plunged into water, of a temperature of 40° Centigrade (104° Fahr.), it will not, it is asserted, live more than two minutes, though the head be left out so as to enable it to respire freely; yet a frog will sustain the action of humid air heated to the same temperature, for four or five consecutive hours. A sudden transition, however, from a low temperature to a high one, is generally speedily fatal to these animals. Their proper balance of animal heat is kept up by a regulation of the evaporation of liquid absorbed, or by the transpiration of the matter, the quantity of which is augmented in proportion as the external heat is more intense; and the animal resists it as long as the moisture is not desiccated by the air. When it can no longer repair the loss of the moisture already taken up, by a fresh absorption of liquid, it perishes. The Frogs, in this particular of their organisation, have been compared to the vessels which in Spain are called Alcarazas, used for cooling water, by the transudation permitted by their porous structure. Dr. Townson, who made observations to some extent upon this subject, and had two frogs, which he named Damon and Musidora, found that a frog would sometimes absorb in half an hour as much as half its own weight in water, and, in a few hours, nearly its entire weight. When the animal so filled was placed in a warm and dry situation, it gave off this fluid nearly as rapidly as it had accumulated it. He contends that the Frog Tribe never drink, and general observation goes to prove that the Frogs, Tree-Frogs, and Salamanders do not swallow liquids, being supplied by the process before mentioned. The meagreness of some of these animals, in a state of comparative desiccation, and their apparent plumpness after they have renewed their supply of moisture,' is very striking. If, when so supplied, they are suddenly surprised, they can get rid of their load instantaneously. Few who have come on a frog by surprise, in a moist meadow, have not observed that, during its first leap, it emits a quantity of liquid from its vent. "Whatever this fluid may be," says Dr. Townson, "it is as pure as distilled water and equally tasteless. This I assert as well of that of the toad, which I have often tasted, as that of frogs." This fluid is the liquid absorbed, by the skin of the abdomen principally, and for which toads and frogs are ever on the look-out. The dew on the herbage is a frequent source of this necessary supply, and in dry seasons toads will bury themselves in moist sand or earth for the purpose of sucking up through their skin any aqueous particles which may be around them. The fluid is contained in a sac, generally consisting of two lobes, situated in the lower part of the abdomen under the viscera, and is conducted to the receptacle by particular vessels, which are certainly not the ureters or urinary canals from the kidneys: these urinary canals have their exit lower down in the cloaca. Blumenbach, and even Cuvier, in his 'Leçons d'Anatomie Comparée,' considered this bilobated bag as the urinary bladder in the frog and toad; but Townson shows that it has no connection with the ureter, which, as we have seen, has its posterior opening lower down in the cloaca, while these receptacles terminate in the front of that intestine.

Brain, Nervous System, and Senses.—The brain and nervous system of the *Anourous Amphibia* are, as in the Reptiles generally, composed of an encephalon consisting of a cerebrum, cerebellum, and medulla oblongata; a spinal cord; and the nerves which are given off from these sources to the different organs of the body. So far the system is modelled upon that of Mammiferous Animals and Birds, but the cerebellum is proportionally much less. The Reptiles have also a ganglionary nervous system, or a great double sympathetic nerve.

Touch.—The naked skin and its sensibility to variations of temperature would seem to indicate a considerable degree of perception, as to the physical and even chemical nature of the bodies with which it comes in contact. But touch, properly so called, can hardly exist in a high state of development in the greater part of the *Anourous Amphibia.* They have, indeed, no nails on their toes, which are much longer in the frogs than in the toads; and in many of the genera and species the toes are terminated by fleshy appendages, as in *Pipa*, which has also an elongated fleshy muzzle; the Tree-Frogs (*Hyla*) also, have the extremities of their toes dilated into fleshy disks, which, like the acetabula of the *Sepiadæ*, adhere by their circumference. These enable the animals to walk in all directions upon flat surfaces, and to adhere to them even when they are of the smoothest nature. The sense of touch is probably more highly developed where this organisation is manifested.

Taste.—Probably not at all acute. The tongue, as we have seen, is an organ for the capture of the prey, which is swallowed entire almost in the same moment that it is taken.

Smell.—This sense would seem to be almost rudimentary in the *Amphibia.* A simple opening pierced from the end of the muzzle to the front of the palate, with a fleshy and concave membrane at its external extremity, moving in unison with the respiratory action, is strongly contrasted with the intricate and beautiful structure of the nasal organs which are so highly developed in the Carnivorous Mammalia and Birds.

Hearing.—There is a considerable difference in the structure of the organ of hearing among the *Anourous Amphibia.* The *Pipa*, for instance, has a sort of small valve upon the tympanum, somewhat similar to that possessed by the crocodiles, and probably intended to protect the membrane against the pressure of the water when the animal resorts to great depths. *Hyla* and *Rana* have the tympanum distinctly manifested by the delicacy of its structure when compared with the other integuments of the head. In the Toads the tympanum is not apparent. Examples of the structure of the ear may be seen in some of the preparations in the museum of the College of Surgeons.

Sight.—The precision with which a Toad measures the distance of an insect, and captures it with its tongue the moment the victim is within reach of that organ, shows a high and accurate development of the organs of sight, as applicable to short distances at least. The pupil is, in general, round, but in the *Anourous Amphibia* whose habits are nocturnal (the toad, for instance) it is angular or linear. The humours vary in their proportions in the different genera, but the crystalline humour has been noticed of greater density and of a more spherical figure in the aquatic species. The orbits are generally incomplete, and sometimes protected, as in *Ceratophrys*, by folds of thickened cuticle.

Reproduction.—The special reproductive tissues of the male in the *Anourous Amphibia* are situated in the cavity of the abdomen below the kidneys, and the deferent canals terminate in the cloaca. The ovaries in the females are found in the same situation with the corresponding parts in the males, and are of considerable volume. Their free extremity forms a sort of trumpet-shaped opening, and the oviduct terminates in the cloaca, whence the eggs are excluded. Blumenbach describes the Frogs of his country as having a large egg-cavity, divided by an internal partition into two parts, from which two long convoluted oviducts arise, and terminate by open orifices at the sides of the heart. The ovaria, he says, lie under the liver, so that it is difficult to conceive how the eggs get into the above-mentioned openings. The egg-cavity, he adds, opens into the cloaca. The Toads, according to him, have not a large egg-cavity; but their oviducts terminate by a common tube in the cloaca.

At the season of reproduction, besides the vocal manifestations, there are others which visibly distinguish the male in many of the *Amphibia.* At each croak, the male Green Frogs project from the commissure of the mouth two globular bladders into which the air is introduced, and the throat swells and becomes coloured. In the males of the Red Frog the thumbs of the anterior feet become considerably swollen and covered by a black and rugose skin at this period. The eggs are not fecundated until after they have been extruded into the water. These eggs are enveloped in a sort of delicate, mucous, permeable membrane; they are, when excluded, most frequently agglomerated either in glutinous masses or chaplets, and increase considerably after they are plunged in the water. There are however some curious modifications of the disposition of the eggs in certain species of the *Anourous Amphibia.* In the Toad, called by Laurenti from its habits *Bufo obstetricans*, the male, for instance, after the exclusion of the eggs, takes up the chaplets, and disposes them round his thighs, something in the form of a figure of 8. He is then said to carry them about till the eyes of the embryo become visible. At the proper period for hatching, he conveys his progeny to some stagnant piece of water, and deposits them, when the eggs break and the tadpoles come forth and swim about. The male *Pipa*, or Surinam Toad, as soon as the eggs are laid, places them on the back of the female, and in that situation they become fecundated. The female [see figures] then takes to the water, and the skin of her back swells, and forms cellules, in which the eggs are hatched, and where the young pass their tadpole state, for they do not quit their domicile till after the loss of their tail and the development of their legs. At this period the mother leaves the water, and returns to dry land.

Swammerdam gives the number of eggs in a female frog as 1400, and M. de Montbeillard counted 1300. In these eggs there is a greenish albumen which is not easily coagulable. The yolk or vitellus is absorbed by the embryo, and an abdominal cicatrix indicates the umbilicus in young individuals. It is not rare to meet with double germs in a single egg, but most of these prove abortive, though some produce monsters with two heads, six legs, and two tails, as well as hermaphrodites. In our climates, the early part of the spring is the season of mating, when the frogs and toads of both sexes quit the localities of their late hybernation and their ordinary haunts, and move instinctively to those stagnant waters which are proper for their purpose, and where they are then collected in swarms.

The young of the *Amphibia* enter life under an entirely different form from that which they are afterwards to assume; and undergo, like the insects, a series of metamorphoses or transformations, till they arrive at their perfect state. In their first stage, the young have an elongated body, a laterally compressed tail, and external branchiæ;

their small mouth is furnished with horny hooks or teeth for the separation of vegetable matter, and they have a small tube on the lower lip by which they attach themselves to aquatic plants, &c. The external branchiæ next disappear, and become covered with a membrane, being placed in a sort of sac under the throat; and the animal then, as we have observed when treating of its respiration, breathes after the manner of fishes. The head, which is furnished with eyes and nostrils, is confounded with the large globular trunk distended with the great extent of the digestive canal, and it has a large tail for swimming. In this state it is called in English a *Tadpole*, and in French *Têtard*, from the great apparent volume of the head. Soon the posterior limbs are gradually put forth near the origin of the tail, and are developed first; the anterior feet then begin to show themselves; the tail gradually becomes less and less, shortens, shrinks, and seems at last to be absorbed; the mouth widens, and loses its horny processes or jaws; the eyes are guarded by eye-lids; the belly lengthens and diminishes in comparative size; the intestines become short; the true lungs are developed, and the internal branchiæ are obliterated; the circulation undergoes an entire change; and the animal, hitherto entirely aquatic and herbivorous, becomes carnivorous, and for the most part terrestrial.'

Mr. Thomas Wharton Jones ('Zool. Proc.,' March, 1837) observes, that when the right gill of the Tadpole disappears, it is not, as is usually supposed, by the closure of the fissure through which it protrudes, but by the extension of the opercular fold on the right side towards that of the left, forming but a single fissure, common to the two branchial cavities, through which the left gill still protrudes. He also remarks, that conditions analogous to those which occur during several stages of this process exist in the branchial fissures of the Anguilliform genera, *Sphagebranchus*, *Monopterus*, and *Synbranchus*.

Particular Excretions.—The alleged venom of the Common Toad, so long a subject of popular belief, had been rejected by many modern naturalists, among whom Cuvier may be particularly mentioned. Dr. Davy, however, found the venomous matter to be contained in follicles, chiefly in the true skin and about the head and shoulders, but also distributed generally over the body and on the extremities. Pressure causes this fluid to exude or even spirt out to a considerable distance, and a sufficient quantity may be thus collected for examination. Dr. Davy found it extremely acrid when applied to the tongue, resembling the extract of aconite in this respect; and it even acts upon the hands. With a small residuum it is soluble in water and in alcohol; acetate of lead and corrosive sublimate do not affect the solutions. It remains acrid on solution in ammonia; and when dissolved in nitric acid, it imparts a purple colour to it. Combined with potash or soda, it becomes less acrid, apparently in consequence of partial decomposition. It is highly inflammable as left by evaporation of its aqueous or alcoholic solutions; and the residuum which appears to give it consistence seems to be albumen. More acrid than the poison of the most venomous serpents, it produces no ill effect when introduced into the circulation. A chicken inoculated with it was not affected. Dr. Davy conjectures that this 'sweltered venom' is a defence to the Toad from carnivorous animals; and we have seen a dog, when urged to attack one without hesitation, drop the animal from its mouth in a manner that left no doubt that he had felt the effects of this excretion, which Dr. Davy thinks may be auxiliary in decarbonising the blood.

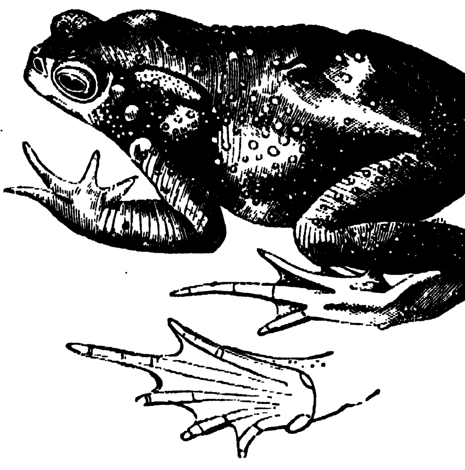
The Toads are also said to possess, besides, two glandular masses (parotids), which, when pressed, exude through small holes a yellowish thick humour of a musky odour. The other odours also which many species of Toads produce, it does not seem yet ascertained from what source, are very remarkable. Roesel, author of the beautiful work on Frogs, compares some of these to the smell of garlic or of volatilised sulphur of arsenic, or even ignited gunpowder; others again, he says, produce an effect on the nose like the vapour of horse-radish, mustard, or the leaves of monk's-hood rubbed between the fingers. In one instance only he states it to be probable that this emanation comes from the cloaca; and such seems to be the opinion of M. Duméril, who states that he has been assured that, in certain instances, the water in which some of these animals had been placed and there purposely irritated or excited, had become so acrid that the tadpoles of frogs and salamanders introduced therein hardly survived the immersion.

Geographical Distribution and Habits.—Warm and temperate but moist climates are the localities most favourable to the *Anourous Amphibia*. Extreme cold is fatal to them, and so is extreme dry heat. They are unable to sustain violent and sudden changes of temperature. In moderately warm climates, and those where there is a considerable degree of cold during a part of the year, they bury themselves, in winter, either under the earth or in the mud at the bottom of the water, and there pass the season of hybernation without taking food or air, till the spring calls them forth; when the same frog which had passed so many months without respiration would expire in a few minutes if prevented from shutting its mouth and so supplying itself with air by deglutition. The general habits of the tribe may be collected from the different sections of this article, and from the descriptions of those forms in it which may be noticed in the course of this work.

The following cuts will convey to the reader an idea of some of the leading forms among the *Anourous Amphibia* in their adult state:—

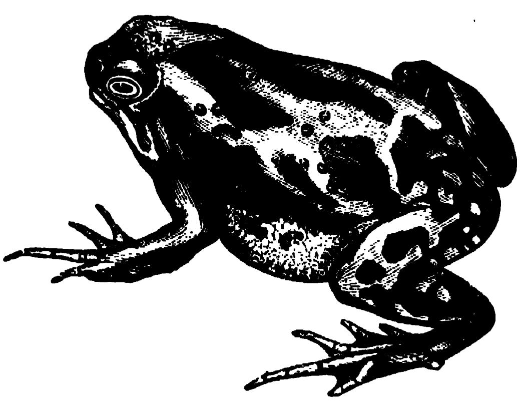
Marsh Frog (*Rana palustris*). Two-thirds natural size. Europe.

Ceratophrys granosa. Two-thirds natural size. America.

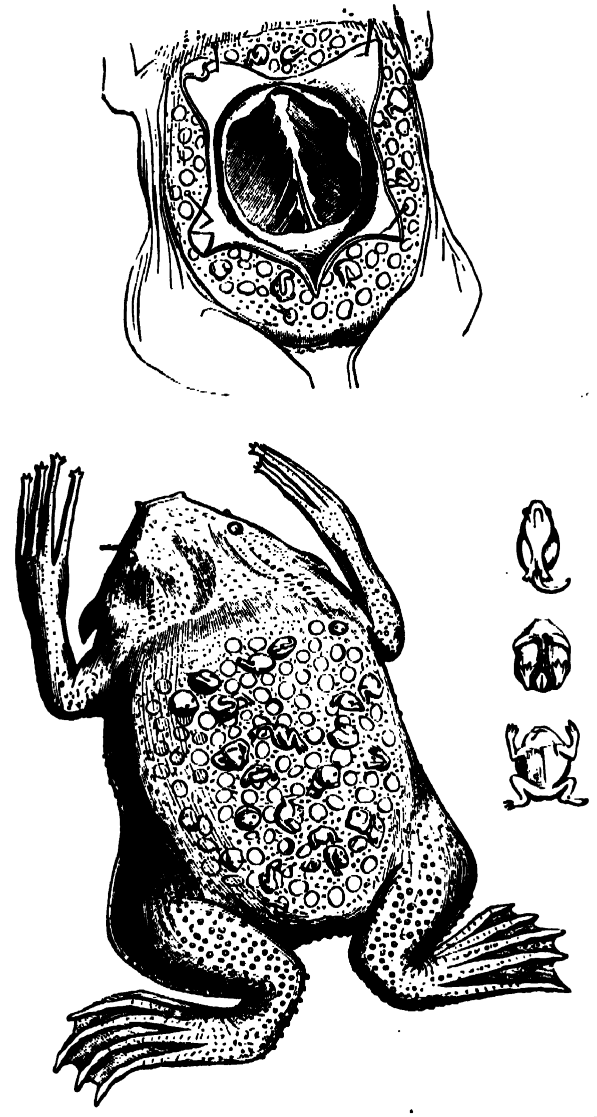


Common Toad (*Bufo vulgaris*). Half natural size. Europe. With an under view of the foot.

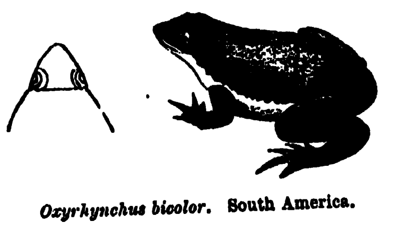
Hyla bicolor. Half natural size. South America.



Engystoma marmoratum. India.



Pipa monstrosa, Laurenti (*Asterodactylus*, Wagler), Surinam Toad, female, reduced. The upper figure shows the disposition of the cells, and their situation in the skin, which is turned back, and the muscle seen below. The small separate figures are Tadpoles, in different stages of development.



Oxyrhynchus bicolor. South America.

Messrs Duméril and Bibron ('Erpétologie') make the Bufoniform Family of the *Anourous Amphibia* (*Anoures Phanéroglosses*) consist of the following genera:—

Dendrobates, Wagl. (*Hylaplesia*, Boie, Tschudi.) Example, *Dendrobates tinctorius.* (Cayenne.)

Rhinoderma Dum. and Bibr. Example, *Rhinoderma Darwinii.* (Chile.)

Atelopus, Dum. and Bibr. Example, *Atelopus flavescens.* (Guyana.)

Bufo, Laur. Example, *Bufo vulgaris*, the Common Toad. (Europe, Japan.) Messrs. Duméril and Bibron record 18 species of this genus.

Phryniscus, Wieg. (*Chaunus*, Tschudi.) Example, *Phryniscus nigricans*, Wieg. (Montevideo.)

Brachycephalus, Fitzing. (*Ephippifer*, Coct.) Example, *Brachycephalus ephippium*, Fitzing. (Brazil, Guyana.)

Hylædactylus, Tschud. Example, *Hylædactylus baleatus.* (Java.)

Plectropus, Dum. and Bibr. Example, *Plectropus pictus.* (Manilla.)

Engystoma, Fitzing. (*Microps*, Wagl.; *Stenocephalus*, Tschudi.) Example, *Engystoma ovale.* (Surinam, Buenos Ayres.)

Uperodon, Dum. and Bibr. Example, *Uperodon marmoratus.* (Montavalle, Indian Peninsula.)

Breviceps, Merrem (*Engystoma*, part, Fitzing.; *Systoma*, Wagl., Tschudi). Example, *Breviceps gibbosus.* (South Africa, near the Cape of Good Hope.)

Rhinophrynus, Dum. and Bibr. Example, *Rhinophrynus dorsalis.* (Mexico.)

Geographical Distribution of the Family.—Messrs. Duméril and Bibron state that the number of species of the Bufoniform Family known to them (1841) was 35, a much less number than that of the Raniform Family, which includes 51, and less still than the Hyliform, or Tree-Frog Family, which comprises 64.

Nevertheless, observe these excellent herpetologists, species of this family exist in all the five parts of the world, where they are distributed in a manner not less unequal than the Raniform and Hyliform species, and always with a greater proportion for America, whilst the smallest portion of them belong to Europe, which has not even a single species peculiar to itself; for the two there found, the Common Toad and the Green Toad (*Bufo viridis*, Laur.), also inhabit Africa and Asia, which produce moreover, the one *Bufo pantherinus* and *Breviceps gibbosus*, the other *Plectropus pictus*, *Engystoma ornatum*, *Hylædactylus baleatus*, *Uperodon marmoratum*, and *Bufones cruentatus*, *scaber*, *biporcatus*, *isos*, and *asper*.

Oceania, which after America is, they observe, best furnished with Hyliform species, and where two of the Raniform Family are found, has not hitherto yielded more than a single Bufoniform species, namely, *Phryniscus Australis.*

America, besides six species of *Bufo*, namely, *strumosus*, *melanotis*, *musicus*, *Americanus*, *margaritifer*, *d'Orbignyi*, and *Leschenaultii*, furnishes *Dendrobates tinctorius*, *obscurus*, and *pictus*; *Rhinoderma Darwinii*; *Atelopus flavescens*; *Phryniscus nigricans*; *Brachycephalus ephippium*; and *Engystomata ovale*, *Carolinense*, *rugosum*, and *microps*.

Mr. Darwin, speaking of the Fauna of the Galapagos Archipelago, says: "Of snakes there are several species, but all harmless. Of toads and frogs there are none. I was surprised at this, considering how well the temperate and damp woods in the elevated parts appeared adapted to their habits. It recalled to my mind the singular statement made by Bory St. Vincent, namely, that none of this family are to be found on the volcanic islands in the great oceans. There certainly appears to be some foundation for this observation, which is the more remarkable when compared with the case of lizards, which are generally among the earliest colonists of the smallest islet. It may be asked whether this is not owing to the different facilities of transport through salt-water of the eggs of the latter, protected by a calcareous coat, and of the slimy spawn of the former." ('Journal.')

URODÈLES, or TAILED AMPHIBIA.

Under this designation the following genera are included:—*Pleurodèles*, Waltè.; *Bradybates*, Tsch.; *Salamandra*, Linn.; *Pseudosalamandra*, Tsch.; *Ambystoma*, Tsch.; *Onychodactylus*, Tsch.; *Plethodon*, Tsch.; *Cylindrosoma*, Tsch.; *Œdipus*, Tsch.; *Salamandrina*, Fitz.; *Geotriton*, Bonap.; *Hemidactylium*, Tsch.; *Cynops*, Tsch.; *Hynobius*, Tsch.; *Pseudotriton*, Tsch.; *Triton*, Laur.; *Xiphonura*, Tsch.; *Megalobatrachus*, Tsch. (*Sieboldia*, Bonap.); *Andrias* (fossil) Tsch.; *Menopoma*, Harl.; *Siredon*, Wagl. (*Axolotl*); *Amphiuma*, Gard.; *Menobranchus*, Harl.; *Hypochton*, Merr. (*Proteus*); *Siren*; and many others.

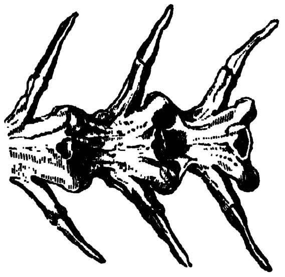
Skeleton.—The skull of the Terrestrial Salamander (*Lacerta Salamandra*, Linn.; *Salamandra terrestris*, Aldr. and Ray) is well described by Cuvier as being nearly cylindrical, widened in front in order to form the semicircular face, and behind for the two crucial branches resembling those of the frogs, and containing the internal ears. But though the composition of the head resembles that of the frogs in the back and under parts, it differs remarkably in other parts: there is no girdling bone (*os en ceinture*), and the only representation of the ethmoïd bone appears in a membranous state.

Above, the cranium is divided nearly equally between the two frontal and the two parietal bones. The anterior part of the frontal bones is articulated forwards with the bones of the nose, and, laterally, with the anterior frontal bones. The apophyses rising from the intermaxillary bones are very large, which places the external osseous nostrils very far apart. The nasal bone is placed on the upper part of each of them, between the intermaxillary, the frontal, the anterior frontal, and the maxillary bones. The anterior frontal bone occupies the cheek in front of the anterior angle of the orbit, but does not descend into the cavity, the anterior wall of which is simply membranous. Cuvier believed that he saw a very small lachrymal bone at the external angle of the anterior frontal bone. The dental part of the upper maxillary bone is carried backwards as usual, but without forming a junction with either the pterygoïd or jugal bones. Cuvier found only two occipital bones, as in the other Batrachians, and each of them was intimately united with a part analogous to the os petrosum (*rocher*). A great round hole serves for the entry to the vestibule, and consequently to the fenestra ovalis. In the living animal it is closed by a cartilaginous plate, without any stem, and entirely hidden under the muscles. To this bone, which occupies the place of both the occipital, lateral, and petrous bones, are attached three others, the lower of which (the pterygoïd), with its triangular figure, brings to the mind of the observer the three branches of which it is formed in the frogs. Its anterior angle, as has been stated, does not reach the maxillary bone, and is only connected to it by a ligament; neither does the internal angle reach the sphenoïd bone: the external angle exists under the second of the three bones here noticed, namely, the intermediate bone —that to which belongs the facet for the articulation of the jaw. This bone, Cuvier remarks, is very difficult to define; and he further says that he shall perhaps be considered very rash if he names it the jugal bone, for, far from being placed horizontally, and going forwards to join the maxillary, it lies transversely on the posterior border of the pterygoïd bone; nevertheless, there is a ligament which unites it to the posterior point of the maxillary bone. The third and upper of these bones lies upon the preceding, and in the same direction; it is oblong and flat, and is attached by its internal extremity upon the lateral occipital bone, without reaching to the parietal. Supposing the jugal bone to be well named, this would be the tympanic bone; and, in fact, if the little plate which covers the fenestra ovalis had a handle (*manche*), it would pass behind the bone of which we speak, as in the frogs it passes behind the tympanic bone.

Below there is only a single sphenoïd bone, which is oblong. Two large triangular bones, which are manifestly analogous to those named vomers by Cuvier in the frogs, form the flooring of the nostrils below, and give off each a slender apophysis, which extends backwards under the sphenoïd parallel to its correspondent. It is to those bones and to their apophyses that the two longitudinal rows of the palatal teeth of the Salamanders adhere. Between the anterior part of these bones, behind the intermaxillaries, is a large oval space, which is filled by the membrane of the palate only; their posterior and dentary apophysis extends nearly as far backwards as the sphenoïd bone. Perhaps, observes Cuvier, it is divided at certain periods into two by a suture, and a palatine bone may then be distinguished, but he had not been able to perceive one. There is in the orbit, at its anterior wall, a great membranous space between the maxillary bone, the anterior frontal, and the vomer; and it is at the bottom of this space, and in a notch of the vomer, that the internal nostril is pierced on each side. The bottom of the orbit, on the side of the cranium, between the frontal and parietal bones on one side, and the vomer and sphenoïdal bones on the other, is occupied by an oblong bone in which the optic hole is pierced, and which can only answer to the orbital wing of the sphenoïdal bone. It is this part which is membranous in the frogs, and has no existence in the serpents, in which the parietal and frontal bones each supply it by halves; here it is elevated to the state of a particular bone. The two occipital condyles are very much separated from each other, and placed at the two sides of the occipital hole.

The cranium of the European Aquatic Salamanders differs in general from that of the Terrestrial in having the entire head more oblong, the external nostrils more approximated, the space between the vomers a simple small hole, the pterygoïd bone a mere plate, wide behind and pointed before, &c. They also differ among themselves.

The os hyoïdes is subject to changes in the Salamanders, as in the frog. In its larva state it has two hyoïdian branches springing from the occipital bones, uniting forwards under the lower jaw, and a cartilaginous branchial apparatus suspended at the point of union of those branches, and supporting four arches on each side, the first of which is attached to an intermediate stem, the three following to a second two-jointed stem, and these two pairs of stems to an unequal branch, as is more clearly manifested in the *Axolotl*. The adult Aquatic Salamanders preserve in the bony state the branches which still are attached below the fenestra ovalis, and terminate forward by a truncation under the middle of the lower jaw; but the anterior articulation of these branches is now become membranous. The unequal stem, in the bony state, supports on each side an osseous branch consisting of two joints, terminated by a cartilaginous point, and moreover, internally, another branch which is simple and reduced to a filament, which goes from the unequal stem to the second articulation of the external branch. In the Terrestrial Salamander, which can only pass a very short time in the larva state, all remains cartilaginous. The two suspensive branches or anterior horns are delicate and flat, and do not join the cranium; and the unequal stem with its two branches soldered on each side by their two ends, forms only a single chevron-shaped cartilage, each branch of which is pierced with a considerable gap. This remainder or vestige of the branchial apparatus does not prevent the co-existence of a larynx and the rudiment of a sternum; both indeed weak and membranous rather than cartilaginous. The shoulder of the Salamander is very curious on account of the close junction of its three bones into a single one, which has the glenoïd fosset at its anterior edge, sends towards the spine a square lobe slightly enlarged above, which is the omoplate, and towards the breast a rounded disk, slightly lobated, which is composed of the clavicle and coracoïd bone, where a suture which separates them may for a long time be observed, and where there always remains a small hole. The omoplate has its spinal edge augmented by a cartilaginous prolongation. The cleido-coracoïd is also surrounded with a great cartilaginous blade in form of a crescent, which crosses upon its congener under the breast; for the only vestige of a sternum remaining is a cartilaginous blade placed behind the two preceding, and which represents the xiphoïd. The atlas of the Salamander is articulated with the head by two concave facets, and with the second vertebra by the face of its body, which is also concave; for, contrary to the case of the frogs and lizards, all the anterior faces of the bodies of the vertebræ are convex in the Salamanders, and all the posterior faces concave; the upper part is flat. The articular apophyses are horizontal, and united on each side by a crest, which, joined to that of the other side, gives to the vertebra a sort of roof which is rectangular, but with its lateral borders a little re-entering. The posterior parts of a vertebra lie on the anterior parts of that which follows it. In lieu of spinous apophyses, there is only a slight appearance of a longitudinal ridge. The body of the vertebra, which is cylindrical and narrowed in its middle, adheres under the roof above noticed. The transverse apophyses also adhere under the lateral crests, are directed slightly backwards, and divided by a furrow on each of their faces, so that their extremity has as it were two tubercles for carrying those into which the base of the small rib is divided. These small ribs adjoin all the cervical, dorsal, and lumber vertebræ, except the atlas, but are only two or three lines in length, and are far from surrounding the trunk or reaching the sternum. Among the Aquatic Salamanders, the *Triton Gesneri* has the crest of the dorsal vertebræ more elevated and sharp than the Terrestrial Salamander; this crest is also rather more developed in *Triton alpestris*, and even in *Triton punctatus* and *Triton palmatus*; but what, adds Cuvier, is very singular, it is precisely in *Triton cristatus* that this crest is most effaced, and the upper part of the vertebra nearly plain. The vertebræ of the tail (25 or 26 in number) in the Terrestrial Salamander have crests and transverse apophyses like those of the back; they become smaller and smaller, and, counting from the third caudal, there is under the body a transverse blade directed obliquely backwards, pierced with a hole at its base, which represents the chevron-bones of the lizards and the other long-tailed genera. Cuvier counted 33 caudal vertebræ in the *Triton alpestris* and *Triton cristatus*, 34 in *Triton Gesneri*, and 36 in *Triton punctatus*. They form, he observes, a tail flattened laterally, in consequence of the elevation of their upper and lower crests. The bones of the limbs are, says Cuvier in continuation, proportioned to the smallness of the members themselves. The humerus has, above, a round head; a little lower, forwards, there is a compressed and obtuse tuberosity; and backwards, a little lower still, another very pointed one. Its lower head is flattened from before backwards, and widened to suit the condyles, between which is an articular head, rounded for the fore-arm, and above, forwards, a small fosset. The Aquatic Salamander has this bone more widened above than the Terrestrial species. The fore-arm is composed of two separate bones. The radius has a round upper head, a narrowed body, and a compressed and widened lower head. The cubit is more equal in size, and its olecranon is very short and rounded. The carpus has 5 bones and 2 cartilages which occupy the place of bones, 7 pieces in all: the whole of these are flat, angular, disposed in a pavement-like order, and in some respects announce the structure to be seen in the *Icthyosaurus*. In the first rank are two, of which the smallest or radial is cartilaginous. The greatest belongs to the radius and ulna; between them on the second rank is a single one; then come, on the third rank, four for the metacarpals. The first remains cartilaginous. The metacarpals are short, flat, and narrowed in their middle. Cuvier found only one phalanx ossified on the first finger, two on the second and fourth, and three on the third. The variety of points by which the pelvis is attached to the spine is, he remarks, a very singular thing. He had individuals of the Terrestrial Salamander in which it was suspended from the 15th vertebra (counting in the atlas), and others in which it was suspended from the 16th; and he refers to a specimen (species undetermined) seen by M. Schultze, in which it was suspended on one side to the 16th vertebra, and on the other to the 17th. With regard to the Aquatic Salamanders, Cuvier found it constantly suspended to the 14th in *Triton palmatus* and *Triton alpestris*, to the 15th in *Triton punctatus* and *Triton Gesneri*, and to the 17th or 18th in *Triton cristatus*. He had an individual of the last-named species, in which it was suspended on one side to the 17th vertebra, and on the other to the 18th. The pelvis itself is quite differently formed from that of the frogs. The vertebra which supports it is like those which precede it, and has, like them, on each side a small rib, at the extremity of which the os ilii is suspended by a ligament. It is cylindrical, and widens a little on arriving at the cotyloïd cavity. The pubis and ischium are soldered together, and form, with those of the other side, from which they are distinct, a large disk, concave above, flat below, cut square in front and at the anterior parts of the sides, notched laterally and narrowed behind the cotyloïd fossæ, and terminated backwards in a concave arch.



Vertebræ of *Sieboldia.*

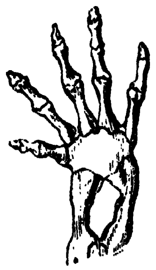
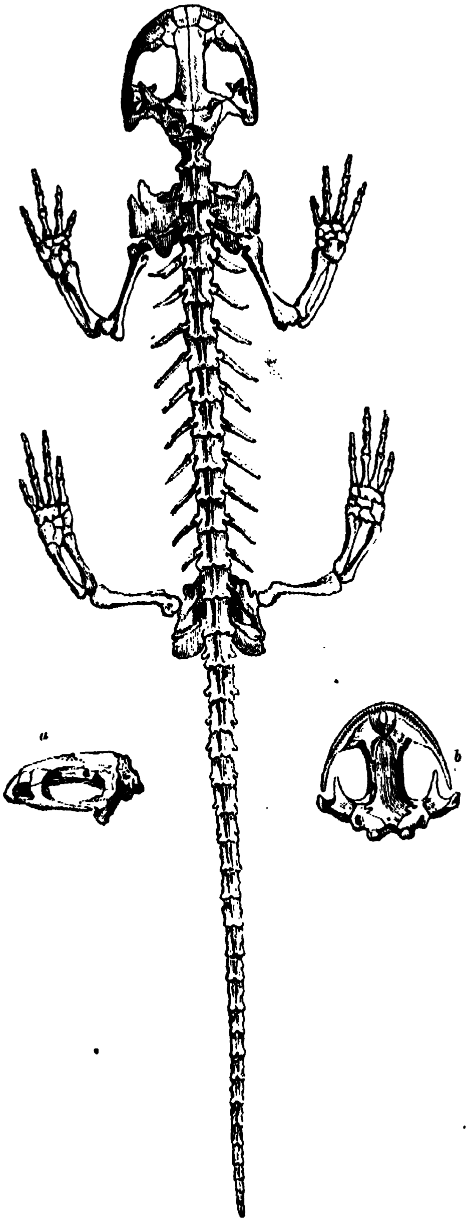
Skull of *Sieboldia*, seen from below.



Fore-hand of *Sieboldia.*



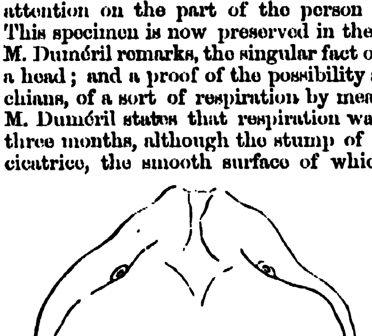
Skeleton of Terrestrial Salamander. *a*, Skull in profile ; *b*, from below.

The pubis remains cartilaginous much longer than the ischium, with which it is united by a suture which makes a cross with the symphysis, and in front of this symphysis is a cartilage in the form of a Y in the muscles, which recalls to the observer the marsupial bones of the

Opossums. The upper head of the femur is oval; at the internal face of the neck, there is a very pointed apophysis, occupying the place of a trochanter: the lower head is widened and flattened from before backwards. There are two bones in the leg. The tibia, which is very stout upwards, has in front a ridge, which detaches itself from the upper part of the bone in the form of a slender stem, resembling the vestige of a fibula discernible in various Rodents, but this does not prevent the development of a true fibula as large as the tibia, and which descends a little lower. There are 9 tarsal bones, all flat and disposed in a pavement-like order: the lower rank has 5 for the five metatarsal bones; the four others consist of one small (the tibial) at the internal border, one great (the fibular) at the external border, an oblong one between them, placed obliquely and answering to the tibia and fibula, and one square in the middle of all the others. Cuvier found but one phalanx on the first finger, two on the second, three on the third and fourth, and two on the last.

Reproduction of Parts.—The power of reproducing excised or injured parts has been observed in no family among the reptiles more carefully than in the *Tailed Amphibia.* Plateretti, Spallanzani, Murray, and others have recorded their observations with respect to this power; and Bonnet particularly has given most accurate descriptions and figures of his careful experiments. The arms or thighs of Tritons amputated sometimes on one side, sometimes on the other, or both on the same side, were constantly reproduced, and the toes were again gradually formed and endowed with motion. The tail, too, cut off at various points, was renewed, pushing out by little and little from the amputated base. In one case the same limb was reproduced four times consecutively in the same animal. Bonnet found that this reproduction was favoured by heat and retarded by cold. He observed that the parts of excised limbs were often reproduced with remarkable alterations, either of defect or excess; the deficiency or exuberance of certain parts taking upon themselves very singular forms. In many species of Tritons the long bones of the limbs detached from their principal articulation, and remaining suspended by some points which still caused them to adhere to the flesh, were found completely consolidated in a few days. The most extraordinary observation was that consequent on the total extirpation of the eye, which was entirely reproduced and perfectly organised at the end of a year. Dufay has recorded their faculty of remaining frozen up in ice for a long period without perishing.

Their tenacity of life was strongly shown in an experiment made by M. Duméril. Three-fourths of the head of a *Triton marmoratus* was removed with a pair of scissors. The mutilated animal was placed by itself at the bottom of a large glass vessel in fresh water about half an inch deep, and which was carefully renewed at least once a-day. The animal, although deprived of the four principal senses, without nostrils, without eyes and ears, and without a tongue, continued to live and move slowly. Its only communication with externals was carried on by touch alone. M. Duméril relates that it was evidently conscious of existence, and walked slowly and cautiously. It raised the stump of its neck towards the surface of the water, and during the first days was seen making efforts to breathe. In less than three months reproduction and cicatrisation had so done their work that there remained no aperture for the lungs, or for food. At the end of three months, M. Duméril was compelled to leave it to the care of another during an absence, and it died, in all probability, as he observes, from want of attention on the part of the person who undertook the care of it. This specimen is now preserved in the Paris Museum, and exhibits, as M. Duméril remarks, the singular fact of an animal having lived without a head; and a proof of the possibility and necessity, even in the Batrachians, of a sort of respiration by means of the skin. In this animal M. Duméril states that respiration was certainly thus carried on for three months, although the stump of the amputated part presented a cicatrice, the smooth surface of which proved, even when examined by a magnifying glass, that there was a complete obturation of the œsophagus and larynx.



Head of *Protonopsis*, seen from above.

Dr. Von Siebold has also recorded his observations on the reproduction of wounded or lost parts in the *Triton niger.*

The following are some of the more remarkable genera belonging to the *Tailed Amphibia*:—

Protonopsis.

Head flat, broad; two concentric rows of teeth (the inner row palatine) in the upper jaw, and a single row only in the lower jaw; tongue free in front; operculum situated about half way between the posterior edge of the rictus of the mouth and the fore-leg; three opercular cartilages, between the posterior, two of which form the aperture; feet fimbriated on their outer edge; toes four on the anterior feet, and five on the posterior; of the latter the fourth and fifth are webbed and without claws.

This is the *Abranchus* * and *Menopoma* of Harlan; *Protonopsis* of Barton; *Cryptobranchus* of Leukardt and Fitzinger; *Salamandrops* of Wagler.

There are two species known, the *Protonopsis horrida* and *P. fusca.* The first species is well known. Its length is about two feet; head broad and flattened; mouth wide; nostrils projecting; body thick and stout; tail compressed vertically, and nearly as long as the body; legs stout and short; colour slaty with dark spots on the body; a dark line runs through the eyes.

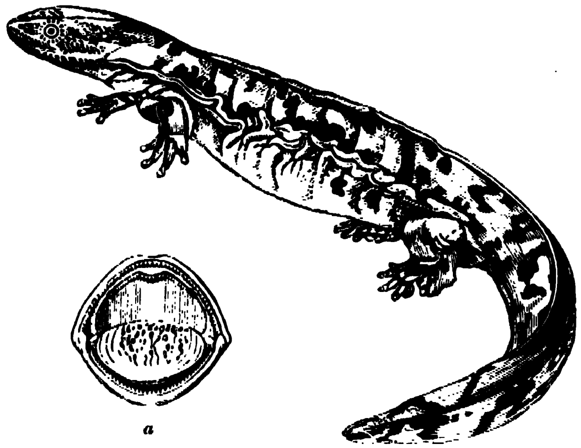
This is the *Hellbender, Mud Devil, Ground Puppy,* and *Young Alligator* of the Anglo-Americans; and *Fisch-Salamander* of the Germans.

It inhabits the Ohio and Alleghany rivers.

This Batrachian is carnivorous and very voracious; nothing that it can devour is spared by it. The fishermen dread it very much, and believe it to be poisonous. Indeed the appearance of the animal is altogether uncouth and forbidding.

Michaux appears to have been the first traveller who discovered and noticed the *Protonopsis.* He states that in the torrents of the Alleghanies is found a species of Salamander, called by the inhabitants 'Alligator of the Mountains,' and that there are some which are two feet in length.

There is a well-preserved skeleton of *Protonopsis horrida* in the museum of the Royal College of Surgeons in London.



Protonopsis Alleghaniensis.
a, Mouth open, showing the arrangement of the teeth.

Sieboldia.

Head large, trigono-ovate; rostrum produced, vertex convex; forehead concave; nostrils, in the anterior margin of the maxilla, approximate; eyes very small, hardly distinguishable; no parotids; tongue not distinct; palatine teeth numerous; a crest on the anterior margin of the vomers; posterior feet with cutaneous appendages; toes small, free, with depressed cutaneous lateral lobes; tail rather round at the base, very much depressed in the middle and behind, head thickly covered with glands; body depressed, with transverse folds and a long thick cutaneous appendage on each side.

Figures of the skull, showing the teeth, of the skeleton of the fore-hand, and of some of the vertebræ, are given on the preceding page.

This is the genus *Megalobatrachus* of Tschudi; but the Prince of Canino's name, *Sieboldia*, has the right of priority. The genus belongs to the sub-family *Andriadina* of the Prince's *Salamandridæ.*

Sieboldia maxima is the *Salamandria maxima* of Schlegel ('Fauna Japon.,' vii., tab. vi., vii., viii.), and was found by Dr. Von Siebold in a lake on a basaltic mountain in Japan. He brought away a male and a female; but the former devoured the latter during the passage. The gill-aperture slit always remains open in *Protonopsis*, but in this great newt the slits are closed. This animal is the nearest living analogue of *Andrias Scheuchzeri*, the celebrated *Homo Diluvii Testis* of Scheuchzer.

Triton.

Head rounded, convex; vertex somewhat flattened; tongue small, semi-globular, slightly free at each side, free and pointed behind; palatine teeth numerous, disposed in two rows; body granulous; no parotids; tail compressed, as long as the body; glandular pores behind and over the eyes, and a longitudinal row of distant and similar pores along each side. Toes four on the anterior and five on the posterior feet. Crests of the back and tail (in the male) separate.

Example, *Triton cristatus.*

The colour is blackish, orange-coloured beneath, sprinkled with round black spots; sides dotted with white; upper lip overhanging the lower, but not having a distinct lobe; body warty or tuberculated; tail rather smooth, compressed, sharp, trenchant above and below. Length six inches.

Male (in the spring) with an acute toothed dorsal crest; tail with a longitudinal white stripe. In winter without a crest, and much resembling the female.

---

* Afterwards changed to *Menopoma* by Dr. Harlan, *Abranchus* having been pre-occupied by Van Hasselt to designate a genus of mollusks.

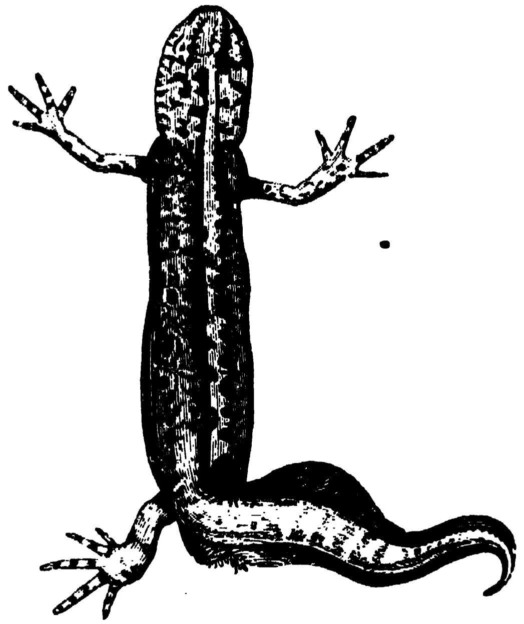
Female.—No crest; lower edge of the tail orange.

Young.—Olive-brown with a sulphureous dorsal line; abdomen orange, spotted with black; lower edge of the tail orange-red.

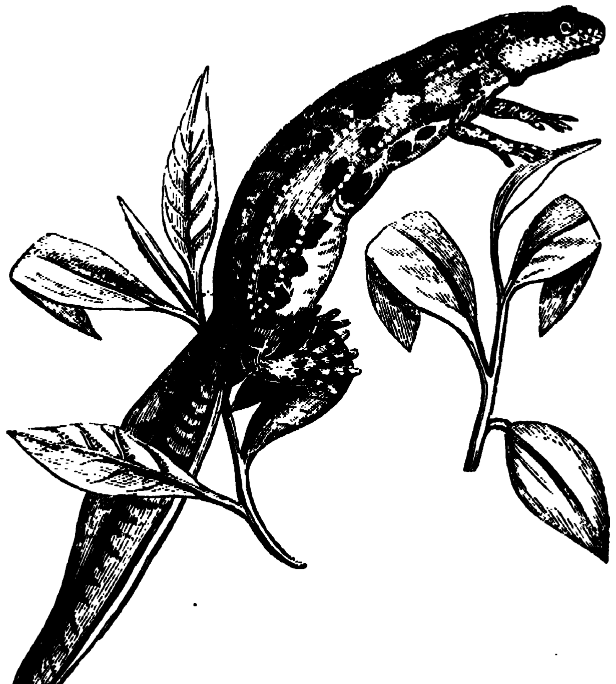
This is the *Lacerta palustris* of Linnæus; *Salamandra aquatica* of Ray; *Salamandra cristata* of Schneider, Daudin, &c.; *Triton palustris* of Fleming; *Salamandra platycauda* of Rusconi; *Molge* of Merrett; *Molge palustris* of Merrem; *Grosse Wasser-Salamander* and *Sumpf-Salamander* of Bechstein; *Warty Lizard* of Pennant; *Common Warty Newt* and *Great Water-Newt* of the British.

It is ditributed over the whole of Europe, and is found in western and northern Asia.

Habits.—The ponds and ditches of this country abound with this the largest British Newt, and a most voracious animal it is. Aquatic insects, and indeed any small living animals which come in its way, are unsparingly devoured. It is a great destroyer of tadpoles, and the smaller Water-Newt (*Lissotriton punctatus*) frequently falls a victim to its ferocity and voracity. Mr. Bell has taken them more than once in the act of swallowing an individual of the smaller species, which was so large as to occasion great difficulty and delay in the act of deglutition. In swimming, the legs are turned backwards to lessen resistance, and the animal is propelled principally by the tail. Every one has observed the Newts, or Efts, as they are called in many places, floating motionless at the surface of the water, with their limbs extended at right angles with the body, and their toes spread out. Their progression at the bottom of the water, and on land, is performed creepingly with their small and weak feet.



Triton cristatus, male, in the spring season, seen from above.

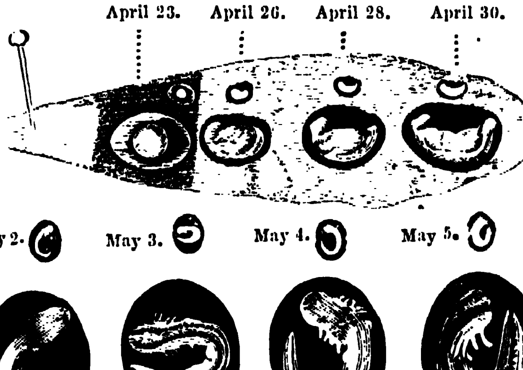


Triton cristatus, female, in the act of compressing a turned leaf upon her included egg. The leaves folded back represent those in which eggs have already been thus laid. (Rusconi.)

Generation.—For our knowledge of this subject we are chiefly indebted to the observations of Rusconi. Mr. Bell, in his work on 'British Reptiles,' has confirmed most of Rusconi's observations, and also added some of his own.

Rusconi enters into minute details of the actions of the male from the time of its first pursuit of the female to the period of fecundation, for which we refer the reader to the work itself. ('Amours des Salamandres Aquatiques, et Developement du Têtard de ces Salamandres depuis l'Œuf jusqu' à l'Animal Parfait,' Milan, 1821.) Prior to the time of depositing her eggs, the female remains immoveable; at last she moves, and slowly goes in search of a plant proper for receiving her eggs, choosing almost always, when present, the *Polygonum Persicaria.* She first approaches her head to the edges of a leaf, and turns it with her snout in such a way that the lower surface of the leaf, which was towards the bottom, is turned towards her breast: then with her fore-paws she passes the turned leaf beneath her belly, seizes it with her hind-paws, and conducts it beneath the vent, folding it at the same time, and forming with it an angle the opening of which is directed towards the tail. The egg in escaping from the vent would thus pass through the middle of the angle formed by the leaf, but the salamander stops it in its fall by her hind-feet, shuts up this angle with them, and thus forms in the leaf a fold in which the egg is held. Still on the removal of the feet the egg would fall to the bottom of the water; but the careful parent, before she quits the leaf, folds it so firmly with her hind-feet that the gluten with which the envelope of the egg is surrounded spreads from the pressure on the two internal surfaces of the leaf, and prevents the folds from opening. When several eggs have been laid in this manner, in different leaves, the female remains quiet until another male comes to caress her. Rusconi did not ascertain how long the period of laying continued; but he found eggs as early as the middle of April and as late as the middle of July.

The following figures, given by the same author, exhibit the several stages of the evolution of the egg which was kept on its proper leaf: these stages are denoted by the dates of the days on which the drawings were made. Thus, the figure marked 23rd April shows the egg of its natural size, and the figure below it the same magnified.

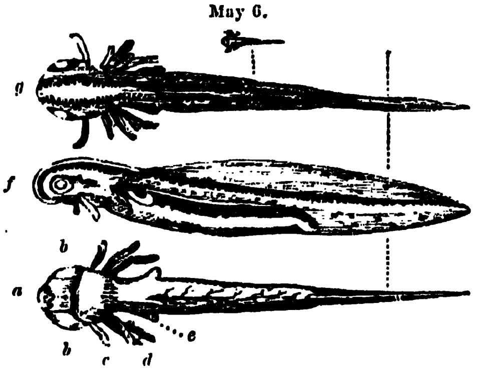


April 23.
April 26.
April 28.
April 30.
May 2.
May 3.
May 4.
May 5.

The temperature of the water during the period of Rusconi's observations varied from 22° to 27° Centigrade (71·6° to 80·6° Fahr.) The globule in the centre of the ovum is white with a yellow tint, and is environed with a glairy matter, to which it is not attached, so that it can move freely in every direction. Its envelope is membranous, of glassy transparence, and covered with a very clear viscid matter: the specific gravity of this matter appears to be less than that of the globule. In three days the globule had undergone the change exhibited at April 26. Under the microscope may be observed in the embryo the commencement of the parts which are to become the head, the belly, and the tail. The globule at first becomes enlarged, then elongated, and its previously smooth surface presents some small eminences. If it has not been fecundated, or has lost its prolific power, it enlarges, nevertheless, during the first days, as in ordinary cases, but afterwards changes so as to resemble a vesicle half filled with water: when this appearance comes on, the egg has lost its vitality.

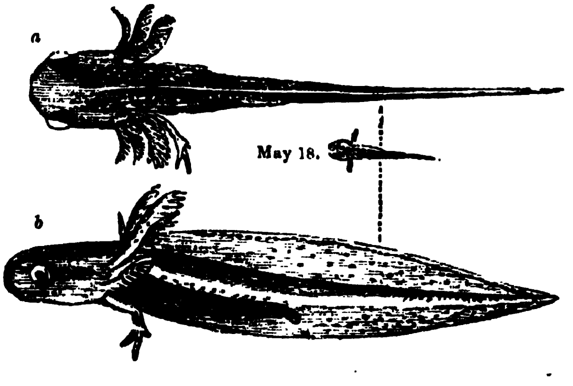
On the 28th of April (fifth day) the embryo has grown so long that it becomes bent in order to accommodate itself to the circumscribed envelope. Now the head, abdomen, and tail are easily distinguishable, and near the head (the larger extremity) small elevations (the rudiments of gills and fore-feet) are perceptible. These parts become more apparent by the 30th, when in the concave side of the embryo and towards the head a small furrow is seen which separates the head from the abdomen, and the rudiments of a spine are distinctly visible along its convex border.

By the 2nd of May the position of the embryo is changed, and the tail has already assumed its oar-like form. The embryo begins to move, and its heart may be seen to beat; colour, too, begins to be present. This appears to be a critical state of the embryo; for almost half of those of which the development was watched by Rusconi, died at this period or soon after. 3rd May. On one side of the head, and before the two elevations which are the rudiments of the fore-feet, filaments to the number of four on each side may be observed. 4th May. The changes of position become frequent. In that here presented the embryo shows the lower part of its head and trunk, which is white inclining to green. On the chest between the gills of the two sides, where the pulsations of the heart are seen, small irregular blackish spots are observable. Before the two claspers are seen also other blackish spots, forming the junction of the two bands which run along the back, as shown in the preceding figure. The circulation of the blood, which is simple, and performed by a single curved vessel, is seen in the gills, which are of a glassy transparence, and consist only of a single filament without leaflets as yet. 5th May. Traces of the eyes may now be just seen; and the rudiments of the two leaflets are perceptible on the two longest gills. 6th May. The upper small figure shows the young Salamander, seen from above, and of the natural size, just escaped from the envelope. Before its escape, the embryo as it enlarges gradually dilates the envelope, which at last it tears, and so forces its way out. As yet the eyes are scarcely defined, though they form two prominences on the sides of the head, and its mouth is so slightly traced that attentive observation is required to detect it; for it is indicated only by a slight transverse depression beneath the head, and between the two prominences formed by the eyes, and in the middle of the space between the anterior border of the head and the origin of the neck. Its fore-feet begin to separate like buds from the gills, which last are gradually furnished with small leaflets.



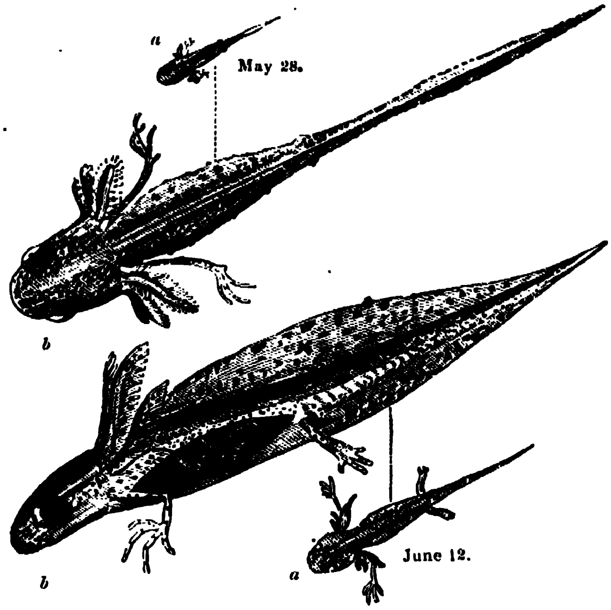
Stages of development of *Triton cristatus* after exclusion from the egg.

a shows the Salamander in this stage, magnified and seen from below; *bb* are the two prominences formed by the globes of the eyes, and between them is the slight depression which afterwards becomes the mouth; *c*, the hook of the right side; *d*, the gills of the same side; *e*, rudiment of fore-feet of the same side; *f* represents the same seen in profile, and *g* the same seen from above.



Further stages of development of *Triton cristatus*.

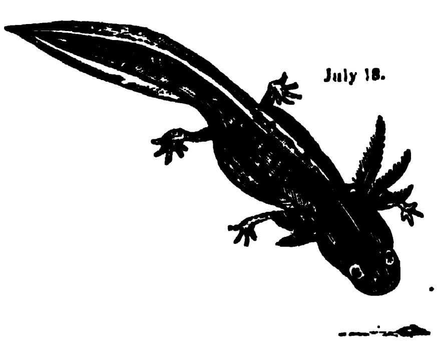
The middle and small figure above shows the natural size of the Salamander-Tadpole on the 18th of May, twelve days after its exclusion from the egg. By this time the fore-feet have become [illegible], and are divided at their extremity like a bicuspid teeth; these two tubercles elongate, and are converted into two toes. Now the eyes are disclosed; the pupil black, the white speckled with various colours. The yellow back of the little animal has become green, and the gills are now furnished with leaflets, in which red blood circulates. The transverse depression between the eyes above noticed has become a very large mouth, whose extremities extend on the sides of the head to the eyes. The head, hitherto narrow behind, has become much enlarged near the origin of the gills. The two hooks by which the animal anchored itself have disappeared, and the opaque body has become so transparent that the action of the heart and the form and disposition of the abdominal viscera may be observed in the living animal. With this advance in organisation the sluggishness of the animal has vanished, and its habits are now manifested. It may be seen near the surface, hiding beneath leaves or swimming with rapidity. If, while it floats at rest, a small aquatic insect should pass before it near the surface, it pursues it deliberately, and as soon as it approaches within reach, darts upon it and swallows the prey. Here then we have the little Salamander in the enjoyment of active animal life.



Further stages of development of *Triton cristatus*.

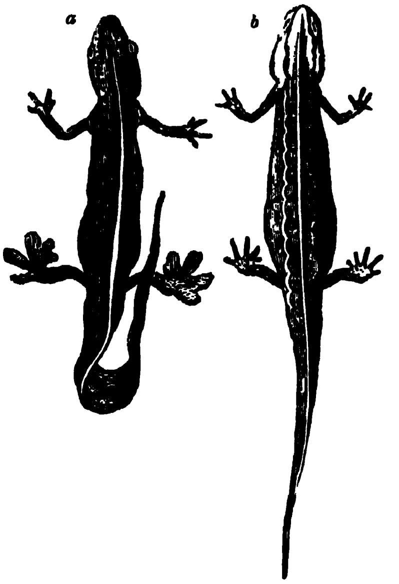
a, shows the young Salamander at this stage, natural size, seen from above; and *b*, the same magnified, seen from above and in profile.

By the 28th of May the Salamander has put on the form above given in the upper figures, seen from above. About this time the hind-feet begin to appear, and the fore-feet are well developed; these last are, as will be seen, long in proportion to the trunk. The following are the principal points manifested under the microscope in this stage:—1, two small eminences or excrescences, extending from the axillæ to the abdomen; 2, the parietes of the abdomen take the colour of the insects on which the animal feeds; 3, the changes of colour from yellow to green, during the growth of the tadpole, are purely accidental, and commence immediately on the escape of the animal from the egg; 4, the inner toes first push forth, and this holds good also with regard to the hind-feet; 5, the amylaceous bone of the organ of hearing is now formed, and may be seen through the skull and skin; 6, at this period, and even sooner, the animal begins to expel air from the mouth. The two lower cuts show the same salamander on the 12th June; the small figure represents it of the natural size and as seen from above, and the larger figure magnified and in profile. Now the hind-feet have almost attained their development, though the fifth toe is wanting. The lungs extend about half-way down the trunk, and are visible through the parietes of the abdomen. The longest gills, which were furnished with only 13 or 14 leaflets 13 or 14 days previously, have now nearly 20.



Last stage of the tadpole of *Triton cristatus*.

On the 18th of July the young Salamander, as represented above, had arrived at the maturity of its tadpole state, and it is represented watching a small mollusk to ascertain whether it is living and fit for prey. Rusconi found that on this day the gills appeared rather shorter than on the day before. On the next day the leaflets at the extremities of the gills were obliterated, and the gill-stem itself was shortened. On the 27th of July the Salamander had lost even the smallest trace either of gills or of branchial apertures. It respired atmospheric air only, and having arrived at its perfect state, made strong efforts to escape from the vessel in which it had undergone its metamorphosis.



Lissotriton punctatus, seen from above. *a*, Male, the toes of whose hind-feet are furnished in the breeding season with a black-spotted membrane, in the act of lashing his tail; *b*, female.

In its complete state this species habitually lives in the water, and is seldom to be found on land unless the pond which has been its abode is dried up, and the animal finds itself obliged to walk in search of another.

The development of the Common Smooth Newt (*Lissotriton punctatus*, Bell; *Triton punctatus*, Auct.; *Triton palustris*, Laur.; *Salamandra punctata*, Daud.; *Molge punctata*, Merr.; *Salamandra exigua*, Rusc.; and *Brown Lizard* of Pennant) was also observed by Rusconi; but it did not require particular notice, being very similar to that of *Triton cristatus*. *Triton punctatus*, however, showed itself much the more brisk animal of the two; and the lashings of the tail of the male in his approaches to the female were much more rapid.

Salamandra.

Head thick; eyes large; gape of the mouth ample; tongue broad; palatine teeth arranged in two long series; parotids large; body sprinkled with many small glands; toes free; tail rather smooth.

Example, *Salamandra maculosa*, Laur.

This species is black with yellow spots, and has numerous prominent warty excrescences on the sides; tongue very large; palatine teeth spatuliform; toes smooth.

This is the *Salamandra* of Gesner; *Salamandra terrestris* of Aldrovandus, Ray, and others; *Salamandre de Terre* of the French; and *Gefleckte Erd-Salamander* of the Germans.

It inhabits Central Europe and the mountainous parts of the south of Europe.

The Land Salamander, unlike the Tritons, is ovoviviparous, though the young at first inhabit the water and undergo metamorphoses till they arrive at the mature state which fits them for living upon land, where they haunt cool and moist places, being not unfrequently found about fallen timber or old walls. Their food principally consists of insects, worms, and small molluscous animals. In the winter they retire to some hollow tree or hole in an old wall, or even in the ground, where they coil themselves up, and remain in a torpid state till the spring again calls them forth.

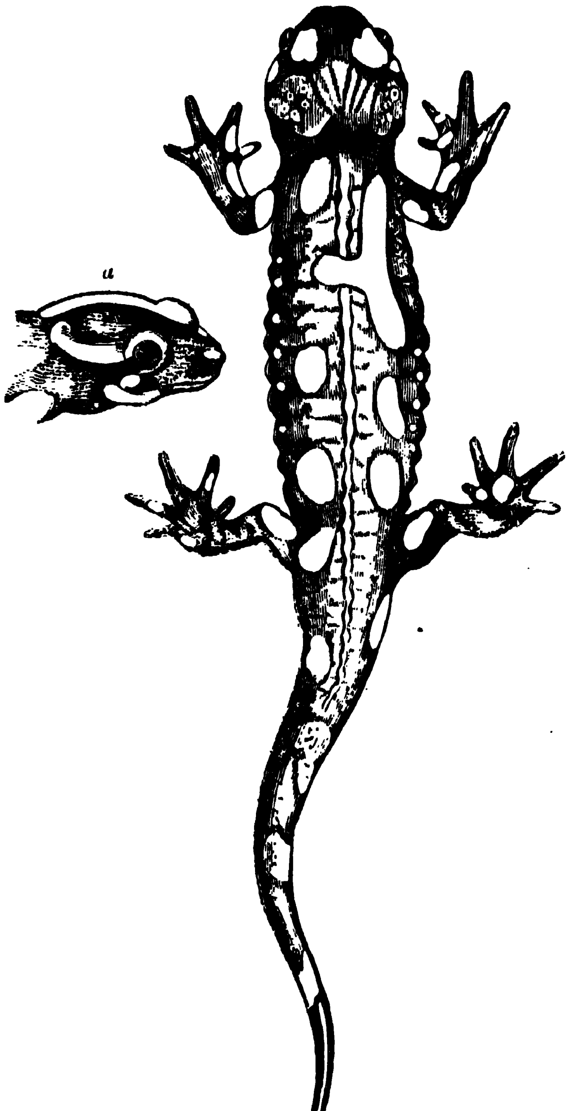
The body of the Salamander is largely covered with warty glands. These secrete a milky fluid of a glutinous and acrid nature like that of the toad, which, if not capable of affecting the larger and more highly-organised animals, appears to be a destructive agent to some of those which are less highly organised. Thus Laurenti provoked two gray lizards to bite a Salamander, which at first attempted to escape from them, but being still persecuted ejected some of this fluid into their mouths; one of the lizards died instantly, and the other fell into convulsions for two minutes, and then expired. Some of this juice was introduced into the mouth of another lizard; it became convulsed, was paralytic on the whole of one side, and soon died.

This is the only foundation for the long-cherished notion that the Salamander was one of the most venomous of animals. Nicander, in his 'Alexipharmaca,' gives an appalling picture of the symptoms produced by its bite. The Romans looked on it with horror, as most destructive; and considered it as deadly a part of the poisoner's laboratory as aconite or hemlock. Hence came a proverb that he who was bitten by a Salamander had need of as many physicians as the animal had spots; and another still more hopeless: "If a Salamander bites you, put on your shroud."

Not only was its bite considered fatal and the administration of the animal itself taken internally believed to be deadly, but anything that its saliva had touched was said to become poisonous. Thus, if it crept over an apple-tree, it was supposed to poison all the fruit with its saliva; and even herbs on which the fluid fell were believed to affect those who tasted them with vomiting. These fables had taken such strong hold, that it was thought worthy of record in the 'Acta Acad. Nat. Cur.' that a man had eaten a Salamander, which his wife had put into his food in the hope of becoming a widow, without suffering any inconvenience.

But the grand absurdity of all was the belief that the Salamander was incombustible; that it not only resisted the action of fire, but extinguished it; and, when it saw the flame, charged it as an enemy which it well knew how to vanquish.

Aristotle, whose Salamandra (σαλαμάνδρα) this appears to be, has been quoted as giving his sanction to this belief, and indeed he cites it as a proof that there are animals over which flame has no power: "the Salamandra, as they say, when it goes through fire, extinguishes it." ('Hist. An.,' v. 19.) Now this is evidently only a reference to report; and it is not improbable that a copious secretion of the fluid above noticed might, in a rapid and short passage, so damp the fire that the animal might get through comparatively unhurt. Ælian (ii. 31) says not only that it will live in the flames, but that it attacks fire like an enemy. Nicander, Dioscorides, and Pliny all add their authority; and the latter not only relates that they extinguish fire by their touch, but that they are without sex and produce nothing. He dwells on their poison as being of the worst description, and is profuse in his catalogue of remedies. ('Hist. Nat.,' xxix. 4.) But even so late as 1789 there was an attempt to revive these wondrous tales. A French consul at Rhodes relates that, while sitting in his chamber there, he heard a loud cry in his kitchen, whither he ran and found his cook in a horrible fright, who informed him that he had seen the devil in the fire. M. Pothonier then states that he looked into a bright [illegible] and there saw a little animal with open mouth and palpitating throat. He took the tongs and endeavoured to secure it. At his first attempt the animal, which he says had been motionless up to that time (two or three minutes), ran into a corner of the chimney, having lost the tip of its tail in escaping, and buried itself in a heap of hot ashes. In his second attempt the consul was successful drew



Salamandra maculosa, seen from above. *a*, profile of head.

the animal out, which he describes as a kind of small lizard, plunged it into spirit of wine, and gave it to Buffon. This appears to be very circumstantial, and M. Pothonier, whose head was evidently filled with preconceived opinions, may be acquitted of any intention to deceive.

That the skin of an animal which could resist the action of fire should be considered proof against that element is not to be wondered at. We accordingly find that a cloth said to be made of the skins of salamanders was incombustible, as is noticed by Marco Polo, who however was shrewd enough to observe that these fire-proof cloths were really made of a mineral substance (asbestos, no doubt, which the old writers termed Salamander's Wool). Such most probably was the Salamander-Cloth sent by the Tartar king to the Roman pontiff, in which the Holy Napkin (*Sudarium Domini*) is preserved.

Among the other fables may be noticed the belief that the saliva of the Salamander was depilatory—having the power to remove hair, and substitute bald places for luxuriant tresses. Martial has an epigram, of which this notion forms the point (lib. ii., ep. lxvi).

Its heart, worn as an amulet, was considered to be a prophylactic against fire, and it was used in medicine to eradicate leprosy.

It could hardly be expected that the alchymists would neglect animals of which such wonders were rife; and we accordingly find that the power of transmuting quicksilver into gold was attributed to them. To this end the wretched reptiles were placed in a vessel on the coals, and quicksilver introduced through an iron tube was poured upon them. This experiment was supposed to be accompanied with danger to the life of the operator. Those who would further dwell on the legends connected with this subject may consult Funk's work, 'De Salamandræ Terrestris Vita, Evolutione, et Formatione.'

In the catalogue of the specimens of *Amphibia* in the British Museum the following arrangement is adopted. The catalogue of the first suborder, the *Anourous Amphibia*, is not yet published (June, 1853).

Order I. BATRACHIA.

Suborder I. SALIENTIA (including the Frogs and Toads).

(Arrangement not yet published.)

Suborder II. GRADIENTIA.

Fam. I. SALAMANDRIDÆ.

Name.	Locality.
Salamandra nigra	Europe.
„ *maculosa*	„
Pleurodoles Waltl	„
Triton Poiretii	North Africa.
„ *cristatus*	Europe.
„ *marmoratus*	„
„ *alpestris*	„
Notophthalmus miniatus	North America, East Coast.
„ *viridescens*	„ „
Euproctus platycephalus	Corsica and Sardinia.
Cynops pyrrhogaster	Japan.
Taricha torosa	California.
„ *lugubris*	North America.
Bradybates ventricosus	Spain.
Lophinus punctatus	Europe.
„ *palmatus*	„
Ommatotriton vittatus	Syria.
Seiranota perspicillata	Europe.

Fam. II. MOLGIDÆ.

Hynobius nebulosus	Japan.
Molge striata	„

Fam. III. PLETHODONTIDÆ.

Onychodactylus Japonicus	Japan.
Heterotriton ingens	North America, East Coast.
Xiphonura Jeffersoniana	„ „
Ambystoma Carolinæ	„ „
„ *tigrinum*	„ „
„ *talpoideum*	„ „
„ *opacum*	„ „
„ *punctulatum*	„ West Coast.
„ *macrodactylum*	„ „
„ *mavortium*	„ „
„ *episcopus*	„ East Coast.
„ *erythronotum*	„ „
„ *Haldemani* (?)	„ „
„ *frontale* (?)	„ „
Plethodon glutinosum	„ „
„ *granulatum*	„ „
Desmognathus niger	„ „
„ *fuscus*	„ „
„ *auriculatus*	„ „
Hemidactylum scutatum	„ „
Batrachoseps attenuatus	„ West Coast.
„ *quadridigitatus*	„ East Coast.
Spelerpes longicauda	„ „
Spelerpes cirrigera	North America, East Coast.
„ *bilineata*	„ „
„ *gutto-lineata*	„ „
„ *rubra*	„ „
„ *montana*	„ „
„ *salmonea*	„ „
„ *porphyritica*	„ „
„ *Bellii*	Mexico.
Geotriton fuscus	Italy.
Œdipus variegatus	North America, West Coast.
Ensatina Eschscholtzii	„ „
Axolotl	Mexico.
„ *maculata*	„

Order II. PSEUDOSAURIA.

Fam. I. PROTONOPSIDÆ.

Sieboldia maxima	Japan.
Protonopsis horrida	North America, East Coast.
„ *fusca*	„ „

Fam. II. AMPHIUMIDÆ.

Amphiuma means	North America, East Coast.
Murænopsis tridactyla	„ „

Order III. PSEUDOPHIDIA.

Fam. I. CÆCILIIDÆ.

Cæcilia gracilis	Tropical America.
„ *tentaculata*	„
„ *compressicauda*	„
„ *rostrata*	„
„ *oxyura*	Malabar.
„ *squalostoma*	West Africa.
Siphonops interrupta	Tropical America.
„ *Mexicana*	„
Icthyophis glutinosus	Ceylon.
Rhimatrema bivittatum	Tropical America.

Order IV. PSEUDOICTHYAS.

Fam. I. LEPIDOSIRENIDÆ.

Lepidosiren paradoxa	Tropical America.
Protopterus annectens	West Africa.
„ *rhinocryptis*	„

Order V. MEANTIA.

Fam. I. PROTEIDÆ.

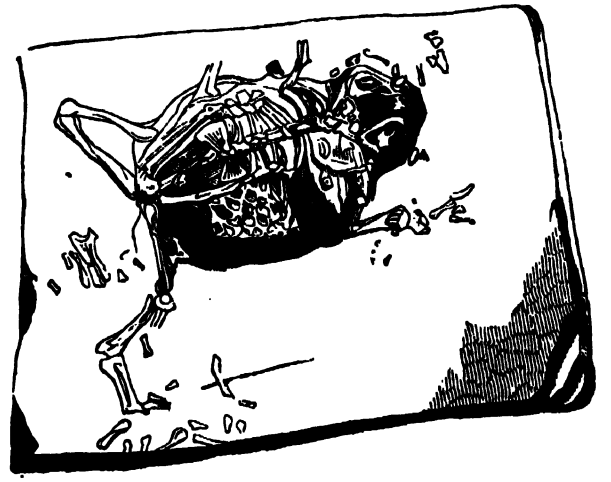
Proteus anguinus	Europe.
Necturus maculosus	North America, East Coast.
„ *lateralis*	„ „

Fam. II. SIRENIDÆ.

Siren Lacertina	Carolina.
„ *intermedia*	Texas.
Pseudobranchus striatus	North America, East Coast.

FOSSIL AMPHIBIA.

Fossil Anourous Amphibia.—Fossil Frogs have been found in the Coal-formation of the Rhine (*Papier-Kohl*) in company with the fishes *Leuciscus macrurus* and *L. papyraceus.* Two species have been described, and there are many examples in the museum at Bonn. In this country specimens are to be found in the collections of the Earl of Enniskillen and Sir Philip Egerton, Bart.



Palæophrynos Gessneri. (Tschudi.)

Fossil Toads.—Here may be noticed the fossil specimens from the Œningen Beds—*Bombinator Œningensis,* Agass. (*Pelophilus Agassizii,* Tschudi), and *Palæophrynos Gessneri*, Tschudi. (See 'Classification der Batrachier' of J. J. Tschudi, pp. 84, 89, tab. 1, ff. 2, 3.)

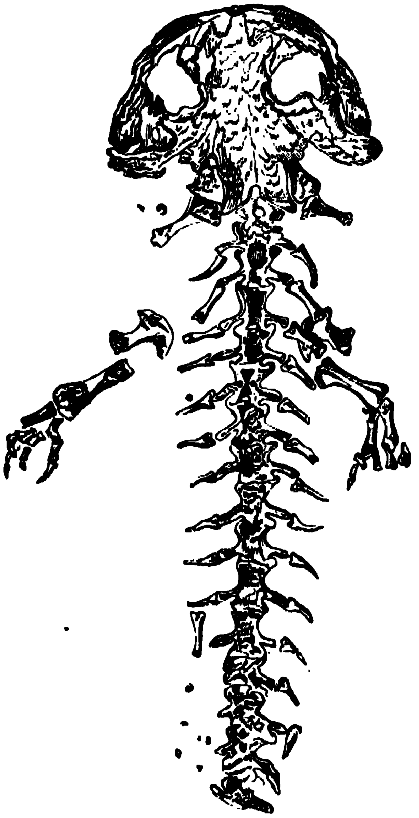
Fossil Salamandridæ.—Few fossils have awakened more curiosity than the *Homo Diluvii Testis* of Scheuchzer, who was unwearied in collecting organic remains, which he considered irrefragable evidence of the general deluge. At length he obtained from the Œningen Beds (Miocene Period of Lyell) a fossil which he viewed with transport as the unequivocal remains of Man himself. A short description of this specimen was published by him in the 'Philosophical Transactions' for 1726. He again brought forward this piece of 'good fortune'—(in his rapture he writes the last two words in Greek—) in his 'Physica Sacra,' where he tells us that previously he had only possessed two dorsal vertebræ. Of the humanity of his prize he certainly entertained no doubt. In his rapturous vision he saw in the fossil not only one part of the human skeleton, but many parts. No fancy could possibly lead astray in a case where there were appearances of bones, and flesh, and even the softer parts of flesh, impressed on the solid stone. Here indeed was a rarity above all rarities. He gives no bad figure of the fossil in tab. xlix. of the work last quoted. When we look at that figure, it is difficult to conceive how such remains could have appeared to a physician, who must have had some acquaintance with osteology, to be those of man; and we can only account for it by the blindness which an excited imagination and a determined adherence to theory can produce. The iteration and determination of Scheuchzer had its effect, and naturalists adopted his opinions. Gesner (1758) appears to have been the first who threw deserved doubt on the alleged nature of the fossil; for though he quotes it as an anthropolite, he nevertheless, having become possessed of a similar specimen, offers his conjecture that it was a fossil fish (*Silurus glanis*, Linn.), and the obsequious naturalists were now as ready to follow him as they had been eager to run after Scheuchzer.

Gesner's specimen does not appear to have been engraved, nor another which was said to be in the convent of Augustins at Œningen; but a third specimen, more complete than Scheuchzer's, came into the possession of Dr. Ammann of Zürich, and is now in the British Museum. A figure of this was published by Karg, in the 'Memoirs of the Society of Naturalists of Suabia.'

Cuvier well observes that a comparison of the specimen with the skeleton of Man must at once have destroyed the idea that it was anthropolite; and it would be a waste of space to repeat here the details of that comparison which Cuvier so well follows out, and to which we refer. ('Ossemens Fossiles,' tom. v., pt. 2, p. 433, ed. 1824.)

Karg, after figuring Dr. Ammann's specimen, expressly stated that he had no doubt that the fossil was a *Silurus*, an opinion which Jäger refuted by placing by the side of the figure of the fossil, one of the skeleton of *Silurus glanis*. Cuvier disposes of this opinion with the same success as attends his former demonstration.

The rounded head and great orbits of the fossil struck Cuvier as strongly resembling the head of a frog or a salamander; and he states that, as soon as he beheld Karg's figure, he perceived in the vestiges of the hind-feet and the tail evidence in favour of the last-named genus.



Anterior part of *Andrias Scheuchzeri*, Tschudi, seen from above. (Cuvier.)

Cuvier, being at Haarlem in 1811, obtained permission to work upon the stone which contained the pretended anthropolite of Scheuchzer, for the purpose of uncovering any bones which might be still hidden there. During the operation, the figure of the skeleton of a salamander was placed before the operators; and Cuvier relates the pleasure which they felt, as they saw, while the chisel chipped away pieces of the stone, the bones which the figure had already announced.

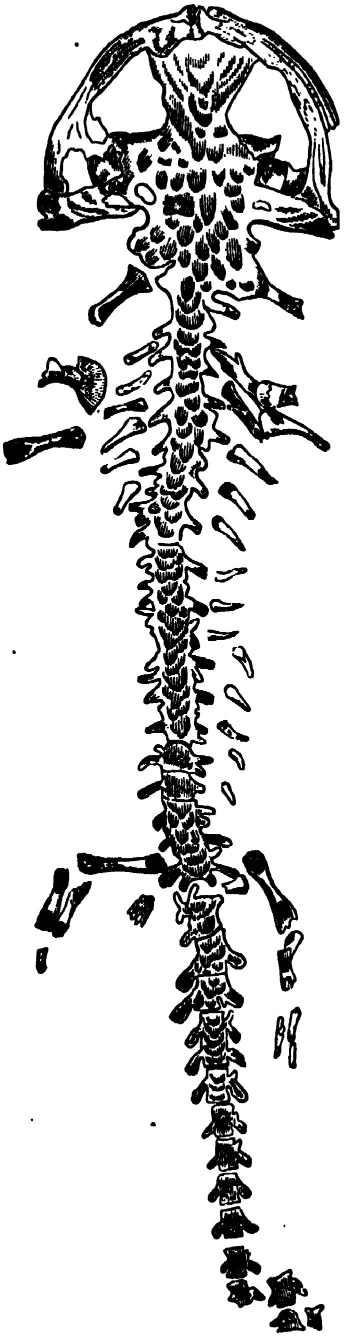
But by far the finest head of *Andrias Scheuchzeri* is figured by Tschudi, in his work above quoted, tab. 3; and many most interesting details are given in tab. 4 and tab. 5. These show how nearly allied this gigantic Fossil Newt was to *Sieboldia maxima*.

Salamandra ogygia, Goldf., is found in the Braunkohle (Tertiary), where also *Triton Noachicus*, Goldf., occurs. *Triton palustris* (?) *fossilis* of Karg is from the Œningen Slate.

Under the generic title *Salamandroïdes*, Professor Jäger described a fossil reptile from the German Keuper, giving it the specific name of *giganteus*. This fossil now appears to be identical with *Mastodonsaurus* and *Phytosaurus*. Professor Owen therefore proposes to designate this gigantic genus of extinct Batrachians—for to that order he has satisfactorily shown that the form belongs—by the name of *Labyrinthodon* (from the extraordinary structure of its teeth), in his paper 'On the Teeth of Species of the Genus *Labyrinthodon* (*Mastodonsaurus*, *Salamandroïdes* and *Phytosaurus* (?) of Jäger) from the German Keuper and the Sandstone of Warwick and Leamington.'

The following description of the teeth of this animal, from the 'Proceedings of the Geological Society,' will afford some idea of the peculiarity of its structure:—

"The plan and principle of the structure of the tooth of the *Labyrinthodon* are the same as those of the tooth of the *Ichthyosaurus*, but they are carried out to the highest degree of complication. The converging vertical folds of the external cement are continued close to the centre of the tooth, and instead of being straight simple lamellæ, they present a series of irregular folds, increasing in complexity as they proceed inwards, and resembling the labyrinthic anfractuosities of the surface of the brain; each converging fold is slightly dilated at its termination close to the pulp-cavity. The ordinary laws of dental structure are however strictly adhered to, and every space intercepted by a convolution of the folds of the cement is occupied by corresponding processes of the dentine. These characters were presented by a transverse section of a fragment of a tooth of the *Labyrinthodon Jägeri* from the German Keuper, which included about the middle third part of a tooth, and Mr. Owen considers that the entire length of the tooth might be 3¼ inches, and the breadth at the basis 1¼ inch.



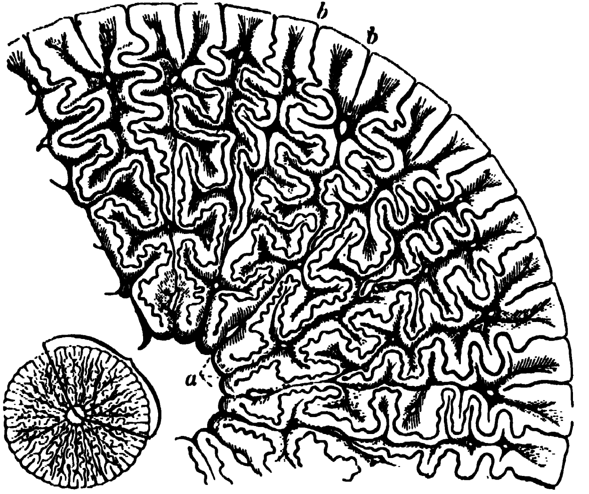
Andrias Scheuchzeri, Tschudi, seen from above. (Cuvier.)

"The external longitudinal grooves, which correspond to the inflected folds of the cement, extend upwards from the base of the tooth to about three-fourths of its height, decreasing in number as the tooth diminishes in thickness, and disappearing about half an inch from the summit of the tooth. Each fold of cement penetrates less deeply as the groove approaches its termination; and Mr. Owen conceives that the structure of the upper part of the tooth may be more simple than that of the lower, but he has not yet been able to extend his investigations to it.

"The dentine consists of a slender, central, conical column, or 'modiolus,' hollow for a certain distance from its base, and radiating outwards from its circumference a series of vertical plates, which divide into two, once or twice, before they terminate at the periphery of the tooth. Each of these diverging and dichotomizing vertical plates gives off throughout its course narrower vertical plates, which stand at nearly right angles to the main plate, in relation to which they are generally opposite, but sometimes alternate. Many of the secondary plates which are given off near the centre of the tooth also divide into two before they terminate. They partake of all the undulations which characterise the inflected folds of the cement.

"The central pulp-cavity is reduced to a line, about the upper third of the tooth; but fissures radiate from it, corresponding in number with the radiating plates of the dentine. One of these fissures is continued along the middle of each plate, dividing where it divides, and penetrating each bifurcation and process; the main fissures extend to within a line or half a line of the periphery of the tooth; the terminations of these, as well as the fissures of the lateral processes, suddenly dilating into subcircular, oval, or pyriform spaces. All these spaces constitute centres of radiation of the fine calcigerous tubes, which, with their uniting clear substance, constitute the dentine. The number of these calcigerous tubes, which are the centres of minor ramifications, defies all calculation. Their diameter is the $\frac{1}{7000}$th of a line, with interspaces equal to 7 diameters of their cavities."

By the permission of Professor Owen we are enabled to give a section of this highly complicated tooth, from his elaborate 'Odontography' (pl. 64, A.), in which the subject is treated with minute detail (part ii., p. 203, &c.).



Transverse Section of Tooth of *Labyrinthodon Jägeri* (Owen); ***Mastodonsaurus Jägeri*** (Meyer); natural size, and a segment magnified. *a*, pulp-cavity, from which the processes of pulp and dentine radiate; *b*, cement.

In connection with this subject we may call the reader's attention to some facts of considerable interest, which have lately been studied with much care and success, and have become of such importance as to constitute a distinct branch of inquiry under the name of *Ichnology* (Ιχνος, a footstep, and λόγος, a discourse).

This department of geological investigation is conversant with the phenomena of footsteps impressed by animals on the strata of the earth.

In 1828 Mr. Duncan's account of tracks and footmarks of animals impressed on sandstone in the quarry of Corn-Cockle Muir, Dumfriesshire, appeared in the 'Transactions of the Royal Society of Edinburgh.' Dr. Buckland caused a living *Emys* and *Testudo Græca* to walk on soft sand, clay, and paste or unbaked pie-crust. He found the correspondence of the footsteps of the latter with the fossil footsteps sufficiently close, allowing for difference of species, to render it highly probable that the fossil footsteps were impressed by *Testudo Græca.*

In Saxony, at the village of Hessberg, near Hildburghausen, fossil footsteps were, a few years ago, discovered in several quarries of gray Quartzose Sandstone alternating with beds of Red-Sandstone, nearly of the age of the Red-Sandstone of Corn-Cockle Muir. Dr. Hohnbaum and Professor Kaup state that those impressions of feet are partly concave and partly in relief; the depressions are described as being upon the upper surfaces of the Sandstone slabs, but the footmarks in relief are only upon the lower surfaces, and cover the depressions. In short, the footmarks in relief are natural casts formed in the subjacent footsteps as in moulds. On one slab, 6 feet long by 5 feet wide, many footsteps of more than one animal and of various sizes occur. The larger impressions, which seem to be those of the hind-foot, are generally 8 inches in length and 5 in width, and one was 12 inches long.

The name of *Chirotherium* was proposed by Professor Kaup as the provisional name for the great unknown animal that impressed the larger footsteps, from a supposed resemblance in the marks of both the fore- and hind-feet to the impress made by a human hand; and he thought that they might have been derived from some quadruped allied to the *Marsupialia.* Dr. Sickler, in a letter to Blumenbach (1834), gave a further account of those footsteps. Fragments of bones were found in the quarries where the footsteps had been impressed, but those fragments were destroyed.

The existence of footprints of this kind soon became more extensively known. In his address to the Geological Society, in 1840, Dr. Buckland says:—"Further discoveries of the footsteps of *Chirotherium* and five or six smaller reptiles in the New Red-Sandstone of Cheshire, Warwickshire, and Salop, have been brought before us by Sir P. Egerton, Mr. J. Taylor, jun., Mr. Strickland, and Dr. Ward. Mr. Cunningham, in a sequel to his paper on the footmarks at Storeton, has described impressions on the same slabs with them, derived from drops of rain that fell upon thin laminæ of clay interposed between the beds of sand. The clay impressed with these prints of rain-drops acted as a mould, which transferred the form of every drop to the lower surface of the next bed of sand deposited upon it, so that entire surfaces of several strata in the same quarry are respectively covered with moulds and casts of drops of rain that fell whilst the strata were in process of formation. On the surface of one stratum at Storeton, impressed with large footmarks of a *Chirotherium,* the depth of the holes formed by the rain-drops on different parts of the same footstep has varied with the unequal amount of pressure on the clay and sand, by the salient cushions and retiring hollows of the creature's foot; and from the constancy of this phenomenon upon an entire series of footmarks in a long continuous track, we know that this rain fell after the animal had passed. The equable size of the casts of large drops that cover the entire surface of the slab, except in the parts impressed by the cushions of the feet, record the falling of a shower of heavy drops on the day in which this huge animal had marched along the ancient strand. Hemispherical impressions of small drops, upon another stratum, show it to have been exposed to only a sprinkling of gentle rain that fell at a moment of calm. In one small slab of New Red-Sandstone found by Dr. Ward near Shrewsbury, we have a combination of proofs as to meteoric, hydrostatic, and locomotive phenomena, which occurred at a time incalculably remote, in the atmosphere, the water, and the movements of animals; and from which we infer, with the certainty of cumulative circumstantial evidence, the direction of the wind, the depth and course of the water, and the quarter towards which the animals were passing: the latter is indicated by the direction of the footsteps which form their tracks; the size and curvatures of the ripple-marks on the sand, now converted to sandstone, show the depth and direction of the current; the oblique impressions of the rain-drops register the point from which the wind was blowing at or about the time when the animals were passing."

Soon after this address was delivered, Professor Owen proved the existence of a gigantic Batrachian at the period when the New Red-Sandstone was formed, and described three species of *Labyrinthodon.* He concluded that those creatures produced the foot-prints that had been observed, and maintained the following positions:—

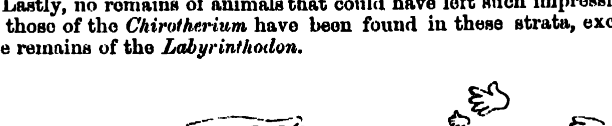
1st. Proof from the skeleton that *Labyrinthodon* had hind extremities much larger than the anterior extremities.

2nd. That the foot-prints of *Chirotherium* are at least as much like those of certain Toads as those of any other animals.

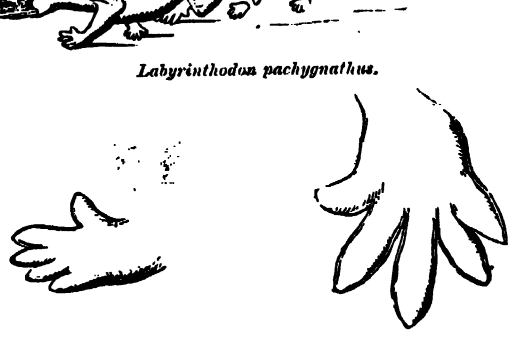
3rd. That the size of the known species of *Labyrinthodon* corresponds with the size of the foot-prints of the different species of *Chirotherium;* e.g. *Labyrinthodon Jägeri,* with the foot-print of *Chirotherium Hercules* (Egerton); *Labyrinthodon pachygnathus,* with the foot-marks of the common *Chirotherium;* and *Labyrinthodon leptognathus* with the impressions of the smaller Batrachian figured in the memoir by Sir Roderick Murchison and Mr. Strickland.

4th. *Labyrinthodon* occurs in the New Red-Sandstone strata to which Chirotherian impressions are peculiar. And

Lastly, no remains of animals that could have left such impressions as those of the *Chirotherium* have been found in these strata, except the remains of the *Labyrinthodon.*



Labyrinthodon pachygnathus.



Fore and hind-foot of the same.

It is true that the structure of the foot is still wanting, and that a more connected and complete skeleton is required for demonstration; but the circumstantial evidence above stated is strong enough to produce the conviction that Chirotherian and Labyrinthodontic foot-impressions are identical; and that *Mastodonsaurus, Salamandroïdes, Phytosaurus, Chirotherium,* and *Labyrinthodon* are one and the same genus, which ought for the future to be designated by the last-mentioned name. We owe this evidence principally to the use of the microscope in skilful and judicious hands; and it is impossible not to be struck with the wonderful applicability of that instrument to the largest of created bodies as well as to the smallest, when we look at the results of Professor Owen's discovery of the highly-organised dental structure in *Labyrinthodon,* an extinct animal of a low grade, where it could hardly have been expected to occur.

The reading of Professor Owen's memoir was accompanied by the exhibition of a diagram representing a restoration of two species of *Labyrinthodon.* By the Professor's kindness, we have been enabled to give a greatly reduced copy of one of them. [See the preceding column.] The bones which appear within the outline are those which were known when the paper was read. The animal is represented as impressing its footsteps on a shore of sand, now New Red-Sandstone. There is reason for believing that this Batrachian was not smooth externally, but was protected, on certain parts at least, by bony scutella.

Specimens of the foot-prints may be seen in the British Museum and in that of the Royal College of Surgeons in London.

AMPHIBOLE, a mineral belonging to the group of silicates of magnesia, lime, iron, and manganese. [AUGITE.]

AMPHIBOLI'TE, a name sometimes given to the simple mineral more commonly called *Hornblende,* and which was introduced by Haüy, the mineralogist, who uselessly changed many names. He called Hornblende *Amphibole,* because it is easily mistaken for Augite, another simple mineral closely allied to it in composition, from ἀμφίβολος, equivocal.

AMPHIDESMA, a genus of Marine Bivalve Shells, which are found in the sand on the sea-coast of tropical climates. The shells are oval or rounded, sometimes rather twisted and slightly gaping behind. They have two hinge teeth in each valve, and often distinct compressed lateral ones. The elastic cartilage is placed in a small triangular cavity just behind the hinge teeth. The animals of these shells are unknown; but they are supposed to have long syphons, like the Tellens, as the shells have a broad deep inflation on the back edge of the submarginal scar, formed by the attachment of the muscles which retract these syphons, as in the Tellens, from which genus it simply differs in the position of its cartilage.

Lamarck gave the name of *Amphidesma* to this genus, because he observed that it had a ligament and a cartilage, which he regarded as peculiar to this genus, he having, like the rest of the zoologists before the appearance of the Conchological Observations in the 'Zoological Journal,' considered what is usually called the ligament of bivalves as only one substance. It is however two substances, of very different structure and use; the outer, or ligament, being inelastic, and only employed to keep the two valves together, is formed of fibres extending from the edge of one valve to the other; but the cartilage is elastic, and formed of perpendicular fibres, like the prismatic crystalline-structured shell, its use being to separate the valves from one another when the muscles which keep them closed are relaxed. When the valves are closed, this part is compressed by their edge. For this purpose it is sometimes, as in the shell under consideration, placed in a small triangular cavity close to the hinge, when the shell is said to have an internal cartilage, the ligament being still in its usual place. In other shells it is placed, along with the ligament, on the margin of the valves, and is pressed, when the valves are closed, against the ligament itself, which forms its outer wall. The resistance which the ligament offers is the means of opening the shell. The cartilage has opaline reflections, and the cartilages of some large shells, as the mother-of-pearl shells, are sold by the jewellers under the name of Peacock-Stone, or Black Opals. They are not so much used now as formerly, but they are still much sought after on the Continent, especially in Portugal.

AMPHI'DETUS, a genus of *Echinidæ,* found in the Crag of Suffolk.

AMPHIGENE, a mineral abundant in the lava of Vesuvius, consisting of silica, alumina, and potash. [LEUCITE.]

AMPHI'ON (Pander), a genus of Fossil Crustacea (*Trilobites*), four species of which have been described, from Tyrone and Waterford, by Colonel Portlock.

AMPHIOXUS. [BRANCHIOSTOMATA.]

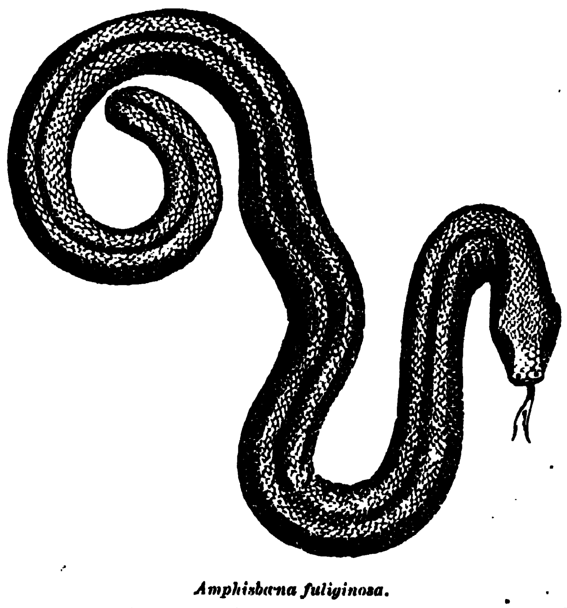
AMPHIROA. [ACALEPHÆ.]

AMPHISBÆNA (from ἀμφισβαινα, which signifies 'an animal that can walk in both directions'), a genus of Serpents, distinguished by their bodies having nearly the same uniform thickness from the head to the extremity of the tail, by their small mouths and extremely diminutive eyes, their remarkably short tails, and the numerous rings of small square scales which completely surround this organ and the body. A range of small pores runs in front of the vent, which is situated nearly at the end of the tail; the jaws alone are provided with a single row of small conical teeth, the palate being without any; and even those of the jaws are few and distant from one another. They are moreover destitute of fangs, and are consequently harmless and inoffensive, living for the most part upon ants and other small insects, and inhabiting ant-hills and burrows which they themselves construct under-ground. The nature of their food does not require these animals to possess the power of dilating the mouth and gullet to the extraordinary extent that is observed in the boas, pythons, and other serpents in general, which live for the most part upon animals proportionally much larger than themselves, and in order to admit the huge mouthful have the upper and under jaws both equally moveable upon the cranium. In the *Amphisbæna,* on the contrary, the upper jaw is fixed to the skull and intermaxillary bones, as in birds and mammals, so that the head remains constantly in the same plane with the body—a form which permits the animal to move equally well either backwards or forwards, and which has acquired for it the name by which it is distinguished.

The head of the *Amphisbæna* is so small, and the tail so thick and short, that it is difficult at first sight to distinguish one from the other, and this circumstance, united to the animal's habit of proceeding either backwards or forwards as the occasion may require, has given rise to the popular belief very generally spread throughout Brazil and other parts of South America, the native countries of this genus, that it possesses two heads, one at each extremity, and that it is impossible to destroy the animal by simple cutting, as the two heads mutually seek one another in case of such a serious accident, and soon re-unite as if nothing had happened. Ignorance is the parent of superstition and absurdity, and one wonder naturally produces twenty. It is not therefore surprising that, among an ignorant and credulous people, the singularity of the *Amphisbæna's* form and habits should have given rise to this and a multitude of other gross fictions. "Another snake," says Stedman, in his 'History of Surinam,' "which I also observed here, is about 3 feet long, and annulated with different colours; it is called *Amphisbæna,* from the supposition of its having two heads; and the truth is, that from its cylindrical form the head and tail so much resemble each other that the error is almost pardonable; besides which, the eyes are nearly imperceptible. This is the snake which, being supposed blind, and vulgularly said to be fed by the large ants already described, is in this country honoured with the name of King of the Emmets. The flesh of the *Amphisbæna,* dried and reduced to a fine powder, is confidently administered as a sovereign and infallible remedy in all cases of dislocation and broken bones; it being very naturally inferred that an animal which has the power of healing an entire amputation in his own case, should at least be able to cure a simple fracture in the case of another." Two centuries have scarcely passed since opinions equally credulous and absurd were universally prevalent among the most enlightened nations of Europe, when grave and learned physicians administered the bezoar or rhinoceros' horn with as much confidence as the simple Brazilian at the present does the powdered flesh of the *Amphisbæna.*

The genus *Amphisbæna,* as at present defined, contains only American species, which are confined to Brazil, Surinam, and other tropical parts of the Continent. Of these the following are the principal:—

1. The *A. fuliginosa,* the first and still the best-known species of the whole genus, is, like all the other Amphisbænas, confined to the hotter regions of South America, and does not inhabit Ceylon or any other part of the East Indies, as Linnæus and Lacépède have erroneously supposed, and asserted on the authority of Seba. The general colour of this serpent is a deep brown, varied with shades of white, more or less intense according to the difference of the individual and the season of casting the old and acquiring the new external skin. It grows to the length of 18 inches or 2 feet, of which, however, the tail measures only 1 inch or 15 lines. The body is surrounded by upwards of 200 rings, and the tail by 25 or 30; the eyes are covered and almost concealed by a membrane, which, added to their naturally diminutive



Amphisbæna fuliginosa.

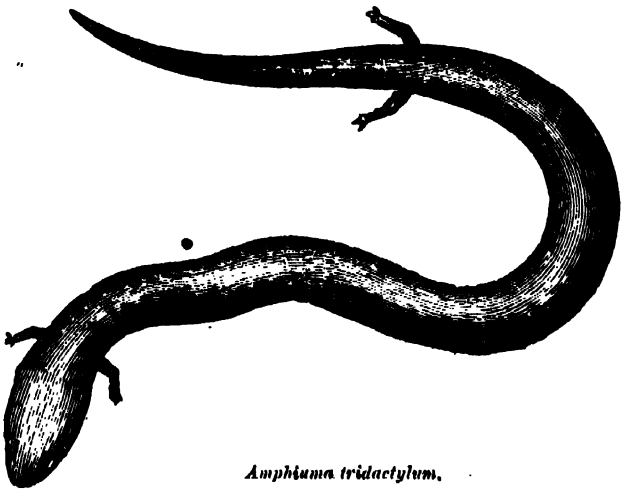
size, has given rise to the popular opinion that the animal was entirely deprived of sight; an opinion extended with no better reason to the Common Blind-Worm (*Anguis fragilis*). It lives upon worms and insects, particularly ants, in the mounds of which it usually conceals itself. The antipathy which most people entertain against serpents in general has given rise to a belief common among travellers, that this species is venomous, but without the slightest foundation in reality, as it is entirely destitute of fangs, and its teeth in other respects so small as to be incapable of inflicting a wound.

2. *A. alba*, so called from its colour, which is that of uniform pale straw without any marks or spots. The head of this species is short and thick, and its mouth small. The body usually measures from 1 foot 6 inches to 1 foot 9 or 10 inches, and is surrounded by 223 rings; the tail is from 1½ to 3 inches in length, and is surrounded by 16 or 18 rings. The thickness of the body seldom exceeds that of a man's fore-finger, and is uniform throughout its whole length; that of the former species, on the contrary, equals the thickness of the wrist of a child of 10 or 12 years old. The *A. alba* inhabits the same localities and lives in the same manner as the *A. fuliginosa*, from which indeed it differs only in size, colour, the proportionate length of the tail and body, and in having the mouth provided with a greater number of teeth, all, however, equally small and weak.

3. *A. cæca*, a species mentioned by Baron Cuvier in the second edition of the 'Règne Animal,' but without any detailed description. It inhabits the island of Martinique, and is said to be entirely deprived of sight, at least M. Cuvier was unable to discern any trace of eyes. He supposes it, nevertheless, to be identical with the *Amphisbæna vermicularis* of Spix, which that naturalist describes as having eyes scarcely perceptible.

AMPHITHE'RIUM (Blainville). This Fossil Mammal, from Stonesfield, is now termed *Thylacotherium* by Owen.

AMPHIUMA, a singular genus of Amphibian Reptiles, first noticed by Dr. Garden in 1771, in a letter to Linnæus. The remarkable and anomalous order *Amphibia*, to which this genus belongs, is more extensively spread throughout the New World, and exhibits a far greater diversity of organic modification in the western hemisphere, than in all the rest of the earth together. It is here alone that the *Menopomæ*, the *Amphiumæ*, the *Axolotls*, the *Menobranchi*, and the *Sirens*, are to be found. These singular animals abound in all the lakes and stagnant waters, and astonish the observer equally by the variety as by the novelty of their forms. [AMPHIBIA.]



Amphiuma tridactylum.

The external form of the *Amphiuma* is very similar to that of the common eel, but the whole anatomy and physiology of the animal approximates it more nearly to the Common Water-Newt (*Triton marmorata*) than to any other known species. From this creature indeed it differs principally in the extreme length of its body and the diminutive size of its extremities, which rather resemble small tentaculi than actual legs. The only two known species inhabit the stagnant pools and ditches in the neighbourhood of New Orleans, and those in Florida, Georgia, and South Carolina. They bury themselves in the mud at the bottom of the ditches, particularly on the approach of winter, and vast numbers of them are sometimes found in draining and clearing ponds, at the depth of 3 or 4 feet from the surface. They are also capable of existing on land, but as their food in all probability exists only in the water, they never voluntarily abandon that element. The two known species, *A. didactyla* and *A. tridactyla*, differ principally in the number of their toes, the one having only two, the other three on each foot.

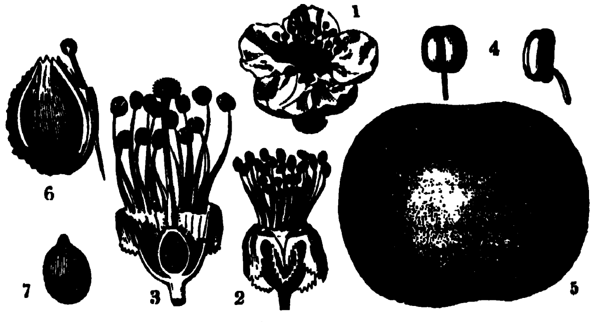
AMPHODELITE, a mineral allied to *Scapolite*, from which it differs in possessing magnesia instead of lime. It is composed of silica, alumina, and magnesia. [SCAPOLITE.]

AMPLEXUS (Sowerby), a fossil genus of *Madrephylliæa*, remarkable for the simplicity of its structure and the variability of its general figure. It occurs in the Mountain Limestone and Devonian Limestone.

AMPULLA'RIA, a genus of Fresh-Water Spiral Univalve Shells, which are found in the rivers and ponds of India, Africa, and South America. They are of a globular or rather depressed form, are covered with a thick olive or black periostraca, and often banded. Their mouth is ovate, with the lips complete all round, and often slightly thickened or reflexed. The animals are somewhat similar to the Common Pond-Snail (*Paludina*), but they have the front of the head nicked and furnished with two slight conical horn-like processes; and they have long slender tentacles, with the eyes placed on small pedicles at their outer base: these horns and the tentacles often contract into a spiral form. But the great peculiarity of these animals is, that, unlike all other molluscous animals with comb-like gills, they have a large bag, which opens beneath, placed on the side of the respiratory cavity, which they probably can fill with water; and it is this structure which most likely gives them the power of living for a long time out of water, specimens having been brought from Egypt to Paris alive, by only packing them in a little sawdust. Their operculum is formed of concentric rings with the nucleus nearly in the centre; in the species which come from India, this part is generally shelly, but in those of America and Africa it is always horny. The Indian species lay globular pale-green eggs about the size of small peas, which are placed in clusters on sticks and other things in the ditches; the eggs when dry form most beautiful objects. Some of the African species are reversed, or have the whorls of the shell turned from the right to the left, and these have been separated into a genus, under the name of *Lanistes*, on this account. It has been generally supposed by the geologist, that all the species of this genus are purely freshwater, but the large Egyptian species, *A. ovata*, discovered by Olivier in Egypt, lives in Lake Mareotis, where the water is salt; therefore there is no proof that some of the fossil species are not marine.

AMPYX (Dalman), a genus of Fossil Crustacea (*Trilobites*), four species of which have been described by Colonel Portlock, from Tyrone.

AMYGDA'LEÆ (*Drupaceæ* of Lindley), a sub-order of the natural order *Rosaceæ* [ROSACEÆ], among which it is known by its bearing the kind of fruit called a drupe, by the stamens being numerous and arising from the orifice of a tubular calyx, and by the leaves and other parts of the plant yielding hydrocyanic acid. Owing to the last circumstance, the species are all more or less poisonous, especially in those parts where the prussic acid is concentrated, as the leaves of the common laurel, the skin of the kernel of the almond, &c. On the other hand, those parts in which the prussic acid exists either in very minute quantity, or not at all, as the succulent fruit, and sometimes the kernel, are harmless, and are often valuable articles of food. It is on this account that, while the general character of the foliage is either unwholesome or suspicious, the fruit of many of them is much cultivated. The peach, the nectarine, the plum, the cherry, the almond, the apricot, prune, damson, and bullace are produced by different species of this order.



Amygdaleæ.

1. An expanded flower.
2. The same with the corolla removed.
3. The same cut through.
4. Anthers
5. Drupe.
6. Stone.
7. Embryo.

The bark of *Amygdaleæ* yields a gum which is similar in its properties to gum arabic; and an astringent substance which gives some of the species so much efficacy in fevers, that their bark has been compared for utility to Peruvian Bark.

AMYGDALOID, the name of a variety of the Trap-Rocks, when in a uniform base there are imbedded round or almond-shaped bodies, consisting of agate, calcareous spar, or zeolites, like almonds in a cake: the term is derived from the Greek ἀμυγδαλοειδὴς, resembling an almond.

AMY'GDALUS, a genus of plants, the type of the sub-order *Amygdaleæ*, comprehending the almond, and the peach and nectarine, besides a few bushes, the chief interest of which arises from their gay appearance.

A. communis, the Common Almond, is a native of Barbary, whence it had not been transferred into Italy in the time of Cato; it has, however, been so long cultivated all over the south of Europe and the temperate parts of Asia as to have become, as it were, naturalised in the whole of the Old World from Madrid to Canton. In this country, it is only grown for the sake of its beautiful vernal flowers; but in the countries that have a long and hot summer, it is the fruit for which it is esteemed. This, which is produced in very large quantities, is partly exported into northern countries, and partly pressed for oil, or consumed for various domestic purposes. Although botanists distinguish only one species of eatable almond, yet there are many varieties, of which the principal are the Bitter Almond and the Sweet Almond; of each of which the French and Italians have several sub-varieties distinguished by the hardness or softness of their shell, and the form or size of the kernel. These have all been introduced into England, but none of them are capable of ripening their fruit in the neighbourhood of London, except in unusually fine hot summers, preceded by mild and uninterrupted springs.

A. Persica, the Peach, once called the Persian Apple, because it was introduced from that country into Europe, has for ages been an object of careful cultivation for the sake of its delicious fruit, and has almost naturalised itself in America. In the country round about Buenos Ayres it is one of the most conspicuous trees, and bears abundant and delicious fruit. In our gardens many varieties are known, which are classed under the two heads of peaches and nectarines according as their fruit is smooth or downy; of the varieties there are few that are not worthy of cultivation, but the best are, perhaps, the Red Magdalen Peach, the Noblesse Peach, the Royal George Peach, and the Smith's Newington or Tawny Nectarine. For a late crop of peaches, the Têton de Venus may be recommended; but not the Catherine, nor indeed any of the thick-skinned October peaches, which, however excellent in the south of Europe, seldom ripen, and never acquire their natural flavour in this country. For preserving, the Blood-Red Peach, or Sanguinole, the flesh of which is of the deepest crimson, is worth a place in a garden.

AMYRI'DACEÆ, *Amyrids*, a natural order of plants consisting of tropical trees or shrubs, the leaves, bark, and fruit of which abound in fragrant resin. It is known among the Polypetalous Dicotyledonous orders by its hypogynous stamens, which are twice as numerous as the petals, by the large disk in which the ovarium is inserted, by its one-seeded fleshy fruit, covered all over with resinous glands, and generally dotted leaves.

The species are natives of tropical India, Africa, and America.

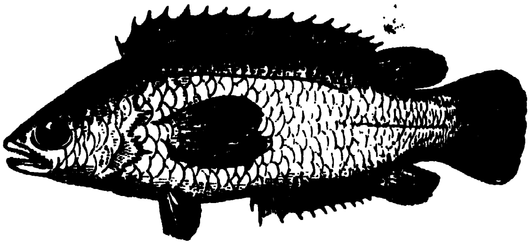
This order is remarkable for yielding various fragrant resins as Myrrh, Frankincense, and other products. The Frankincense of India is the produce of a species of *Boswellia*. Olibanum is yielded by *Boswellia senata*. Myrrh is obtained on the Abyssinian coast from the *Balsamodendron myrrha*. *B. Opobalsamum* yields the Balm of Mecca. Bdellium is produced in Africa by *B. Africanum*. American Elemi comes from *Icica Icicariba*. Resin of Courina from *I. ambrosiaca*. The Gum Elemi of commerce is said to be yielded by several species of *Amyris*. (Lindley, *Vegetable Kingdom*.)

A'NABAS (from ἀναβαίνω, to ascend), the name given by Cuvier to a genus of Acanthopterygious Osseous Fishes, remarkable for the power possessed by the species of living for some time out of water, and making their way on land. This power depends on a structure characteristic of the family of which it is the type, part of the pharangeals being labyrinthiform; that is to say, divided into a number of irregular lamellæ, more or less numerous, forming cavities and little cells capable of retaining a certain quantity of water. This apparatus is so protected, that when the animals are out of their native element the evaporation of the contained water takes place very slowly, and the gills are kept moist, by means of which remarkable provision the fishes of this family are enabled to leave the rivers and marshes where they usually reside, and to travel over land for considerable distances, creeping among the herbage or along the ground. Although this fact has been but recently known to modern naturalists, the ancients appear to have been well acquainted with it, and Theophrastus has recorded the existence in India of certain little fishes which leave the rivers for a time, and again return to them: he doubtless alludes to the *Anabas* and its allies.

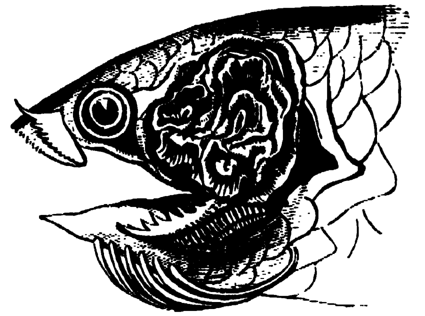
The genus *Anabas*, of which there is but one species, the *Anabas scandens* (*Perca scandens* of Daldorf, *Anthias testudineus* of Bloch), is distinguished by a well-marked character, the borders of its opercle, subopercle, and interopercle being denticulated, whilst the preopercle is not so, nor even distinctly marginated. The head is round and broad; the muzzle is very short and obtuse, the eye placed very near its extremity. The mouth is small, and large scales cover the head. The body is oblong, compressed centrally and behind. The lateral line is interrupted at its posterior third, recommencing a little lower. The tail is somewhat rounded. The whole body is covered with large scales. There is a single dorsal and an anal fin, nearly equal in height, and in both the spinous rays prevail.

In colour it appears to vary, being brown or bluish-black or dark green, paler beneath and having violet fins. In form the individuals are constant, and reach the length of 6 inches.

This fish inhabits all parts of India and the Indian Archipelago, living in marshes and feeding on aquatic insects, and Dr. Cantor observed it at Chusan. Respecting its habits there has been much discussion. In 1797 a Danish gentleman, M. Daldorf, communicated an account of its habits to the Linnæan Society of London, in which he stated that he had observed it in the act of ascending palm-trees near marshes, and had taken it at a height of no less than 5 feet above the surface of the water, effecting its movements of ascent by means of its fins and tail and the spines of its opercles, in a similar manner to that by which it progressed along the ground. Another Danish observer, M. John, published a similar statement, adding that it is called in Tranquebar by a name which signifies Tree-Climber. Other naturalists, who have equally observed it in its native countries, such as Reinwardt, Leschenault, and Hamilton Buchanan, whilst they record its habit of creeping on the ground and living a long time out of water, deny or omit all mention of its power to ascend trees.



Anabas scandens.



Head of *Anabas scandens*, laid open to show the peculiar pharyngeal apparatus.

To the same family with *Anabas* belong the genera *Helostoma*, *Polyacanthus*, *Colisa*, *Macropodus*, *Osphromenus*, *Trichopus*, and *Spirobranchus*, of which the habits are as yet very imperfectly known, though the peculiarities of their anatomy warrant us in supposing that they have a similar power of living out of water.

(*Linnæan Transactions*, vol. iii.; and Cuvier and Valenciennes, *Hist. Nat. des Poissons*, tom. vii.)

ANABATHRA, a Fossil Tree, from Allenbank, Berwickshire, is thus named by Mr. Witham, and figured in 'Foss. Veg.' t. 8 and t. 10.

A'NABLEPS (from ἀναβλέπω, to look up), a genus of Malacopterygious Osseous Fishes, remarkable for the curious structure of their eyes, which, in consequence of the division of the iris and cornea by transverse ligaments, have two pupils, and appear as if double, whilst there is only one crystalline humour, one vitreous humour, and one retina. There is no other example known of such a modification of structure among the *Vertebrata*. This peculiarity of the *Anableps* has given rise to several stories of four-eyed fish, with exaggerated accounts of their habits. The *Anableps tetrophthalmus* inhabits the rivers of Guyana and Surinam. Its body is cylindrical, and covered with strong scales; its head is flattened, and snout blunt. The upper jaw projects beyond the lower.

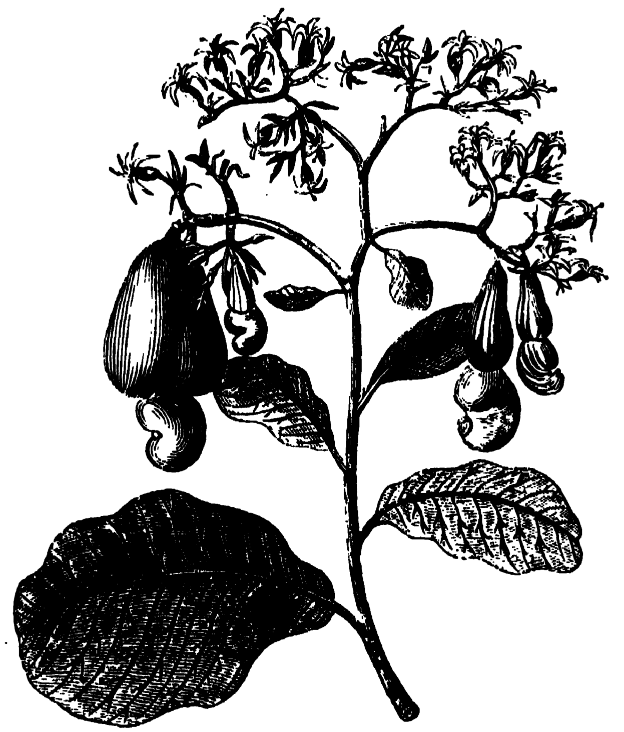
ANACARDIA'CEÆ, *Anacards* or the *Cashew Tribe*, is a natural order of plants, consisting exclusively of woody plants, abounding in an acrid resin, which is easily discovered by bruising the leaves, but which is not indicated by its being collected in transparent receptacles in the leaves, as is most commonly the case. They are polypetalous dicotyledons, with perigynous stamens, a simple one-seeded superior fruit, and alternate leaves without stipules.

Their juice is often used as a kind of varnish, for which it is well adapted in consequence of its turning hard and black when dry. It is, however, often dangerous to use, because of the extreme acridity of the fumes, which are apt to produce severe inflammation in many constitutions. The best-known genera of the order are, in the first place, *Rhus*, or the Sumach, of which so many species are cultivated in our gardens; and the *Pistacias*, the nuts of which are served at desserts, and their juice is commonly sold in the shops under the name of Mastich and Scio Turpentine. Besides these, there are the Chilian *Duvauas*, which resemble myrtles, the *Mango*, the fruit of which is so delicious in tropical countries, and the Cashew or Acajou Nut, *Anacardium*, from which the order takes its name.

The last, *Anacardium occidentale*, is a small tree found all over the West Indies, where it is much cultivated for the sake of its bunches of fragrant rosy flowers, as well as of its fruit. Its stem, if wounded, yields abundantly a milk, which, when inspissated, becomes intensely black and hard, besides which, it secretes a gum not inferior to gum arabic. The nut is a kidney-shaped body, seated on a large fleshy protuberance, and being, in fact, the extremely dilated disk or receptacle; the latter is sometimes red, sometimes white. The nuts contain, in abundance, beneath the outer shell, the black caustic oil of the order, which, when volatilised by heat, as happens in the process of roasting, is apt to produce erysipelas and other disagreeable affections in the face of persons standing over the fumes; the kernel is a well-known wholesome article of food. In the West Indies it is used as an ingredient in puddings, is eaten raw, and is roasted for the purpose of mixing with Madeira wine, to which it is thought to communicate a peculiarly agreeable flavour. In this country the Cashew Nut never flowers, and can only be cultivated as a tender stove-plant.

Duranta dependens.

1. Male flower. 2. Hermaphrodite do. 3. Back of do. 4. Fruit. 5. Section of do. All slightly magnified.



Cashew Nut (*Anacardium occidentale*).

The *Spondias*, or Hog Plum, which is the type of the order *Spondiaceæ*, is referred by Lindley to this order. [SPONDIACEÆ; RHUS.]

ANAGA'LLIS, a genus of plants of the natural order *Primulaceæ*, among which it is known by its flat or wheel-shaped corollas and by its capsule opening into two halves, of which the upper fits the under like the lid of a box. A very common species is the Pimpernel, or Poor Man's Weather-Glass, so called because its flowers generally open at eight in the morning and close in the afternoon, and also refuse to expand in rainy weather. It is a little trailing plant with brick-red flowers, very abundant in corn-fields; it was once thought useful in cases of madness, especially such as arose from the bite of rabid animals, but it is in no esteem at the present day. There is a purple variety called by Sir J. E. Smith *A. cærulea.* A far more beautiful species is the *Anagallis tenella* (Bog Pimpernel), which grows in the drier parts of marshes, along with *Pinguicula* and *Drosera;* it has delicate flesh-coloured flowers, in the centre of which grows a cone of stamens covered all over with glittering transparent hairs; these and its peculiarly neat appearance, entitle it to be called the queen of British wildflowers. Some botanists regard it as a distinct genus, and describe it under the name of *Irasekia.* One or two foreign species, with large blossoms, are cultivated in greenhouses.

ANALCIME, also called *Cubicite* and *Sarcolite*, is a mineral belonging to the group of hydrous silicates of alumina. It contains according to analyses by Rose and Connell, the following constituents:—

	Rose.	Connell.
Silica	55·12	55·07
Alumina	22·99	22·23
Soda	13·53	13·71
Water	8·27	8·22
	99·91	99·23

It is found crystallised, the primary form being a cube. The cleavage is parallel to the face of the cube, but is obtained with difficulty. It has an uneven undulating fracture. It scratches glass, but not readily. It is brittle, and is of a white colour with a shade of red. The streak is white, and it has a vitreous but not brilliant colour. It is either transparent, translucent, or opaque. The specific gravity is 2·068. It melts into a clear glassy globule by the blow-pipe on charcoal. It gelatinises in hydrochloric acid. It is principally found in the Basaltic and Amygdaloidal rocks of Scotland, Ireland, the Tyrol, and other countries.

ANAMIRTA, a genus of plants belonging to the natural order *Menispermaceæ*, including some of the species of the old genus *Cocculus.* [COCCULUS.]

ANAMORPHO'SIS. (Botany.) [METAMORPHOSIS OF ORGANS.]

ANANASSA, a genus of plants belonging to the natural order *Bromeliaceæ*, found wild in the woods of South America, and now commonly cultivated in the gardens of rich Europeans. It is distinguished from the *Bromelia*, to which it was once referred, by its succulent fruit collected in a compact head.

Of *Ananassa sativa*, the Common Pine-Apple, a great number of varieties are known, of which the Moscow and Common Queen, the Black Jamaica, and the Antigua Queen are the best for summer use, the Enville and the Trinidad the largest, the Black Jamaica the best for winter use, and the Blood-Red the worst for any purpose or season.

The fruit is a mass of flowers, the calyxes and bracts of which are fleshy and grow firmly together into a single head; it is the points of these parts that together form what gardeners call the pips, that is to say, the rhomboidal spaces into which the surface is divided. When wild, Pine-Apples bear seeds like other plants; but in a state of cultivation, generally owing to the succulence of all the parts, no seeds are produced, and consequently the plants can only be multiplied by suckers, or by their branches, which gardeners call the gills and crown. The latter, which surmounts the fruit, is in reality the end of the branch round which the flowers are arranged, and if it has any tendency to ramification, as sometimes happens, it becomes what is called double.

The Pine-Apple was undoubtedly unknown before the discovery of America; its incomparable flavour soon however caused it to be introduced into Africa and Asia, where, in a suitable climate, it multiplied so rapidly as to acquire as firm a footing in those countries as their aboriginal plants. In Asia it has even improved so much in quality, that the Birmese Pines, which have never yet reached England, are said to be the finest in the world. With this exception it is believed that we already possess the best varieties that exist; and it is undoubted that, except in the kingdom of Birma, the most delicious specimens of the fruit are produced in England. Within a recent period Pine-Apples have been imported largely into England from the West India Islands, where the cultivation has in consequence been more carefully attended to, the quality greatly improved, and this branch of commerce largely extended. [PINE-APPLE, in ARTS AND SC. DIV.]

ANANCHY'TES (Lamarck), a fossil genus of *Echinodermata*, found abundantly in the Chalk.

ANA'RRHICAS, a genus of Acanthopterygious Osseous Fishes, established by Linnæus, and retained by subsequent ichthyologists. They are very nearly allied to the Blennies, so that Cuvier remarked they might be regarded as Blennies without ventral fins. They have round smooth blunt heads; elongated bodies, covered by minute scales; a single long dorsal fin, and an extended anal fin, both separated from the caudal; no ventrals; the mouth armed with formidable teeth of two kinds, conical incisors and flat grinders. One species, the Wolf-Fish, Sea-Cat, or Cat-Fish (*Anarrhicas Lupus* of Linnæus), is common in the northern seas, and in Britain is frequently taken on the east coast of Scotland and the Orkneys, though rare on the English shores. Its range extends to Greenland. It grows to the length of 6 feet, and is a ferocious and formidable animal, destroying the nets of fishermen; when caught it defends itself to its last gasp, inflicting severe wounds by means of its powerful teeth and jaws. It lives chiefly on crustacea and testaceous mollusca, and, like most fish which subsist on such food, its flesh is excellent eating, though, from the ugly appearance of the animal, usually rejected. It finds its way however to the Edinburgh market, where, by naturalists especially, whose knowledge of its good qualities enables them to vanquish their prejudices against its aspect, it is much esteemed. The Cat-Fish is of a light gray colour marked with seven or eight broad vertical bands of bluish gray. When old it becomes darker. Its skin is covered with slime. (Yarrell's *British Fishes.*)

ANAS, the Duck, a genus of birds under which Linnæus included a great number of species now separated into several genera by recent naturalists. [Ducks.]

ANASTATICA, a genus of plants belonging to the natural order *Cruciferæ*. One species, *A. hierochuntina*, is the Rose of Jericho. [Jericho, Rose of.]

ANASTO'MOSIS, from ἀνὰ, through, and στόμα, a mouth, signifies the communication of blood-vessels with each other by the opening of the one with the other. The blood-vessels are the tubes by which the different parts of the body are supplied with nourishment. If the blood-vessels destined to nourish a part be obstructed, so that it cannot receive a due supply of blood, that part must necessarily die, or, as it is technically termed, mortify. But the blood-vessels are soft compressible tubes, liable by innumerable circumstances to have their sides brought so closely into contact as to prevent the flow of a single particle of blood through them. In order to prevent the consequences that would result to the system from the operation of causes thus tending to impede the circulation, provision is made for the freest possible communication between the main trunks of the blood-vessels and their branches, and between one branch and another. All the branches which form such communications are called *anastomosing* branches, and this union of branch with branch is termed *Anastomosis.*

ANATASE, in Mineralogy, a variety of Titanic Acid. [Titanium.]

ANATHERUM, a genus of Grasses, belonging to the group of which species yield fragrant volatile oils. *A. muricatum* is the *Vetian* of the French and the *Khus* of the Hindoos. Its fragrant roots are employed in making tatties, covers for palanquins, &c. It is administered medicinally, and has stimulating and diaphoretic qualities. *A. nardus* is also, on account of the volatile oil it contains, called Ginger-Grass, or Koobel.

ANA'TIDÆ (Leach), the Duck kind, a group formed by Dr. Leach to include his genera formed from the great genus *Anas* of Linnæus. [Ducks.]

ANA'TOMY, from a Greek term (ἀνατομή), which literally signifies the separation of a thing into parts by cutting;' the term Anatomy is used to signify particularly, dissection, or knowledge acquired by dissection. Anatomy is at once an art and a science; an art, inasmuch as the pursuit of it requires skilful manipulation; and a science, inasmuch as certain general principles are deducible from it. The object of anatomy is to ascertain the structure of organised bodies. Of the two great kingdoms of nature, the inorganic and the organic, it comprehends the whole range of the latter. Like the organised kingdom itself, it forms two divisions, the one including the structure of plants—Vegetable Anatomy; the other the structure of animals - Animal Anatomy. Animal Anatomy is divided into comparative and human: Comparative Anatomy includes an account of the structure of all classes of animals, excepting that of man; Human Anatomy is restricted to an account of the structure of man only. Human Anatomy is subdivided into descriptive, general, and pathological. *Descriptive Anatomy* comprehends a description of all the various parts or organs of the human body, together with an account of their situation, connections, and relations, as these circumstances exist in the natural and sound, or, as it is technically termed, the normal, condition of the body. The human stomach, for example, is composed of a number of membranes, which are united in a particular manner; a number of blood-vessels which are derived from particular arterial trunks; a number of nerves which proceed from a particular portion of the brain and spinal cord; a number of absorbent vessels, and so on; moreover, this organ is always placed in a particular cavity of the body, and is always found to have certain specific connections or relations with other organs. The anatomy of the human stomach comprehends an account of all the particulars of this kind, which are uniformly found to concur in all human bodies in which the conformation is regular or natural; and so of every other organ of the body: and because such an exposition of the structure of the various organs includes a description of all the circumstances that relate to their organisation, it is called Descriptive Anatomy.

After the study of the human body in this mode has been carried to a certain extent, with a certain degree of success, it necessarily gives origin to a second division of the science, that termed *General Anatomy.* It is found, that many of the circumstances which belong to any one organ, belong at the same time to several organs; and that thus several individual circumstances are common to many organs. Of the membranes, for example, of which it has been stated that the stomach is composed, some are common to it and to the intestines, to the bladder, to the heart, to the air-passages, and so on. In like manner with respect to any one of these membranes, when its structure is carefully examined, it is found that in many points its organisation is exactly similar to that of all other membranes. This view extended leads to further important and interesting results. All the arteries of the body, whatever their situation, size, or office, are found to be composed essentially of the same substances, disposed in nearly the same order and form. All the veins have, in like manner, a structure essentially the same. All the absorbent vessels, all vessels of every kind, all the bones, muscles, and nerves, the whole external covering of the body or the skin, widely as these various structures differ from each other, present no material difference as far as regards the organisation of each particular class. Hence various organs of the body are disposed into what are called common systems, and these common systems are said to consist of common substances or *tissues.* All the vessels, for example, are collected and arranged under one common class, called the vascular system: in like manner, all the bones are collected and arranged under another class, called the osseous system; all the muscles under another, called the muscular system; all the nerves under another, called the nervous system, and so on. The material that enters into the composition of each of these systems consists of a substance of a peculiar nature; but as this substance is more or less generally diffused over the whole body, entering as a constituent element into the various organs, it is termed a common substance, or tissue. What is termed the common cellular or areolar tissue, for example, is the substance which enters most commonly into the compositition of the organs of the body; the muscular tissue is the substance of which the muscles are composed; the nervous tissue is the substance of which the nerves are composed: and thus, the structure of the body, analysed in this mode, innumerable and complex as the substances appear to be of which it consists, is ultimately reduced to a very few simple materials, by the combination and modification of which all the different animal substances are produced.

General Anatomy also includes the study of certain fluids from which the membranes or textures are formed. The following is a list of the fluids and textures, given by Dr. Sharpey in Quain's 'Elements of Anatomy:'

The Blood, Chyle, and Lymph.
Epidermis Tissue (including Epithelium, Cuticle, Nails, and Hairs).
Pigment.
Adipose Tissue.
Cellular Tissue.
Fibrous Tissue.
Elastic Tissue.
Cartilage, and its varieties.
Bone or Osseous Tissue.
Muscular Tissue.
Nervous Tissue.
Blood-Vessels.
Serous and Synovial Membranes.
Mucous Membranes.
Skin.
Secreting Glands.

These textures and fluids will be treated of under their respective heads.

Descriptive and general anatomy, then, include an account of the structure of the body as it exists in the state of health. But there is no organ of the body, and no tissue which enters into its composition, which is not subject to disease; in consequence of disease, the regular or natural structure of the component substances of the body becomes changed in a great variety of modes. That part of anatomy which displays these diseased or morbid changes, and which describes all the circumstances relating to them, is called *Pathological* or *Morbid Anatomy.* We may say, then, that Descriptive Anatomy comprehends an account of all the parts or organs of the body as they exist in the state of health; General Anatomy comprehends an account of all the separate substances of which those organs are composed, not as these substances exist combined in organs, but as they form distinct and peculiar substances; Pathological Anatomy comprehends an account of all the changes of structure produced by disease, whether in individual organs, or in the primitive or common substances of which these organs are composed.

The term *Anatomy*, as we have seen, is chiefly applied to the science which determines the nature and relations of the various organs of the human body. A general term is here used in a restricted sense. On the other hand, when we would express the extension of the science of anatomy to the whole animal creation, we employ the general term with the addition of the word *Comparative.* This anomaly has doubtless proceeded from the circumstance that, till within a very recent period, the study of animal structure was almost exclusively confined to the human subject; and that even zoologists were contented with inquiring into the functions of animals, instead of determining the character of the organs which were connected with those functions. By the term *Comparative Anatomy* is understood the science which conveys a knowledge of the differences in the structure and organisation of the whole animal kingdom in all its classes, orders, and species.

It is evident that a science possessing such an extensive range must be exceedingly imperfect; especially when it is borne in mind that scarcely half a century has elapsed since the first attempts were made to simplify, by systematising, its almost infinite details. It has however made sufficient progress, not only to have furnished the most important aids to the study of human anatomy and physiology, but to have supplied a secure and broad foundation for all zoological knowledge, both as regards existing and extinct races. As the basis of modern zoology, comparative anatomy presents a subject of the highest interest, and the most successful methods of classification have been produced mainly by its aid. [ANIMAL KINGDOM.]

ANBURY and CLUB-ROOT, a sort of Galls produced by insects on the roots of cabbages, turnips, hollyhocks, and other species of cultivated plants, and popularly, but incorrectly, supposed to arise from peculiarities of soil, or from growing the same crop successively on the same field, or to be owing to variations of seasons. Nothing can be more simple than the disproof of all these theoretical notions. If we take some of the cabbages or turnips, whose roots are infected with anbury, and keep them in garden-pots covered over with close gauze, in a short time, if the plants be kept growing, the little weevils, evolved from the grubs in the interior of the roots, will make their appearance, ready to multiply their species, by depositing their eggs, as their parents had done, on the first turnip or cabbage they can find. The weevil thus arising continues to be no less, but often more, destructive than the grub had proved to be in feeding on the roots; for it thrusts its beak (rostrum) into the seed-leaf of the turnip, and greatly injures the crop. When the turnip is advanced to the rough leaf, these insects either die, as most insects do, when they have laid their eggs, or betake themselves to some other plant, such as clover, which is suited to their taste.

It will be therefore evident, that no peculiar rotation of crops, nor peculiar manure for dressing the soil, can be of any avail in preventing anbury, or in stopping its progress when the insects have obtained a lodgement within the roots. The destruction of the adult insects before they have laid their eggs, is the only remedy, though in the case of so small a species it is peculiarly difficult to effect.

ANCHOVY (*Engraulus*, Cuvier), a genus of Abdominal Malacopterygious Fishes, separated by Baron Cuvier from the *Clupeæ*, or Herrings of Linnæus, from which they are distinguished by the superior number of their branchiostegous rays, amounting to twelve or upwards, by the gape of the mouth extending behind the eyes, and by the straight and prolonged form of the superior maxillary bones, which form a small muzzle, projecting considerably beyond the mouth. The genus, as at present constituted, consists of six or seven species, all of diminutive size, and with the exception of the Common Anchovy (*E. encrasicholus*), and a nearly allied species distinguished from it by M. Cuvier (*E. meletta*), all inhabitants of the tropical seas of India and America. Whether these latter agree with the European species in the savour and other qualities of the flesh, for which it is so highly esteemed, is a doubtful question; at all events we are not aware that the fishing of the native species has ever been attempted either in America or India.

The Common Anchovy is a small fish, not much longer than the middle finger, of a bluish-brown colour on the back, and silvery-white on the belly. The anal-fin is remarkably short, and the dorsal situated immediately above the ventral; these characters will serve readily to distinguish it from the sprat and other kindred species, with which it might otherwise be confounded, and which are, in fact, not unfrequently imposed upon the public for the real anchovy. It abounds in the Mediterranean along the shores of Spain, Italy, and Greece; in the Atlantic it is found along the coasts of Portugal and France, and occasionally has been taken off the shores of England and Holland. Considerable fisheries of Anchovies are established along the coasts of Provence and Catalonia; but the most productive of all is off Gorgona, a small island west of Leghorn. The latter fishery is carried on only during the months of May, June, and July, at which period the anchovies quit the deep seas and approach the shores for the purpose of depositing their roe; it is then only that they are found in the Mediterranean, which they enter in enormous shoals, by the straits of Gibraltar, at the commencement of the breeding season, and leave it, after fulfilling this duty, to retire again to the depths of the Atlantic. They are fished for only during the night, and are attracted round the boats by means of charcoal fires which are kept burning in the sterns.

After being caught, the heads, gills, and entrails are separated from the bodies, which are salted and arranged in small barrels, varying from 5 to 20 pounds in weight: this is the only preparation which they undergo previous to being sent to market; and if proper means be taken to exclude the air they will in this state keep for a considerable period. If, when the barrels are open, the fish are found to be small and firm, round-backed, with a silvery-white skin and red flesh, and a plump compact form, they are probably the true anchovy; if, on the contrary, they taper very much towards the tail, are of a dark brown colour without, and have flabby pale-coloured flesh, they will probably turn out to be the Sardine (*E. meletta*), another Mediterranean species frequently mixed with real anchovies, or even sold separately as the genuine fish.

No condiment is more generally known and esteemed than anchovy sauce. It was also in use among the Romans, and was one of the kinds of sauce called Garum, which appears to have formed an indispensable article of seasoning in their most expensive and luxurious dishes.

ANCHOVY PEAR. [GRIAS.]

ANCHU'SA, a genus of plants belonging to the natural order *Boraginaceæ*, and to the sub-tribe *Anchuseæ*. The calyx is 5-fid; the corolla funnel-shaped, with a straight tube, the throat being closed by prominent obtuse scales; the stamens are included, and subsessile; the fruit a nut, which is depressed. The species are chiefly inhabitants of the temperate parts of the earth, either on the mountains of tropical regions or the temperate zone. They are all of them rough plants, and are known, as well as the species of *Lycopsis* and *Echium*, by the common name of Bugloss. Some of the species have been used in medicine, while others are employed in the arts for dyeing. Two are inhabitants of Great Britain.

A. officinalis, Common Alkanet or Bugloss, has lanceolate hispid leaves; unilateral crowded spikes, ovate-lanceolate bracts, the segments of the calyx bluntish, hairy on both sides, the scales of the corolla hairy. The flowers are a deep purple. It is an inhabitant of Great Britain, on waste ground, but is a rare plant. In the south of France, Germany, and Switzerland it is everywhere common, in uncultivated places, on old walls, and by the road-side. The young plant is sometimes boiled and eaten. The roots contain a considerable quantity of gum, and when boiled yield a demulcent drink, which was once in repute as a medicine.

A. sempervirens, Evergreen Bugloss, has ovate leaves, with lower leaves on long stalks, the peduncles axillary, each bearing two dense spikes with an intermediate flower, the segments of the calyx hairy on the outside only, the bracts minute lanceolate, scales of the corolla downy, flowers blue; salver-shaped. This plant is found on waste ground, near ruins, in Great Britain, but is rare.

A. tinctoria, Dyers' Bugloss or Alkanet, has diffuse stems, oblong hispid leaves, bracts longer than the calyx, the segments of the corolla shorter than the stamens. The corolla has a deep blood-coloured tube, with the limb deep blue. The root is woody, descending, and of a dark blood-red colour. This plant is a native of Peloponnesus, the island of Cyprus, and the deserts about Alexandria. It is cultivated in the south of France for the sake of the root, which yields a fine red colour to oils, wax, all unctuous substances, and to spirits of wine. Its chief use is in colouring lip-salves, ointments, &c. It is however sometimes employed for staining wood and dyeing cotton. It is also used for colouring many of the beverages sold under the name of port wine, and the corks used for the bottles in which this fluid is sold.

A. angustifolia, Narrow-Leaved Bugloss, has linear lanceolate hispid leaves, ovate-lanceolate bracts, 5-fid calyx, with blunt teeth. The tube of the corolla is pale purple, the limb deep blue. In gardens it attains a height of two feet, but when wild it is not more than a foot high. It grows in Italy, Germany, and Switzerland, by road-sides, amongst rubbish, and on the borders of ploughed fields.

In the cultivation of the species of this genus but little care is required, as they will grow in almost any soil, and are easily increased by seed. The *A. Capensis*, Cape Bugloss, requires the treatment of a greenhouse plant. Many of them are pretty annuals for the garden, as *A. paniculata*, *A. Barrelière*, &c.

ANCILLA or ANCILLA'RIA, are the names given by Lamarck to a genus of Spiral Univalve Marine Shells, allied to the Olives. Like them they are covered with a hard shining coat, destitute of any periostraca, and are immured in the large foot of the animal, so that the middle of the back of the shell can be alone discovered. They chiefly differ from the Olives in the suture of the whorl, being callous and not furnished with a groove, formed by a thread-like filament placed at the end of the mantle, which is wanting in this genus: they are also furnished with a small ovate operculum. The species are numerous, and are chiefly confined to tropical climates; some have a small tooth, like the Unicorn Shell (*Monoceros*), placed at the end of a groove crossing the front of the shell. The best-known species is the Ivory Shell, which with a few others differ from the rest of the genus in having the front of its axis deeply pierced.

ANCYLO'CERAS (D'Orbigny). This Fossil genus of M. D'Orbigny includes several species of *Hamites* (Phillips), from the Speeton Clay and Lower Greensand.

A'NCYLUS is the name of the shell which is usually called the Fresh-Water Limpet. They are small pellucid conical shells, with slightly-recurved tips. The cavity is simple, and marked with a horse-shoe-shaped muscular scar near the margin, which is interrupted on the middle of the left side over the respiratory holes, as in the genus *Syphonaria*. This animal, like the Pond-Snail (*Limnea*), has two compressed triangular tentacles, with the eyes sessile on the outer base; and a respiratory cavity placed on the middle of the back, with an aperture closed by a valve opening in the middle of the left side.

This genus is very nearly allied to the Pond-Snail, from which it chiefly differs in the simple conical form of its body and shell; and some species, as *Ancylus*, are allied to it by having the apex bent on one side, as if making an approach to the spiral form. It has been placed in several orders, but there is little doubt that its true situation is with the lung-breathing mollusca. They are found in Europe, America, and the West Indies, attached to stones and plants, and they will live a considerable time out of the water. They are easily known from the *Syphonariæ*, which are the only shells they can be confounded with, by their being sinistral, very thin, and covered with a hairy periostraca.

ANDALUSITE, a Mineral consisting of

Silica	39·09
Alumina	58·56
Protoxide of Manganese	0·53
Lime	0·21
Water	0·99
	99·38

It occurs crystallised; its primary form being a right rhombic prism. It has an uneven conchoidal fracture. Its colour varies from a flesh-red to a brownish and grayish-red. It has a vitreous lustre. It occurs both transparent and opaque. The specific gravity is 3·104. This mineral is found in Spain, France, and North America. The above analysis is from an American specimen.

ANE′MONE (ἀνημόνη) is a genus of plants belonging to the natural order *Ranunculaceæ*. It consists of lowly herbs, usually perennials, with white, or purple, or scarlet, or even yellow blossoms, in which there is no distinct calyx, and which are succeeded by a cluster of grains, each terminated by a long silky feathery tail. As the species generally grow on open plains or in high exposed situations, their feathery grains produce a singular shining appearance when waved by the breeze, whence their name, and which literally signifies Wind-Flower, their English appellation.

The Anemones possess, in common with other *Ranunculaceæ*, an acrid property. The leaves of *A. pulsatilla* will raise blisters on the skin; if chewed, they produce irritation of the throat and tongue; and their roots, as well as those of *A. pratensis*, a nearly related species, produce nausea and vomiting if administered in very small doses, on which account they have been strongly recommended by some medical men in various complaints. The following are the most remarkable species:—

1. *A. pulsatilla*, or Pasque Flower, grows wild upon exposed downs in various parts of England, as on the Gogmagog Hills near Cambridge, the heath at Newmarket, and on open chalky pastures. It has large purple flowers and finely-cut hairy leaves.

2. *A. nemorosa*, the Wood Anemone, is found abundantly in woods all over England, covering the ground with its neat white flowers under the shelter of bushes as early as March and April. It is a perennial plant with knobby roots, and a short stem having one or two smooth, bright-green, deeply-cut leaves. It is poisonous to cattle.

3. *A. pavonina*, the Peacock Anemone, a native of the vineyards in Provence, about Nice, and in other parts of the south of Europe. This is not very uncommon in gardens, where it is usually, but improperly, named *A. stellata*. It is known by its scarlet or scarlet and white flowers, which are usually double, and have their divisions very sharp-pointed. It is one of the handsomest of the cultivated species.

4. *A. coronaria*, the Common Garden Anemone. Found in a wild state in moist meadows in the south of France, Italy, and Greece, and different parts of Asia Minor; Dr. Russell speaks of it as abundant near Aleppo. In these places it is seen only in a single state, but even then sporting into a variety of colours, the principal of which are white, scarlet, and purple in different shades.

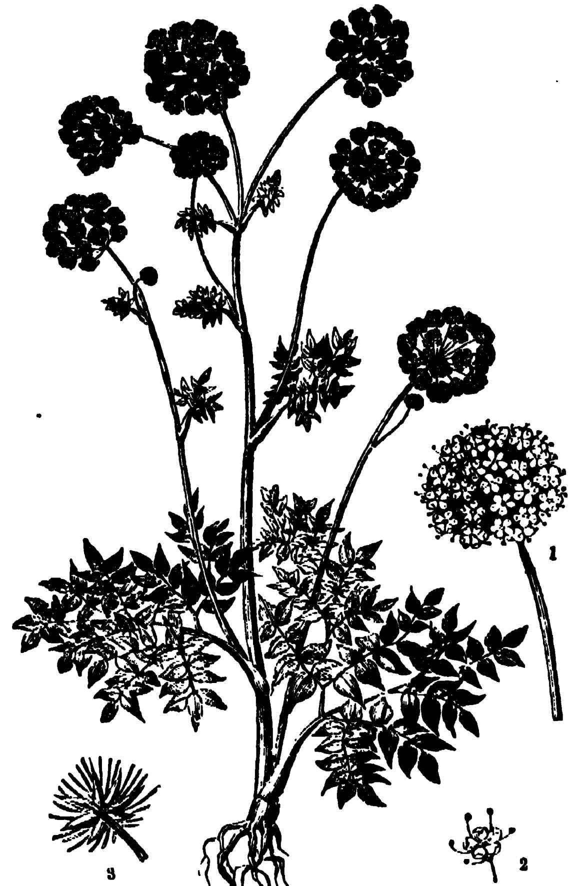
5. *A. stellata* is a native of various parts of Germany, France, and the Levant, and is also often seen in our gardens, where it is called *A. hortensis*. It differs from the last in having smaller and narrower petals, very rarely double flowers, a greater tendency to purple in their colours, and much broader leaves. It is not so liable to vary as the last species.

ANEMONIES, SEA. [ACTINIADÆ.]

ANGEL-FISH. [SQUALIDÆ.]

ANGE′LICA, a genus of plants belonging to the natural order *Umbelliferæ*. It comprehends several species, the principal part of which are to be met with in botanic gardens; and one that was formerly very much cultivated as an esculent plant. This, the *Angelica archangelica*, or *Archangelica officinalis*, is a native of the banks of rivers and of wet ditches in all the northern parts of Europe; in this country it grows abundantly on the banks of the Thames below Woolwich, and in several other places. It is a biennial plant, with a large fleshy aromatic root, blackish externally, but white within; and a stout furrowed branched stem as high as a man. Its leaves are of a clear bright green, shining, and divided into a very large number of heart-shaped finely-serrated lobes. The flowers are white, and disposed in round very compact umbels; they are succeeded by large broad-winged grains of a pale yellowish-brown colour. Each partial umbel is surrounded at its base by 7 or 8 pointed undivided bracts.

For the sake of its agreeable aromatic odour, this plant is much cultivated on the Continent. Its blanched stems, candied with sugar, form a very agreeable sweetmeat, possessing tonic and stomachic qualities. Its roots contain a pungent, aromatic, stimulating principle. A very common wild species, the *Angelica sylvestris*, or Wild Angelica, which is found all over the meadows near the Thames above London possesses similar properties.



Angelica archangelica, a diminished figure.

1. A partial umbel of the natural size. 2. A separate flower.
3. The back of one of the partial umbels, showing the bracts.

ANGLARITE, a name for the native blue phosphate of iron. [IRON.]

ANGLESITE, in Mineralogy, a name for the native sulphate of lead.

ANHYDRITE, the Mineralogical name for the native anhydrous sulphate of lime. It is found at Halle in the Tyrol, Bex in Switzerland, and in the Salt-Mines of Upper Austria and Salzburg. A specimen from Sulz yielded—

Sulphuric acid	56
Lime	42
Silica	2

It occurs both massive and crystallised. The crystals have the form of a right rhombic prism. The cleavage is very distinct, and parallel to the terminal planes and their two diagonals, indistinct parallel to the lateral planes. The fracture is uneven. The colour is white, bluish, violet, or reddish. The streak is grayish-white. The lustre is vitreous and pearly on the cleavage surfaces. It is transparent and translucent. It has a double refraction. The specific gravity is from 2·5 to 2·9. Its hardness 3·0 to 3·5. The massive varieties are amorphous, nodular, or reniform.

ANIMAL FLOWERS. [ACTINIADÆ.]

ANIMAL HEAT. [HEAT, ANIMAL.]

ANIMAL KINGDOM. All natural objects are referred by naturalists to three great divisions, called the *Kingdoms of Nature*. These are respectively called after the objects they include, the *Mineral Kingdom*, *Vegetable Kingdom*, and *Animal Kingdom*. Although at first sight nothing would appear easier than defining these great groups, in such a manner as to afford an easy means of distinction, it is nevertheless one of considerable difficulty. The difficulty, however, does not lie in the typical object of each kingdom, as a rock, an oak-tree, and a man, but in applying the definition to those objects which lie as it were on the limits of each kingdom. The line is perhaps better drawn between minerals, and plants and animals, than between the latter two. It is usual to speak of minerals as forming the *Inorganic Kingdom* or portion of Nature, whilst plants and animals constitute the *Organic Kingdom*. The great distinctive character of the Organic Kingdom, is the fact of their parts originating in and being formed out of cells which give to them many characters by which they are distinguished from minerals. Thus they are unsymmetrical, whilst minerals are symmetrical; they grow irregularly, whilst minerals increase in definite crystalline forms. Each portion of a mineral, however small, consists of the same elements, whilst any part of a plant or animal may be differently composed to another part. The line in fact is nowhere difficult to be drawn, where the presence or absence of cells can be determined.

The distinctions between animals and plants present greater difficulties, and perhaps no mere structural or formal difference can be found. Looked at from one point of view, plants and animals form a great organic unity, connected together by their common modes of cellular growth and functions; and when thus regarded, there seems to be no necessity for drawing an absolute line of distinction between one and the other. Naturalists have however regarded them as distinct, and the study of the two classes of objects have constituted the sciences of Botany and Zoology. Rude definitions of various kinds have been laid down to guide the systematist in his classification of the objects belonging to each. Aristotle was one of the first who sought a distinction, and in stating that an animal possessed a mouth whilst a plant had no such organ, he gave perhaps the simplest and most generally applicable definition that exists. But Aristotle had not the microscope to direct his inquiries, and by the aid of this instrument beings can be made apparent to which other distinctions must be applied before they can be arranged in one kingdom or another. Professor Kölliker describes an animalcule, the *Actinophrys sol* of Ehrenberg ('Microscopical Journal,' Nos. i. and ii.), in which, though no mouth is found, the function of digestion is carried on by an indentation of its skin, temporarily formed for that purpose. Linnaeus, with no better success, gave the following definition: "Minerals grow, plants grow and live, animals grow, live, and feel." To apply this definition, we must define life and feeling, and this cannot be done in such a way as to effect the object of the naturalist. Cuvier thought the possession of a stomach a sufficient distinction for the animal kingdom, but the nature of a stomach must first be understood, and here we have no absolute structural character to guide us. It was at one time a favourite distinction that animals have the power of motion, and that plants are fixed, but we know now that many plants move, whilst many animals are fixed. One of the most recent and philosophical of physiological writers says: "A plant is an organised being, whose vital powers are directed solely to the performance of formative operations, by which its fabric is not merely built up in the first instance, but is continually receiving additions during the term of its existence; and any movements which it may exhibit are destined solely for the furtherance of these operations, and must be regarded as originating in physical or vital forces. On the other hand an animal is an organised being, whose vital powers are not merely directed to the construction and maintenance of its corporeal fabric, but are also subservient to the operations of the conscious mind, which involve a continual disintegration of the structures that minister to them; on the repair of which, rather than on the extension of the fabric, after it has attained its full development, the formative energy is chiefly expended; and of the movements which it may exhibit, though a part are still to be regarded as directly dependent (like those of plants) on causes inherent in its material organisation, there is another part, small though it may often be, in which the consciousness and spontaneity of the individual are necessarily concerned, and which must therefore be distinguished as originating in psychical causes." (Carpenter, 'Principles of Physiology.')

In this way the naturalist and physiologist have tried to contend with the difficulty. Within the last few years chemistry has invaded the domain of the anatomist, and supplied him with materials for determining the problem of the difference of animal and vegetable life. The substances found in animals and plants are found in a great measure to be formed of four elements, carbon, hydrogen, oxygen, and nitrogen. At one time nitrogen was supposed to distinguish animal from vegetable substances. It is now known, not only that plants contain nitrogen, but that they supply this and the three other elements to the animal system. It is found that these four elements are always present in the *protoplasm nucleus*, *cytoblast*, or *primordial utricle*, from which the cells of all plants and animals are first formed. So that they are universally necessary in plants and animals, and have hence been called *Organic Elements*. Three compounds of three of these elements, carbon, hydrogen, and oxygen, and called cellulose, sugar, and starch, were at one time thought to be peculiar to plants. It is now known that cellulose is present in many animals, and that sugar is very generally present in certain animal textures and fluids. Starch yet remains to be found in the animal kingdom, and its presence in doubtful structures is still regarded as evidence of their vegetable nature.

It is clear however that no single character is sufficient to mark the line between these two kingdoms, and that the collective functions performed by animals and plants, accordingly as they are more or less prominent in organised beings, guide the opinions of naturalists. The structural characters of typical animals are so evidently different from the corresponding forms of plants, that we need not dwell on them here; but a view of the functions which animals and plants perform dependently on one another, will give the best possible notion of their antagonistic nature. One of the great functions performed by the animal kingdom is that of *Respiration*. During this process the oxygen of the atmosphere is brought in contact with carbon in the blood of the animal, and the result is a union of the carbon and oxygen, and the formation of carbonic acid gas, which is being constantly thrown off from the structure of the animal—from the whole surface of the body in the lowest animals, from the gills of those that live in water, and from the lungs of those that live in air. It thus consumes oxygen and gives off carbonic acid. The great function of plants is antagonistic to this. They take from the air carbonic acid gas; it is a part of their food. In the tissues of the plant the carbonic acid is decomposed. Its elements are separated; the carbon is retained in the plant, and the oxygen is set free. It thus consumes carbonic acid and gives off oxygen. As far as we at present know there are no exceptions to this law. On tracing the supply of the carbon which is contained in the animal system, and which combines with the oxygen, we find that it is derived by the animal from the plant. The food of the whole animal kingdom is derived from the vegetable kingdom; and the other three elements, as well as the carbon, which are found in the animal, are thus obtained. The animal, in like manner, throws off its nitrogen in the form of excretions, more especially those of the kidneys, which, on decomposing, yield ammonia, a compound of nitrogen and hydrogen; and it is from this substance that plants principally derive their nitrogen. Thus, whilst the animal derives the constituent of its body from the vegetable kingdom, the plant derives its elements from the mineral kingdom. The animal takes up starch, sugar, and protein, from the plant, but the plant takes up carbonic acid and ammonia in their mineral form. The tissues of the plant are engaged in converting mineral into organic substances, whilst the tissues of the animal are engaged in converting organic substances into mineral.

In their relation to the great physical forces, heat and light, we see the same antagonism between plants and animals. Light and heat are essential to the growth of plants. The productions found in their tissues are but the expression of the amount of heat and light they have as it were appropriated. Many of the substances thus formed are taken into the system of animals as food; and whilst in the system of the animal, the heat and the light are again set free in the form of the peculiar vital animal forces.

It is then by regarding the Animal and Vegetable worlds as exhibiting a combination of antagonistic and dependent forces in the great circle of nature, that we shall best form an idea of the real differences that exist between these two kingdoms of nature. Having said this much with regard to the nature of the Animal Kingdom, we shall now proceed to consider some of the methods which have been employed by naturalists to arrange the various members of which it is composed into groups, for the purpose of exhibiting the relation of one animal to another, and of facilitating the study of the whole.

In a crude shape, zoology, or the arrangement of animals, must have been one of the earliest sciences that forced itself upon the attention of the human mind. The very necessity for finding names for the more obvious divisions of living beings must soon have produced a classification into the natural groups of Quadrupeds, Birds, Fishes, and Insects; and certain subordinate sections, as, for instance, the distinction between herbivorous and carnivorous beasts, granivorous and carnivorous birds, harmless and poisonous reptiles, must have followed as a matter of course.

We have in the Bible, and in the engraven and pictorial Egyptian records, the earliest evidence of the attention which had been paid to Natural History in general. The 'navy of Tarshish' contributed to the wisdom of him who not only "spake of the trees, from the cedar of Lebanon even unto the hyssop that springeth out of the wall," but "also of beasts, and of fowl, and of creeping things, and of fishes" (1 Kings iv. 10); to say nothing of numerous other passages showing the progress that zoological knowledge had already made.

The Egyptian records bear testimony to a familiarity not only with the forms of a multitude of wild animals, but with their habits and geographical distribution.

Although it must be admitted that Herodotus was behind the science of his day in physical knowledge, he who, despising the sneers of the half-learned at his wonderful stories, will bring to the perusal of his works a fair share of scientific acquirement, will find many instances of zoological information which have been taken for the mere tales of this excellent traveller and historian, but which modern investigation has confirmed. But it is to Aristotle, justly termed the father of natural history, that we owe the first dawnings of system founded on the only sure basis—the organisation or physiological character of animals.

Aristotle's method was founded on a division of organs, which may be arranged, first, with reference to natural groups (*κατὰ γένος* or *κατ' εἶδος*), Birds or Fishes, for instance, which depend on a similar structure of parts; secondly, according to their excess and defect (*καθ' ὑπεροχὴν καὶ ἔλλειψιν*), as, for example, a division of Birds into those with long bills and those with short bills; those having crests and those having none; thirdly, according to their analogies (*κατ' ἀναλογίαν*); take, for instance, the comparison of a hoof with a claw, the wing of a bird with the fore-foot of a quadruped, a feather with a scale; and, fourthly, according to their situation (*κατὰ θέσιν*); take, for example, animals which have pectoral mammæ: man, apes, and elephants; and animals which have abdominal mammæ: dogs and cats.

The writers who succeeded Aristotle, and mostly copied from his ample stores were: Ælian, Pliny, Athenæus, Albertus Magnus, Belon, Gesner, Aldrovandus, and Johnston. Although some of them recorded new facts they did nothing to supply any further arrangement of the animal kingdom.

To our countryman Ray we are principally indebted for the first clear zoological method. That great naturalist, for originality and comprehensive philosophical discernment, may, without hesitation, be placed next after Aristotle himself.

The brilliant style of Buffon fixed the attention of the civilised world upon the subject which his eloquence at once rendered captivating. A more severe writer might have done greater things for natural history as a science, but Buffon at once secured a willing audience, and made all Europe his class. To him above all others may be conceded the merit of making the subject decidedly popular at once and for ever. The way was thus prepared for Linnæus.

In the last edition of the 'Systema Naturæ,' revised by its great author, the Animal Kingdom is thus arranged:—

Heart bilocular, with two auricles. Blood warm, red.	Viviparous.........	*Mammalia.*
	Oviparous.........	*Birds.*
Heart unilocular, with one auricle. Blood cold, red.	Arbitrary lungs....	*Amphibia.*
	External gills......	*Fishes.*
Heart unilocular, with one auricle. Circulating fluid (*sanies*) cold, white.	With antennæ.....	*Insects.*
	With tentacula....	*Vermes.*

I. *Mammalia.*

Heart bilocular, with two auricles. Blood warm, red. Lungs respiring reciprocally. Jaws incumbent, covered: teeth inserted in most. Penis intrans viviparas, lactiferas. Senses: Tongue, Nostrils, Eyes, Ears, Papillæ. Covering: Hairs, very sparing in the aquatics. Props (Fulcra): Four feet, except in those which are merely aquatic, in which the posterior feet are conjoined in the fin of the tail. A tail in most.

II. *Birds.*

Heart bilocular, with two auricles. Blood warm, red. Lungs respiring reciprocally. Jaws incumbent, naked, exserted, toothless. Penis subintrans absque scroto oviparas crusta calcarea. Senses: Tongue, Nostrils, Eyes, Ears without auricles. Covering: Incumbent imbricated feathers. Props: Two feet, two wings. Rump heart-shaped.

III. *Amphibia.*

Heart unilocular, with one auricle. Blood cold, red. Lungs breathing arbitrarily. Jaws incumbent. Penes bini. Eggs generally membranaceous. Senses: Tongue, Nostrils, Eyes, Ears. Covering: Cutaceous, naked. Props: Various, null in some.

IV. *Fishes.*

Heart unilocular, with one auricle. Blood cold, red. Gills external, compressed. Jaws incumbent. Penes nulli. Eggs without albumen. Senses: Tongue, Nostrils(?), Eyes (not ears). Covering: Imbricated scales. Props: Natatorial fins.

V. *Insects.*

Heart unilocular. Sanies cold. Spiracles, lateral body pores. Jaws lateral. Penes intrantes. Senses: Tongue, Eyes, Antennæ on a head without a brain (neither ears nor nostrils). Covering: Cataphracta, sustaining an osseous cutis. Props: Feet, Wings in some.

VI. *Vermes.*

Heart unilocular, with one ventricle. Sanies cold. Spiracles obscure. Jaws multifarious. Penes varii Hermaphroditis Androgynis. Senses: Tentacles (no head, hardly eyes, neither ears nor nostrils.) Covering: Calcareous, or null except spines. Props: Neither feet nor fins.

This table concludes with the following summary, which will be best given in the original form:—

"Vivarium Naturæ sic alit VI plicis formæ Animalia.

"*Mammalia* pilosa, in Terra gradiuntur, loquentia. *Aves* plumosæ, in aëre volitant, cantantes. *Amphibia* tunicata, in calore, serpunt, sibilantia. *Pisces* squamati, in aqua natant, popyzantes. *Insecta* cataphracta, in sicco exsiliunt, tinnitantia. *Vermes* excoriati, in humido panduntur, obmutescentes."

It is impossible to enter into the details of the arrangement of Linnæus, without being struck with the comprehensive views of the author, when the imperfect light that existed at the time is considered.

The subject was now taken up by able hands; and Pallas, especially in his anatomy of the *Glires*, made a great advance in Comparative Anatomy. Among the most active and enlightened labourers in this department, our own John Hunter stands pre-eminent in England and Blumenbach in Germany.

But the time was now come when a new light was to arise; and George Cuvier, guided by his dissections, became the great leader of his day. The 'Anatomie Comparée,' the 'Ossemens Fossiles,' and, finally, the 'Règne Animal,' were the results of his acute and comprehensive demonstrations. In his hands Comparative Anatomy became a new power among the dynamics of natural history, and by its aid he rebuilt the extinct fossil forms that before his time lay scattered over the face of our earth in wild and apparently inextricable disorder.

Well does this extraordinary man enunciate the valuable truth, that

since Natural History has taken Nature for the basis of its distributions, its relationship with Anatomy has become more intimate. "One of these sciences," says he, "cannot take a single step without the other profiting by it. The approximations which the first establishes often indicate to the other the researches that ought to be made." And again, with equal truth he declares, that "the natural history of an animal is the knowledge of the whole animal. Its internal structure is to it as much as its external form, and perhaps more."

That Cuvier practised what he preached is evident from his own record of his mode of proceeding in constructing his system:—

"I examined," says he, "one by one, all the species which I could procure; I associated those which did not differ from each other, except in size, colour, or the number of some parts of little importance, and on these materials founded what I have called a sub-genus.

"Whenever I could, I dissected at least one species of each sub-genus; and if those to which the scalpel could not be applied be excepted, there exist in my book very few groups of this degree, of the organs of which I cannot produce at least some considerable portion."

As in this work the various articles on the Animal Kingdom will be generally given subordinate to the great divisions indicated by Cuvier, we have added in the following page his arrangement in a tabular form.

The following are the distinguishing characters of the great divisions of this arrangement:

Vertebrate Animals (*Animalia vertebrata.*)—They have all red blood, a muscular heart, a mouth furnished with two jaws placed one either before or above the other, distinct organs of sight, hearing, smell, and taste, situated in the cavities of the face; never more than four limbs, the sexes always separated, and a very similar distribution of the medullary masses and of the principal branches of the nervous system. On examining each of the parts of this great series of animals more closely, there may always be detected some analogy even in those species which are most remote from one another; and the gradations of one single plan may be traced from man to the last of fishes.

In the second form there is no skeleton, the muscles are attached only to the skin, which constitutes a soft contractile envelope, in which in many species are formed stony plates called shells, the production and position of which are analogous to that of the mucous body; the nervous system is contained within this general envelope together with the viscera, and is composed of several scattered masses, connected by nervous filaments, and of which the principal placed over the œsophagus bears the name of brain. Of the four senses, the organs of those of taste and vision only can be distinguished, the latter of which are even frequently wanting. A single family alone presents organs of hearing. There is always, however, a complete system of circulation, and particular organs for respiration. Those of digestion and of the secretions are little less complicated than in the vertebrated animals. We will distinguish the animals of this second form by the appellation of

Molluscous Animals (*Animalia Mollusca.*)—Although the general plan of their organisation is not so uniform, as regards the external configuration of the parts as that of the vertebrates, there is always an equal degree of resemblance between them in the essential structure and the functions.

The third form is that observed in insects, worms, &c. Their nervous system consists of two long cords running longitudinally through the abdomen, dilated at intervals into knots or ganglions. The first of these knots placed over the œsophagus, and called brain, is scarcely any larger than those which are along the abdomen, with which it communicates by filaments that encircle the œsophagus like a collar. The envelope of their trunk is divided by transverse folds into a certain number of rings, of which the teguments are sometimes hard, sometimes soft, but to the interior of which the muscles are always attached. The trunk often bears on its sides articulated limbs, but is frequently unfurnished with them. We will bestow on these animals the term

Articulate Animals (*Animalia Articulata.*)—It is among these that the passage is observed from the circulation in closed vessels to nutrition by imbibition, and the corresponding transition from respiration in circumscribed organs to that effected by tracheæ or air-vessels distributed through the body. The organs of taste and vision are the most distinct in them, a single family alone presenting that of hearing. Their jaws, when they have any, are always lateral.

Lastly, the fourth form, which embraces all those animals known under the name of *Zoophytes*, may be designated

Radiate Animals (*Animalia Radiata.*)—In all the preceding, the organs of sense and motion are arranged symmetrically on the two sides of an axis. There is a posterior and an anterior dissimilar face. In this last division, they are disposed as rays round a centre; and this is the case even when they consist of but two series, for then the two faces are alike. They approximate to the homogeneity of plants, having no very distinct nervous system, nor organs of particular senses: there can scarcely be perceived in some of them the vestiges of a circulation; their respiratory organs are almost always on the surface of the body; the greater number have only a sac without issue for the whole intestine; and the lowest families present only a sort of homogeneous

THE ANIMAL KINGDOM ARRANGED ACCORDING TO THE SYSTEM OF CUVIER.

ANIMALS, arranged in Four DIVISIONS, Nineteen CLASSES, and Seventy-seven ORDERS.	DIVISION I.—VERTEBRATA, arranged in Four Classes, and Twenty-seven Orders.	CLASS I. MAMMALIA, including Eight Orders.			ORDER	I. Bimana	Man.
					...	II. Quadrumana	Chimpanzee.
					...	III. Carnivora	Hyæna.
					...	IV. Rodentia	Rat.
					...	V. Edentata	Armadillo.
					...	VI. Pachydermata	Hog.
					...	VII. Ruminantia	Cow.
					...	VIII. Cetacea	Whale.
		CLASS II. AVES, including Six Orders.			...	I. Rapaces	Hawk.
					...	II. Passeres	Swallow.
					...	III. Scansores	Woodpecker.
					...	IV. Gallinæ	Cock.
					...	V. Grallæ	Heron.
					...	VI. Palmipedes	Duck.
		CLASS III. REPTILA, including Four Orders.			...	I. Chelonia	Tortoise.
					...	II. Sauria	Lizard.
					...	III. Ophidia	Snake.
					...	IV. Batrachia	Frog.
		CLASS IV. PISCES, including Two Series.	Series I. Osseous, including Six Orders.		...	I. Acanthopterygii	Swprd-Fish.
				Malacopterygii.	...	II. Abdominales.	Salmon.
					...	III. Sub-brachiati	Whiting.
					...	IV. Apodes	Eel.
					...	V. Lophobranchii	Hippocampus.
					...	VI. Plectognathi	Sun-Fish.
			Series II. Cartilaginous, or Chondropterygii, including 3 Orders.		...	VII. Sturiones	Sturgeon.
				Branchiæ fixed.	...	VIII. Selachii	Ray.
					...	IX. Cyclostomi	Lamprey.
	DIVISION II.—MOLLUSCA, arranged in Six Classes, and Fifteen Orders.	CLASS I. CEPHALOPODA, having One Order.			...	I. Cephalopoda	Nautilus.
		CLASS II. PTEROPODA, having One Order.			...	I. Pteropoda	Clio australis.
		CLASS III. GASTEROPODA, including Nine Orders.			...	I. Pulmonia	Snail.
					...	II. Nudibranchia	Glaucus.
					...	III. Inferobranchia	Linguella.
					...	IV. Tectibranchia	Bursatella.
					...	V. Heteropoda	Carinaria.
					...	VI. Pectinibranchia	Whelk.
					...	VII. Tubulibranchia	Vermetus.
					...	VIII. Scutibranchia	The Sea-Ear.
					...	IX. Cyclobranchia	Chiton.
		CLASS IV. ACEPHALA, including Two Orders.			...	I. Testacea	Cyster.
					...	II. Acephala	Ascidia.
		CLASS V. BRACHIOPODA, having One Order.			...	I. Brachipoda	Lingula Anatina.
		CLASS VI. CIRRHOPODA, having One Order.			...	I. Cirrhopoda	Barnacle.
	DIVISION III.—ARTICULATA, arranged in Four Classes, and Twenty-four Orders.	CLASS I. ANNELIDA, including Three Orders.			...	I. Tubicola	Amphitrita.
					...	II. Dorsibranchia	Amphinome.
					...	III. Abranchia	Leech.
		CLASS II. CRUSTACEA, divided into 2 Sections.	Section I. Malacostracia, divided into Five Orders.	Compound eyes placed on pedicles and moveable.	...	I. Decapoda	Gebia stellata.
					...	II. Stomapoda	Phyllosoma.
				Eyes sessile and immoveable.	...	III. Amphipoda	Gammarus.
					...	IV. Læmodipoda	Whale-Louse.
					...	V. Isopoda	Anilocra.
			Section II. Entomostracia, divided into Two Orders.		...	VI. Branchiopoda	Branchipus (Cancer stagnalis)?
					...	VII. Pœcilopoda	Dichelestium.
		CLASS III. ARACHNIDA, including Two Orders.			...	I. Pulmonata	Phrynus. (Spider.)
					...	II. Trachearia	Phalangium.
		CLASS IV. INSECTA, including Twelve Orders.			...	I. Myriapoda	Centipede.
					...	II. Thysanoura	Velvet Spring-Tail.
					...	III. Parasita	Louse.
					...	IV. Suctoria	Flea.
					...	V. Coleoptera	Beetle.
					...	VI. Orthoptera	Grasshopper.
					...	VII. Hemiptera	Aphis.
					...	VIII. Neuroptera	Ant-Lion.
					...	IX. Hymenoptera	Ichneumon-Fly.
					...	X. Lepidoptera	Moth.
					...	XI. Rhipiptera	Xenos.
					...	XII. Diptera	Gnat.
	DIVISION IV.—RADIATA, arranged in 5 Classes, and 11 Orders.	CLASS I. ECHINODERMA, including Two Orders.			...	I. Pedicellata	Star-Fish.
					...	II. Echinoderma	Sipunculus.
		CLASS II. INTESTINA, including Two Orders.			...	I. Cavitaria	Cerebratula. (Filaria.)
					...	II. Parenchyma	Planaria cornuta.
		CLASS III. ACALEPHA, including Two Orders.			...	I. Acalepha (simple)	Medusa.
					...	II. Hydrostatica	Diphyes.
		CLASS IV. POLYPI, including Three Orders.			...	I. Actinia	Green Actinia.
					...	II. Gelatinosa	Cristatella.
					...	III. Corallina	Coral.
		CLASS V. INFUSORIA, including Two Orders.			...	I. Rotifera	Wheel Animalcule.
					...	II. Homogenea	Globe Animalcule.

pulp endowed with motion and sensibility. Since the time of Cuvier considerable advances have been made, especially in our knowledge of the lower forms of invertebrate animals, and many of his orders have been broken up and considerably modified.

At the time that Cuvier was working at his arrangement, and almost contemporaneously with a similar movement in botany, some of the more imaginative and philosophic minds began to perceive analogies in organs and parts of the animal frame, which previously had only been regarded under their distinct or individual relations. The close connection between the brilliant generalisations of this nature which first made comparative anatomists acquainted with the bones of the cranium and the essential resemblances, or homologies, as they are termed, of the component elements of a vertebra under their varied forms, for the special purposes of the individual, is too closely connected with similar researches after resemblance and analogies in zoology to be omitted in the present sketch of the history of that science. Göthe, the founder of morphology, or the doctrine of organic analogies in plants, also made the first step in the advancement of similar, or, as they have been termed, transcendental views, in the anatomy of animals. The poet's discovery of the intermaxillary bones in man, the first fruits of this essentially synthetical mode of studying organised beings, has been succeeded by many similar brilliant appreciations of true analogies by his successors Oken and Geoffroy, and the disciples of their school, which have more than compensated for the less substantial results of exuberant imaginations, which have too often had the effect of deterring the sober student of nature from digesting the works of authors from which valuable information is to be obtained.

Germany and the Netherlands have reason to be proud of the names of Illiger, Temminck, Wagler, Lichtenstein, and Rüppell.

In our own country and time, the Quinary System has been brought forward and applied by one of our most accomplished zoologists in his 'Horæ Entomologicæ,' 'Annulosa Javanica,' his 'Remarks on the Comparative Anatomy of certain Birds of Cuba,' in the 16th vol. of the 'Transactions of the Linnæan Society,' and his 'Illustrations of the Annulosa of South Africa,' forming part iii. of Dr. Andrew Smith's valuable 'Illustrations of the Zoology of South Africa.'

Mr. MacLeay brought to bear on this subject a comprehensive knowledge of natural history, much learning, and the close astute reasoning of a mind of no ordinary powers. The system has been applied in this country, by Mr. Vigors, to the Birds, and by Mr. Bennett, to the Mammalia and Fishes. With certain modifications it has been applied, by Mr. Swainson, to the Animal Kingdom generally, who, in his arrangement in the several volumes of the 'Cabinet Cyclopædia' written by him, has however left out Man. On the continent the Quinary System has never found favour, and it has now few if any followers in this country.

The sciences of Zoology and Comparative Anatomy have been studied in England, since the time of Cuvier, with great assiduity and success.

Amongst the most successful cultivators of these sciences is Professor Owen, who, in his courses of lectures as Hunterian professor at the Royal College of Surgeons, and in his published works, has done much for their advancement. In his application of comparative anatomy to the explanation of the structure of extinct animals, he has been scarcely less successful than Cuvier, as his works on 'Fossil Mammals,' 'Birds and Reptiles of Great Britain,' and his papers on the 'Dinornis,' the 'Mylodon,' and 'Glyptodon' testify. He has also successfully applied the principles of the transcendental anatomists to the elucidation of the structure of the vertebrate skeleton in his work on the 'Nomolopos of the Skeleton of the Vertebrata.' Added to his great powers of generalisation, he possesses great industry, and his lecture on 'Comparative Anatomy,' his 'Odontography,' and multitudinous papers, bear witness that there is scarcely any department of our knowledge of the animal kingdom, that does not bear the marks of his genius. Dr. J. G. Gray, as head of the Zoological department of the British Museum, has contributed largely to our knowledge of animal forms. His papers in the Magazines and Transactions of scientific societies amount to nearly 500 separate contributions. The works of Gould have contributed greatly to our recent knowledge of birds. Edward Forbes has most industriously laboured at the Marine Zoology of the British Islands, and his works on the 'Star-Fishes;' the 'Naked-Eyed Jelly-Fishes,' and the 'Mollusca of Great Britain,' have contributed greatly to extend our knowledge of these families; whilst his researches on the distribution of marine animals in depth, have given a new direction to geological inquiries. To Professor Bell, Mr. Yarrell, Dr. Johnstone, and Dr. Baird, zoology is greatly indebted for their works on the 'Mammalia,' 'Birds,' 'Reptiles,' 'Fishes,' and 'Crustacea,' of the British Islands. The natural history catalogues of the British Museum contain descriptions of many new species, especially that devoted to the various forms of Zoophytes, and which has been undertaken by Mr. Rusk. One of the greatest contributions ever made to our knowledge of shells, has been the collection made by Mr. Cuming, who is now resident in London. We ought also to mention the labours of Mr. Dauvin on the family of Cirripedes, the Sea-Acorns, and Barnacles. The voyages of Belcher, Stanley, Kellert, Ross, Fitzroy, and others have added greatly to the number of animal forms.

The 'Marine Vivarium,' recently formed at the Zoological Gardens, Regent's Park, London, will afford great assistance in the study of the organisation and habits of fishes and of marine invertebrate animals. Here may be seen, through the walls of glass tanks, in miniature oceans of sea-water, the daily life of lobsters, crabs, and shrimps (*Crustacea*), of sea-urchins (*Echinidæ*), of star-fishes (*Asterias, Stelleridians*), of the beautiful sea-anemones, or animal-flowers (*Actinidæ*), of sea-mice and sea-eggs (*Annelida*), of barnacles and sea-acorns (*Cirripeda*), and many others.

(Those who would study the subject of the general arrangement of the Animal Kingdom, are referred to the following works: Cuvier, *Règne Animal;* Owen, *Lectures on Comparative Anatomy;* Grant *Comparative Anatomy;* Patterson, *Zoology for Schools;* Rymer Jones, *Outlines of the Animal Kingdom;* Milne-Edwards, *Elemens de Zoologie;* Carpenter, *Principles of Physiology*.)

ANIMA'LCULES, in Zoology, is the name which has been applied to small animals of various classes, which cannot be distinctly seen without the use of a microscope, as the minute radiate animal of the coral, the worms found in paste, vinegar, and vegetable infusions, or the smaller crustacea found in pools, as the *Monoculi*. [INFUSORIA; POLYGASTRICA; ROTIFERA.]

ANKERITE, a mineral found at Salzburg, in the Alps, and other parts of the world, consisting of the carbonates of lime, magnesia, iron, and manganese in the following proportions: Carbonate of Lime, 51·11; Carbonate of Magnesia, 25·7; Carbonate of Iron, 20·0; Carbonate of Manganese, 3·0. It occurs crystallised, and its primary form is a rhomboid. The cleavage is parallel to the primary planes. The colour is white or yellow, or brownish.

ANNE'LIDA (Cuvier), an extensive division or class of animals, established by modern naturalists partly at the expense of Linnæus's heterogeneous class of Worms (*Vermes*). It was Baron Cuvier who in 1802 first proposed to distinguish the *Annelida* as a class, chiefly on account of their blood being of a red colour, as in the leech, and circulating by means of a double system of complicated blood-vessels.

The name is derived from the Latin word *annulus*, a ring, because the animals arranged under this division always have their bodies formed of a great number of small rings, as in the earth-worm. Their external covering, or skin, is soft and pliable; and their bodies, having no bony skeleton, are soft, and in general more or less of a cylindrical form.

The *Annelida* are for the most part oviparous, but the leeches and earth-worms deposit what are termed capsules, or membranous cocoons, containing many embryo young.

There is little variety in their mode of life. Some live in fresh and others in salt water; and others, like the Hair-Worm (*Gordius*), are amphibious. Some species construct tubes in the interior of stones, or in shells, which they perforate, or in madrepores. Some species again form calcareous cases, or cement around them various foreign substances, particularly sand. The sedentary species are timid, and when taken from their retreats can neither escape nor defend themselves. The *Errantia*, on the other hand, are frequently very nimble, and can defend themselves well by means of their bristles.

Although manifestly a low group of the Articulate sub-kingdom to which they belong, Cuvier was so led away by the importance he attached to their possessing red blood, that in his latest edition of the 'Règne Animal' he placed them at the head of the Articulate series, above the Crustaceas, the Arachnidas, and the Insects. A very cursory examination would suffice to show that the *Annelida* represent the caterpillar or larval condition of the insects, and could hardly be regarded as higher in organisation than the perfected insect.

The body of the Annelide is long and soft, and divided into a number of segments which agree in having the same form and nearly the same size throughout. In the lower forms, the first segment is not modified sufficiently to demand the name of a head; but in the higher forms it assumes the character of a head, and has organs adapted to the performance of cephalic functions.

In the most imperfect Annelides the organs of motion are suctorial disks such as are seen in the Trematode worms amongst the *Entozoa*. As we ascend, hairs or hooks project from the lateral segments, as in the Earth-Worm. In others, bundles of hairs on each side take the place of locomotive members, as in *Aphrodita*. These bristles or bundles of hairs act as their weapons of attack and defence, and they are generally sharp or barbed to assist in that office.

The nervous system of the Annelides presents a great advance on that of the class immediately below them, the White-Blooded Parasitic Worms. It embraces a double central cord or chain of small ganglia passing from one end of the body to the other. Most of the species are provided with ocelci or fixed eyes, and the cephalic segment is furnished with soft cylindrical tentacles which have been called 'antennæ.' These are undoubtedly organs of touch, but they differ structurally from the antennæ of insects in the absence of joints. The mouth is seated at the lower surface of the head, and in some species there is also a trunk or proboscis which the creature has the power of pulling in at will, and lateral-curved horny jaws. The alimentary canal is generally straight; in some species quite simple, in others having lateral pouches. The anal orifice is situated above or at the lower end of the body. The blood varies in its degree of redness, being sometimes very pale, at other times of a greenish hue. It has no visible corpuscles, molecules, or cells whatever. There is no distinction into nervous and arterial. The circulating system is very simple, consisting of a dorsal and ventral vessel with lateral branches passing to the tegumentary system, the peritoneal and branchial systems. In the dorsal trunk the blood flows from the tail towards the head, and in the ventral trunk from the head towards the tail.

The respiratory system is in some of the Annelides adapted for obtaining oxygen from the air, and in the rest through the medium of water. The branchial organs or gills by which the blood is aërated in the water are situated externally, and vary much in position.

These are the general features in the anatomical structure of the Annelides. They exhibit great variety in their passage from the lowest to the highest forms. They are divided by Milne-Edwards, who, after Cuvier, has given this family most attention, into four orders:—

1. The *Dorsibranchiatæ* or *Errantes*, including the Sea-Centipedes and Sea-Mice.
2. The *Tubicolæ*, which include those that live in tubes, as the *Serpula*.
3. The *Terricolæ*, inhabiting the earth, including the Common Earth-Worm.
4. The *Suctoriæ*, with suctorial disks, as the Leech.

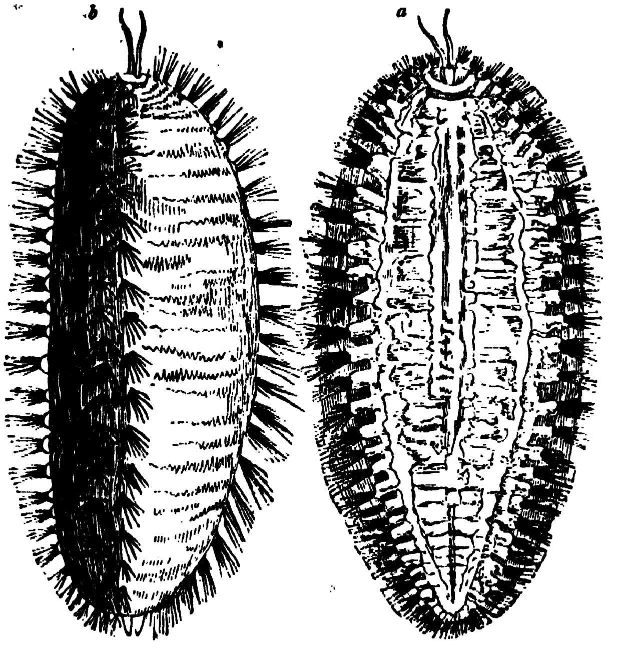
The order *Dorsibranchiatæ* is named from the attachment of the respiratory organs to the dorsal surface of the body, along the whole or the greater portion of the length. All the species belonging to it are aquatic and worm-like. They are active in their crawling, and swim with facility. On account of this last faculty Milne-Edwards has called them *Errantes*, to distinguish them from the next family, which are characterised by opposite habits. Their head is distinct from their trunk. They are furnished with two pairs of rudimentary eyes. The body is sometimes very long, as in the case of the tropical Nereids. [NEREIS.] It has however in the Sea-Mice considerable breadth. This genus, the *Aphrodita* of Linnæus, may be taken as the type of the order.

Cuvier remarks that this genus is easily recognised among the Dorsibranchiate Annelides by the two longitudinal rows of wide membranous scales which cover the back, and under which are hidden their branchiæ, in the form of small fleshy crests. Their body is generally flattened in form, and shorter and wider than it is in the other Annelides. Their very thick and muscular œsophagus is capable of being extruded like a proboscis. They have an unequal intestine, furnished on each side with a great number of branched cæca, the extremities of which go to fix themselves between the bundles of bristles that serve for feet.

Savigny's *Halitheæ* consist of those which have three tentacles, and between them a very small crest; they are without jaws.

Example, *Halithæa aculeata* (*Aphrodita aculeata*, Linn.), the Sea-Mouse.

This is a very beautiful animal, and most superbly coloured. It is oval, 6 or 8 inches long, and 2 or 3 inches wide. The scales of the back are covered and hidden by a kind of flocky down, like tow, which springs upon the sides, and from which issue groups of strong spines, that pierce, in part, the flocky covering, and bundles of flexuous bristles, glittering like gold, and changing into all the colours of the rainbow. Cuvier says, and without exaggeration, that they do not yield in beauty either to the plumage of the humming-birds or to the most brilliant precious stones. Lower down is a tubercle, out of which come spines, in three groups, and of three different sizes, and finally a fleshy cone. There are 40 of these tubercles on each side, and between the first two are two small fleshy tentacles. There are 15 pairs of scales, which are wide and sometimes puffed up, on the back, and 15 small branchial crests on each side.



Prickly Sea-Mouse (*Aphrodita aculeata*).
a, ventral view ; *b*, dorsal and lateral view.

Some of the *Halitheæ* (*Halithées Hermiones*, Sav.) have no flocky down upon the back, and such is *Aphrodita Hystrix* (genus *Hermione*, De Blainv.).

The genus *Polynöe*, Sav. (*Eumolpe*, Oken), is another subdivision. This genus has flocky covering on the back; the tentacles are 5 in number, and their proboscis is furnished with horny and strong jaws. *Polynöe lævis* is an example.

Then there are the genera *Sigalion* and *Acoëtes* of Messrs. Audouin and Milne-Edwards.

The first of these is more elongated in form than the other *Aphroditæ ;* it has cirrhi on all the feet. Such is *Sigalion Mathildæ*.

The second has cirrhi, which alternate with the elytra (as the two rows of membranous scales which cover the back are somewhat oddly called, the term being already applied to the horny external wings of coleopterous insects), in great length ; their jaws are stronger and better toothed. There is a large species at the Antilles which inhabits a sheath or pipe of the consistence of leather.

Here Cuvier places his *Chætopterus*, which has a mouth devoid of jaws and proboscis, furnished above with a lip, to which are attached two very small tentacula. Then comes a disk with nine pairs of feet, then a pair of long bristly bundles, like two wings. The branchiæ, in the form of plates, are attached rather below than above, and are placed along the middle of the body.

Example, *Chætopterus pergamentaceus*. This is 8 or 10 inches long, and inhabits a pipe of the substance of parchment, in the seas of the West India Islands.

The nervous system is more highly developed in the Dorsibranchiate Annelides than in the other orders. It consists of a double chain of ganglia, but the latter are larger generally, and the cephalic more fully developed, to accord with their organs of special sense. There are also observable nerves and ganglia destined to supply the digestive and respiratory organs.

Although the *Dorsibranchiata* are so highly developed, they nevertheless many of them retain the power of regenerating portions of their body which may be broken off; and in certain species which divide spontaneously a whole animal is formed from parts that are separated. In this respect they are related to the lower vermiform animals included in the *Entozoa*. [ENTOZOA.]

The *Tubicolæ* are characterised by having their branchiæ in the form of plumes, or of small arborisations, attached to the head or on the anterior part of the body ; and nearly all inhabit tubes.

Of those which inhabit tubes, some form a calcareous homogeneous one, resulting probably from their transudation, like the shells of the mollusca, but they do not adhere to it by means of muscles ; others construct a tube by agglutinating grains of sand, fragments of shells, or particles of sand, by means of a membrane which they doubtless secrete also; there are others again whose tube is entirely membranous or horny. ('Règne Animal.')

To the first category belongs the genus *Serpula*. The species of this genus are the *Tuyaux de Mer* of the French, and their twisting calcareous tubes cover stones, shells, and other submarine bodies. The section of these tubes is sometimes round and sometimes angular, according to the species.

Cuvier describes the animal as having a body composed of a great number of segments ; its anterior part enlarged into a disk, armed on each side with many bundles of stiff bristle-like appendages, and on each side of the mouth a plume of branchiæ in the form of a fan, ordinarily tinted with vivid colours. At the base of each plume is a fleshy filament ; and one of the two, that to the right or left indifferently, is always prolonged and dilated at its extremity into a disk of different configuration, which serves as an operculum, and closes the aperture of the tube when the animal retires within it. Cuvier further observes that as the most common species has this disk in the form of a funnel, some naturalists have mistaken it for a proboscis ; but it is not pierced ; and the other species have it more or less of a club-shape.

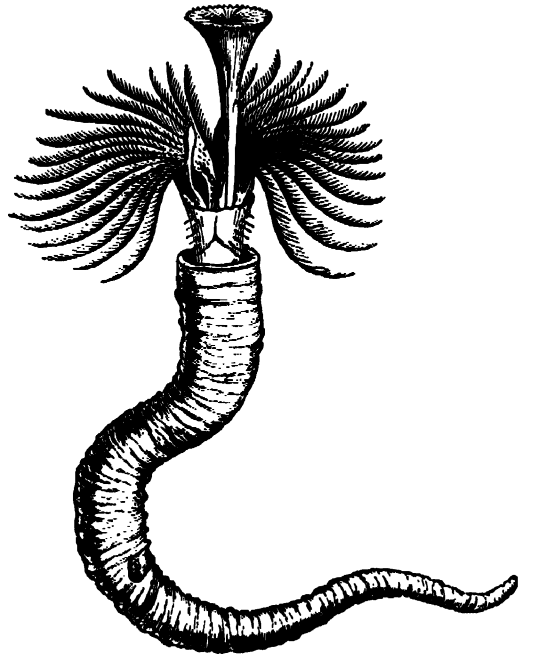
The number of species of *Serpula* (Lam.), admitted into the last edition of 'Animaux sans Vertèbres,' is 60 recent and fossil ; and M. Milne-Edwards adds many more at the end of the genus ; but he observes that very little is known of the specific differences presented by these animals, and that many of the living and all of the fossil species are characterised in a very doubtful manner. The fossils are said to be found in the Tertiary, Green-Sand, Chalk (environs of Münster and Maastricht), Lias, and Oolite beds, &c. Mr. Lea describes a species, *Serpula ornata*, from the Tertiary of Alabama (Claiborne Beds).

Dr. Fitton records 14 named species and two uncertain species from the strata below the chalk, ranging from the Upper Green-Sand to the Kimmeridge Clay.

Sir Roderick Murchison notices *Serpulites* and *Spirorbis* in the Silurian rocks, *Serpulites longissimus* in the upper Ludlow Rock, and *Spirorbis tenuis* in the lower Ludlow Rock, and in the Wenlock Limestone. He also records the presence of *Serpula* (*Serpula omphaloïdes*, Goldf.) in the Devonian Rocks of Russia.

Example, *Serpula contortuplicata*. The tubes of this *Serpula* are round, twisted, and about three lines in diameter. Its operculum is funnel-shaped, and its branchiæ are often of a beautiful red, or variegated with yellow and violet. It quickly covers vases, bottles, or other objects thrown into the sea.

Locality.—The Mediterranean and European Seas.



Serpula contortuplicata.

In other species, as for instance of the genus *Galeolaria*, Lam., the operculum is flat and beset with points.

Cuvier notices another species from the Antilles (*Serpula gigantea*, Pallas), which lives among the madrepores, and whose tube is often surrounded by their masses. Its branchiæ are rolled into a spiral form when they re-enter ; and its operculum is armed with two small branched horns, like the antlers of a stag. This species is the *Terebella bicornis*, 'Abbild. Berl. Schr.' ix. iii. 4 ; *Actinia*, or Animal Flower, Home, 'Lect. on Comp. Anat.' ii. pl. 1. Upon this spiral rolling up of the branchiæ Savigny established his subdivision of *Cymospire Serpulæ*, from which M. de Blainville afterwards established a genus.

The genus *Spirorbis*, Lam., consists of those *Serpulæ* whose branchial filaments are much less numerous, only three or four on each side; their tube is rolled up into a tolerably regular spiral, and they are ordinarily very small.

Sabella.—The species of this genus have the same body and the same fan-shaped branchiæ as the *Serpulæ;* but their two fleshy filaments adhering to the branchiæ each terminate in a point, and do not form an operculum; they are even sometimes absent. The tube of the *Sabellæ* appears, most frequently, to be composed of grains of sand, of clay, or very fine mud, and is rarely calcareous. The known species are rather large, and Cuvier notices their branchial plumes as being of admirable delicacy and brilliancy.

Example, *Sabella protula*, Cuv. (*Protula Rudolphii*, Risso). This beautiful and large species, with a calcareous tube like that of the *Serpulæ*, has the branchiæ of a rich orange.

Terebella.—The species like the greater part of the *Sabellæ*, inhabit a factitious tube; but it is composed of grains of sand and fragments of shells; their body, moreover, has much fewer rings, and their head is differently ornamented. Numerous filiform tentacles, susceptible of much extension, surround their mouth, and on their neck are arborescent branchiæ, not fan-shaped.

Example, *Terebella conchilega.*

Amphitrite.—Cuvier remarks that the species of this genus are easily known by straw-like processes ranged in a pectinated form, or in that of a crown, in one or more rows, where they probably serve for defence, or perhaps as means of [illegible] or collecting the materials for their tube. Around the mouth are very numerous tentacles, and on the commencement of the back on each side are branchiæ in the form of a comb.

Cuvier's genus *Amphitrite* comprehends the *Pectinariæ* of Lamarck, the *Amphictènes* of Savigny, the *Chrysodons* of Oken, the *Cistenes* of Leach, the *Sabellariæ* of Lamarck, the *Hermelles* of Savigny, and the genus *Pherusa* of De Blainville.

Siphostoma (Otto).—The species of this genus, which Cuvier suspects should be referred to this order, have on each articulation above a bundle of fine bristles; below, a simple bristle; and, at the anterior extremity, two packets of strong and golden-coloured bristles. Under these bristles is the mouth, preceded by a sucker surrounded by many soft filaments, which Cuvier thinks may be branchiæ, and accompanied by two fleshy tentacles. The knotted medullary cord may be seen through the skin of the belly. The *Siphostomata* live burrowed in the sand.

Examples, *Siphostoma diplochaitos,* Oken; *S. uncinata* Aud. et Edw. 'Littoral de France, Annel.' pl. ix., f. 1.

The close connection between the *Tubicolæ* and the *Dorsibranchiatæ* is seen in the fact that the young of these orders pass through precisely the same stage before arriving at maturity. It is only during the last stages of change that the embryoes of *Tubicolæ* manifest their ultimate destination by the unequal development of certain of their segments, some of which become almost abortive, whilst others are disproportionately developed.

The *Terricolæ* have a cylindrical body tapering at both ends. The segments of their bodies are not well marked, and the head is not distinct from the trunk. They have neither eyes, mandibles, cirrhi, nor tuberculous feet. This order includes two principal groups, one of which only is terrestrial, whilst the other is aquatic. To the former belong the Common Earth-Worm (*Lumbricus terrestris*), whilst in the latter is included the Lob or Lug-Worm (*Arenicola*). As the Earth-Worm is so well-known we shall refer to its structure and habits to illustrate the order.

Cuvier remarks that the *Lumbrici* ought to be subdivided; and Savigny has, in effect, subdivided the Earth-Worms into the genera *Enterion*, *Hypogæon*, and *Clitellio.* Messrs. Audouin and Milne-Edwards distinguish also the genus *Trophonia.*

Of these *Enterion* has upon each ring four pairs of small bristle-like processes, eight in all.

Clitellio is stated to have two bristle-like processes only on each ring.

Hypogæon has, besides the other bristle-like processes, one on the back of each ring. (This form is noticed as being American only.)

Trophonia has on each ring four bundles of short bristle-like processes, and at the anterior extremity a great number of long and brilliant bristle-like processes which surround the mouth.

Savigny described upwards of twenty species, which he considers to be distinct, and to have been confounded previously under the name of *Lumbricus terrestris.* M. Morren, in his 'Treatise on the Natural History and Anatomy of the *Lumbricus terrestris*,' appears to be doubtful with regard to the number of species described by Savigny and others, and inclines to the opinion that they are merely varieties. M. Milne-Edwards (edit. of Lamarck's 'Animaux sans Vertèbres,' 1838,) considers the characters on which Savigny relied as distinctions for dividing the group into the three genera as of little importance.

Externally the Earth-Worm (*Lumbricus terrestris*, Linnæus) presents a body composed of numerous narrow rings closely approximated to each other; at about one-third of their length may be seen, particularly at the season of reproduction the clitellum, which becomes at that time a highly important agent. The colour of the body is reddish or bluish, and of a shining aspect, and the animal has the power of secreting a viscous substance, which forms a sort of protecting sheath to its body, and greatly facilitates its progress through the earth. The animal is eyeless, and unprovided with either tentacle, branchiæ, or cirrhi.

Respiratory System.—The generally received opinion is that the blood of the Earth-Worm is aërated by means of lateral series of small pyriform vesicles, analogous to the breathing sacs of the Leech, and opening externally by very minute pores.

Digestive System.—The mouth consists of two lips without tentacles or armature of any description; but the upper lip is elongated and proboscidiform. The œsophagus, which is a wide membranous canal, is continued straight down for half an inch, and ends in a dilated bag or reservoir, to which succeeds a muscular stomach or gizzard, disposed in the form of a ring. The intestine is constricted at each segment of the animal by a series of ligaments or partitions, connecting it to the parietes of the body, and swells out the intermediate spaces, when distended by the particles of earth.

Nervous System.—The nervous system of the Earth-Worm consists of a double row of small ganglions close to each other.

Generative System.—Allotriandrous, or with male organs so disposed as to fecundate the ova of a different individual. (Owen.) It has been doubted whether these animals are oviparous, ovoviviparous, or viviparous. The fact is, that after fecundation by another individual, the ova, which are contained in the ovary, are set free in the cavity of the body by the bursting of the ovary, and are gradually propelled to a cavity near the anus. In this spot they undergo the usual changes, and they may or may not emerge from the parent before the egg-membrane is broken.

Organs of Progression. Earth-Worms creep at a good pace by means of muscular contraction and dilatation acting on the rings, which carry on their under-side the bristle-like processes above mentioned: these last operate as feet. The power of elongation is considerable, and the anterior part of the animal acts as a sort of awl in penetrating the earth.

Habits, &c.—The Earth-Worm, as far as relates to its appearance above the surface of the ground, may be considered almost a nocturnal animal. In the night-season and at early morning hundreds may be seen, though not one, unless they are disturbed either by moving the ground or pouring liquids into their holes, is to be found moving about in the day. The power of reproducing parts after mutilation is very great in this animal and the whole of the order.

Utility to Man.—The worm-casts, which so much annoy the gardener by deforming his smooth-shaven lawns, are of no small importance to the agriculturist; and this despised creature is not only of great service in loosening the earth and rendering it permeable by air and water, but is also a most active and powerful agent in adding to the depth of the soil, and in covering comparatively barren tracts with a superficial layer of vegetable mould. In a paper 'On the Formation of Mould,' read before the Geological Society of London, by Charles Darwin, Esq., F.G.S., the author commenced by remarking on two of the most striking characters by which the superficial layer of earth, or, as it is commonly called, vegetable mould, is distinguished. These are, its nearly homogeneous nature, although overlying different kinds of subsoil, and the uniform fineness of its particles. The latter fact may be well observed in any gravelly country, where, although in a ploughed field, a large proportion of the soil consists of small stones, yet in old pasture-land not a single pebble will be found within some inches of the surface. The author's attention was called to this subject by Mr. Wedgwood, of Maer Hall, in Staffordshire, who showed him several fields, some of which, a few years before, had been covered with lime, and others with burnt marl and cinders. These substances, in every case, are now buried to the depth of some inches beneath the turf. Three fields were examined with care: the first consisted of good pasture-land, which had been limed, without having been ploughed, about 12½ years before; the turf was about half an inch thick; and 2½ inches beneath it was a layer or row of small aggregated lumps of the lime, forming, at an equal depth, a well-marked white line. The soil beneath this was of a gravelly nature, and differed very considerably from the mould nearer the surface. About three years since cinders were likewise spread on this field: these are now buried at the depth of an inch, forming a line of black spots parallel to and above the white layer of lime. Some other cinders, which had been scattered in another part of the same field, were either still lying on the surface or entangled in the roots of the grass. The second field examined was remarkable only from the cinders being now buried in a layer, nearly an inch thick, 3 inches beneath the surface. This layer was in parts so continuous, that the superficial mould was only attached to the subsoil of red clay by the longer roots of the grass.

The history of the third field is more complete. Previously to 15 years since it was waste land; but at that time it was drained, harrowed, ploughed, and well covered with burnt marl and cinders. It has not since been disturbed, and now supports a tolerably good pasture. The section here was turf half an inch, mould 2½ inches, a layer 1½ inch thick, composed of fragments of burnt marl (conspicuous from their bright red colour, and some of considerable size, namely, 1 inch by ½ an inch broad, and a ¼ inch thick), of cinders, and a few quartz pebbles mingled with earth; lastly, about 4½ inches beneath the surface was the original black peaty soil. Thus beneath a layer (nearly 4 inches thick) of fine particles of earth, mixed with some vegetable matter, those substances now occurred, which, 15 years before, had been spread on the surface. Mr. Darwin stated that the appearance in all cases was as if the fragments had, as the farmers believe, worked themselves down. It does not however appear at all possible that either the powdered lime or the fragments of burnt marl and the pebbles could sink through compact earth to some inches beneath the surface, and still remain in a continuous layer; nor is it probable that the decay of the grass, although adding to the surface some of the constituent parts of the mould, should separate in so short a time the fine from the coarse earth, and accumulate the former on those objects which so lately were strewed on the surface. Mr. Darwin also remarked that near towns, in fields which did not appear to have been ploughed, he had often been surprised by finding pieces of pottery and bones some inches below the turf. On the mountains of Chile he had been perplexed by noticing marine shells, covered by earth, in situations where rain could not have washed it on them.

The explanation of these circumstances, which occurred to Mr. Wedgwood, although it may at first appear trivial, the author does not doubt is the correct one, namely, that the whole is due to the digestive process by which the Common Earth-Worm is supported. On carefully examining between the blades of grass in the fields above described, the author found that there was scarcely a space of two inches square without a little heap of the cylindrical castings of worms. It is well known that worms swallow earthy matter, and that, having separated the serviceable portion, they eject at the mouth of their burrows the remainder in little intestine-shaped heaps. The worm is unable to swallow coarse particles; and as it would naturally avoid pure lime, the fine earth lying beneath either the cinders and burnt marl, or the powdered lime, would, by a slow process, be removed and thrown up to the surface. This supposition is not imaginary, for in the field in which cinders had been spread out only half a year before, Mr. Darwin actually saw the castings of the worms heaped on the smaller fragments. Nor is the agency so trivial as it at first might be thought, the great number of Earth-Worms (as every one must be aware who has ever dug in a grass-field) making up for the insignificant quantity of work which [illegible] performs.

On the above hypothesis, the [illegible] of old pasture-land, which farmers are always particularly [illegible] to break up, is explained; for the worms must require a considerable length of time to prepare a thick stratum of mould, by thoroughly mingling the original constituent parts of the [illegible], as well as the manures added by man. In the peaty field, in 15 years, about 3½ inches had been well digested. It is probable however that the process is continued, though at a slow rate, to a much greater depth, for as often as a worm is compelled by dry weather or any other cause to descend deep, it must bring to the surface, when it empties the contents of its body, a few particles of earth. The author concluded by remarking, that it is probable that every particle of earth in old pasture-land has passed through the intestines of worms, and hence that in some senses the term 'animal mould' would be more appropriate than 'vegetable mould.' The agriculturist, in ploughing the ground, follows a method strictly natural; and he only imitates in a rude manner, without being able either to bury pebbles or to sift the fine from the coarse soil, the work which Nature is daily performing by the agency of the Earth-Worm.

The most common species of *Arenicola* is the *A. Piscatorum*, or Lug-Worm, which is commonly employed on the coasts of this country as a bait by fishermen.

The genus *Nais*, of Linnæus, includes a number of small Annelides, not well made out. They live in holes which they perforate in the mud at the bottom of the water, from which they protrude the upper portion of their body, which they are incessantly moving.

The *Suctoriæ* are characterised by the body of the animals being destitute of bristles for locomotion, completely apodous, without soft appendages, and furnished with a prehensile cavity in the form of a sucker at each extremity. The head is not distinct, but generally provided with eyes and jaws.

The principal family of this order is the *Hirudinidæ*, which comprehends not only the Leeches properly so called, which live by sucking the blood of various animals, but also includes many other worms which derive their nourishment in a totally different way, and present corresponding differences in organisation. The affinities between the leeches and some of the Setiferous Annelidans, as various species of *Nereis*, *Lumbricus*, *Planaria*, &c., are so close that they hardly admit of being arranged in separate orders, and others of the Leech tribe may even be confounded with some species of *Lernæa* or *Epizoa*.

The ancients appear to have only known the most common species of Leeches. Aristotle makes no mention of them, and they do not appear to have been used in medicine in the time of Hippocrates. Pliny describes them very clearly under the name of *Hirudines* and *Sanguisugæ*, and distinguishes two species. The Sea-Leech is distinctly mentioned by Belon, Rondelet, and by all the writers on natural history since the revival of letters. More recently Linnæus increased our knowledge of the number of species, of which he describes eight in the 12th edition of the 'Systema Naturæ.' Müller afterwards discovered five or six others, so that Gmelin, in his edition of the 'Systema Naturæ,' enumerated fourteen species. Since then, Shaw, Leach, Dutrochet, Savigny, Milne-Edwards, and others, have found many more, and the introduction of new zoological methods has caused a necessity for arranging these various species in different genera, of which we shall enumerate some of those which are best known.

The True Leeches are all destitute of branchiæ or special organs of respiration; and this function has been supposed to be effected by means of the skin generally, but M. Milne-Edwards has recently stated (as was before observed by Cuvier) that "there exists in these *Annelidæ* a series of small membranous sacs, each of which communicates externally by a minute orifice situated on the ventral aspect of the body: these sacs derive from the numerous vessels which ramify upon their parietes a considerable quantity of blood; water penetrates into these organs, and seems to subserve a true respiratory purpose." But though the species of the family *Hirudinidæ* are not provided with distinct branchiæ, these organs are found in a genus which is generally associated with the True Leeches, and which we shall place first in the following list of genera:—

1. *Branchellion*, Savigny, *Branchiobdella*, De Blainville, *Polydora*, Oken. These names have been given to a worm closely resembling a leech in external structure (it being furnished with two suckers), which is found parasitic on the Torpedo in the Mediterranean and other seas. The *Hirudo branchiata*, Menzies, a species observed on the tortoise which is found in the Pacific Ocean, has also been placed in this genus, though Cuvier says that it ought not to be associated with it.

Hirudinidæ proper.

Section I.—*Anterior Sucker separated from the Body by a distinct Strangulation or Neck.*

2. *Albione*, Sav., *Pontobdella*, Leach and Blain., characterised by the body being bristled over with tubercles. Species all marine; seven have been enumerated; two of them are very common in our seas:—1, *Albione verrucosa*, *Hirudo muricata*, Linnæus; 2, *Pontobdella spinulosa*, Leach: both of these worms attach themselves to fish, particularly skates; and the latter species is commonly known to fishermen by the name of the Skate-Sucker.

3. *Hæmocharis*, Sav.; *Ichthyobdella*, Blain. In this genus there are eight eyes, the body is narrow, and the jaws scarcely visible. The only known species is the *Hæmocharis Piscium*, *Hirudo Piscium*, Linn., which lives in fresh waters, where it attaches itself to fish, particularly *Cyprini*.

Section II.—*Anterior Sucker very slightly separated from the Body.*

4. *Geobdella*, Blain., *Trochetia*, Dutrochet, is distinguished by having an enlargement round the orifices of the genital organs. We only know one small species of this genus, the *Geobdella Trochetii*, which inhabits our waters, and which frequently comes on land to pursue the *Lumbrici*, or Earth-Worms.

5. *Pseudobdella*, Blain., has the mouth merely provided with folds of skin, and is destitute of teeth. Only one species is well known, the *Pseudobdella nigra*, *Hirudo nigra*, Linn., the Common Black Leech.

6. *Hæmopis*, Sav., *Hypobdella*, Blain., has the mouth furnished with a few obtuse teeth. Three species are enumerated; the best known is the *Hæmopis sanguisorba*, Sav., *Hirudo sanguisuga*, Linn., the Common Horse-Leech, which is much larger than the Medicinal Leech, and wholly of a greenish-black colour. The Horse-Leech has been reported to inflict dangerous wounds by some observers, while others say that it never attacks vertebrate animals. M. De Blainville thinks that this discrepancy has arisen from this species having been confounded with the foregoing, the Black Leech, which cannot penetrate the skin of vertebrate animals for want of teeth. Both these leeches greedily attack the common earth-worm.

7. *Sanguisuga*, Sav., *Jatrobdella*, Blain. The anterior sucker has its upper lip divided into several segments. Its aperture is transverse, and it contains three jaws, each of which is armed on its edge with two ranges of very fine teeth, which enable these leeches to penetrate through the skin without making any dangerous wound. This genus contains the true Medicinal Leeches, eight species of which have been enumerated: the most common is the *Sanguisuga medicinalis*, *Hirudo medicinalis*, Linn., which is a native of all our stagnant fresh waters.

8. *Bdella*, Sav., has eight eyes and is destitute of teeth: one species is found in the Nile—the *Bdella Nilotica*.

9. *Nephelis*, Sav., *Erpobdella*, Blain., has eight eyes, and the mouth is furnished internally with only three folds of skin. Several species of this genus are enumerated; the most common is the *Nephelis tessilata*, Sav., *Hirudo vulgaris*, Linn. This species has often been confounded with the medicinal and other leeches; it is commonly found in fresh waters, and, like all the other species of this genus, never leaves the water, and is injured by the contact of the air; so that if taken out of the water it quickly dies.

Section III.—*Anterior Sucker wanting.*

10. *Clepsina*, Sav., *Glossopora*, Johnson, *Glossobdella*, Blain. This genus has a widened body and only a posterior sucker; the mouth is in the form of a proboscis. Cuvier thinks it doubtful whether the species of this genus should be arranged with the Leech Family; they

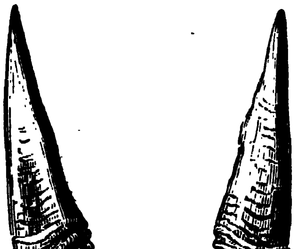
consist of little worms which never leave the water, and live fixed to the stem of aquatic plants, from which they perhaps derive their nourishment: they never swim, but crawl along.

Besides the genera which we have enumerated, several parasitic worms, which live always fixed to the same part of some animal, have been enumerated among the *Hirudinidæ*, and have been arranged by Blainville in the genus *Epibdella.* He also places several other species, which are without distinct articulations, in the genus *Malacobdella.* There still remain several doubtful species of Leech, and some have been confounded with true *Planariæ*, which differ from Leeches in having no sucker at either end.

To this order also is referred the genus *Gordius* of Linnæus, but recent researches have rendered it highly probable that their relations are rather with the *Entozoa.* [ENTOZOA.]

(Williams, *Report of the Structure of Annelida*, 'Brit. Ass. Trans.,' 1851; Owen, *Lectures on Comparative Anatomy;* Cuvier, *Règne Animal;* Carpenter, *Principles of Physiology;* Milne-Edwards, *Élémens de Zoologie.*)

ANOA, a species of Ruminating Animals, so very imperfectly known, that zoologists are undetermined whether to consider it as an antelope or a species of buffalo. This uncertainty arises from the fact, that though the animal has been noticed for many years, only a few fragments of skulls and horns have been hitherto brought to Europe, and even these too imperfect to acquaint us with the zoological characters of the animal. Judging, however, from these materials, the Anoa would really appear to be a species in many respects intermediate between the buffaloes and antelopes, as at present defined; agreeing with the former in the form of its horns, and with the latter in their position.

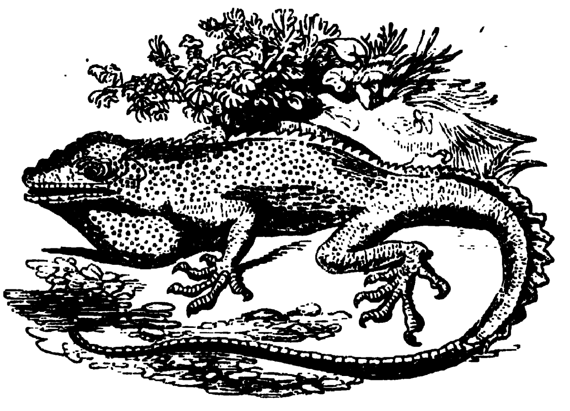


Horns of *Anoa.*

ANOLIS (*Anolius*, Cuvier), a genus of Saurian Reptiles, belonging to that section of the *Iguanias* which Cuvier distinguishes by having teeth in the palate of the mouth as well as in the maxillary bones. They are readily distinguished from the Iguanias, properly so called, the Basilisks, and other genera of this division, by the peculiar form of the antepenultimate phalange of the toes, which is flattened beneath, and furnished with a kind of pad or cushion, grooved or striated transversely, and serving to make the animals adhere more firmly to those substances which they grasp in walking. In this particular point of their structure the Anolis approach the Geckoes, but it does not enable them to exercise the singular power of walking with the legs uppermost, like flies on a ceiling, which some of these reptiles possess. The toes, however, are much longer and better separated than those of the Geckoes, and the claws, instead of being short and flattened, are long, crooked, and sharp-pointed. The body and tail are long and slender, as are also the legs, particularly those behind, which are rather longer than the fore-legs. Each foot has five toes. The whole body and tail, both above and below, are covered irregularly with small round scales, which give the skin a granulated appearance like that of a fine shagreen.

The Anolis are entirely an American genus, and seem, in many respects, to supply in the New World the place which the Chameleons occupy in the Old. The colours of their skins change with the same or even greater rapidity, especially on the loose skin of the throat, which is constantly distended when these animals are actuated by strong passions, either of fear, anger, or love, and in this state they assume an endless succession of ever-varying hues. They differ from the Chameleons, however, in their more slender and graceful proportions, and in the great activity of their movements, displaying all the restlessness and celerity of the common green lizard of Europe. They frequent woody and stony situations indifferently, climb and leap with such swiftness and facility that their motion has been compared to the flight of a bird; and, when overheated or fatigued by their exertions, will stop, open their mouths, and pant like a tired dog. They are extremely timid and harmless, and feed for the most part upon flies and other small insects. There are two small sub-genera, distinguished from one another by the presence or absence of the carinated crest on the upper surface of the tail. The first of these divisions, comprehending those which have this crest, consists of a number of species definitely characterised by M. Cuvier, but formerly confounded under the denominations of *Lacerta principalis* and *Lacerta bimaculata.* The principal species are the following: —

1. *Anolius velifer*, of Baron Cuvier, is of a beautiful dark ashy-blue colour, and perhaps the largest of the whole genus, the body measuring a foot in length, and the tail being about a foot and a half. The crest extends along the top of the tail for half its length from the origin, and is supported by from 12 to 15 rays. The loose skin beneath the throat extends from the chin even to the belly, and when not distended forms a longitudinal fold along the whole under-surface of the animal. The food, from the observation of Baron Cuvier, would appear, at least occasionally, to consist of berries and other vegetable substances. It inhabits Jamaica and the Antilles generally, preferring the woods to the open country, and lodging in decayed trees or small crevices in the ground, where the female likewise deposits her eggs. It is incessantly in motion, and when pleased frequently emits a low but acute chirp; though harmless and extremely timid, it possesses a considerable share of curiosity, and allows itself to be readily caught in little rush snares, which children in the West Indies amuse themselves by placing in its haunts, alluring it from its concealment by imitating its voice.

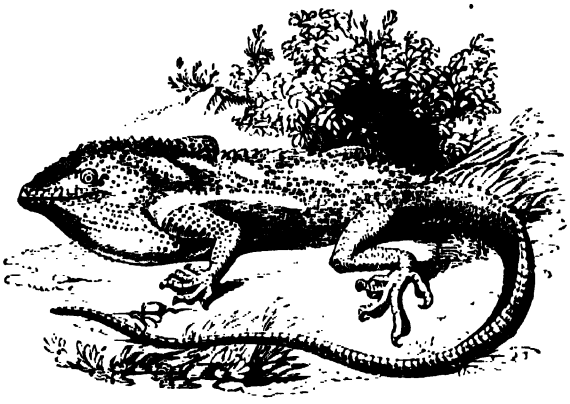


Anolius velifer.

2. *Anolius bimaculata*, of Sparrmann, is little more than half the size of the former species, but with the same general form and habits, and with a similar crest upon the first half of the tail. The general colour is a greenish blue, clear on the top of the head and neck, but mixed with dark brown on the body, tail, and extremities, and marked with numerous small black spots on the head and sides, and two large ones on the shoulders, from which it derives its specific name. It is found in North America, from Pennsylvania to the shores of the Gulf of Mexico, and in the Antilles.

The second subdivision of the genus *Anolius* consists of species without a carinated crest on the tail, but in no other respect differing from those already described. Of these the principal are: —

3. *Anolius equestris*, of Merrem, of which the tail, more flattened on the sides than in the following species, still retains a slight indication of the crest which distinguishes those of the former division. The body of this species measures about a foot in length, and the tail is nearly a foot and a half.



Anolius equestris.

4. *Anolius Cepedii*, of Merrem, is a pretty little species, found likewise in the Antilles, about half the size of the last, of a green colour, with a short muzzle spotted with brown, and, except in the absence of the crest on the tail, very similar to the *Anolius bimaculata.*

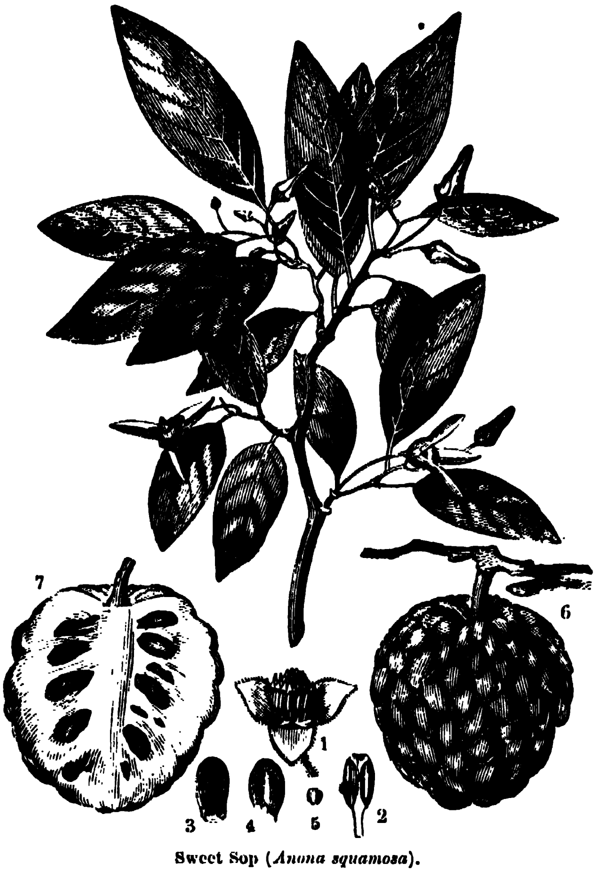
5. *Anolius lineatus*, of Daudin, resembles the last species in its pure bright green colour, but it is rather larger, and is marked along each flank with two parallel lines of oblong black spots, the upper of which passes over the arms and thighs, and the under between the shoulders and hips. It inhabits different parts of South America.

6. *Anolius bullaris*, of Merrem, first described by Catesby in his 'Natural History of Carolina,' under the name of the Green Lizard, is a very beautiful species, of a greenish gold colour, particularly distinguished by a black band on the temples, and the elongated and flattened form of its muzzle.

ANONA'CEÆ, *Anonads*, the *Custard-Apple-Tribe*, a natural order of plants consisting of tropical or subtropical trees and bushes, that usually abound in a powerful aromatic secretion, which renders the flowers of some highly fragrant, the leaves of others a grateful perfume, and the dried fruits of many so highly aromatic as to vie with the spices of commerce; among these last is the Æthiopian Pepper of the shops, which is yielded by the fruit of *Uvaria aromatica.* Of others of this order, the fruit is succulent and abounds in a delicate juice, which renders it a pleasant article of food. Under the name of Sour Sop, Sweet Sop, and Custard-Apple, many kinds are cultivated in the West Indies and South America. Finally, the bark of some separates readily into fibres which make excellent cordage: a large tree called in Brazil Pindaiba, and by botanists *Xylopia sericea,* is advantageously employed for this purpose.

The natural order *Anonaceæ* is known from all other Dicotyledonous orders by its flowers having the calyx and sepals arranged in threes, a number of carpella occupying the centre, as in a ranunculus, and by the curious circumstance of their albumen, which here constitutes the bulk of the seed, being what is called ruminated, that is, perforated in all directions by twisting and crossing passages, like the nutmeg.

The Sweet Sop (*Anona squamosa*) is often only a small bush, growing in all the West India Islands, where it bears a greenish fruit covered with scales, and having the appearance of a young pine-cone. Its skin is half an inch thick, and contains an abundance of thick, sweet, luscious pulp. In many parts of the Indian Archipelago it is a favourite fruit.



Sweet Sop (*Anona squamosa*).

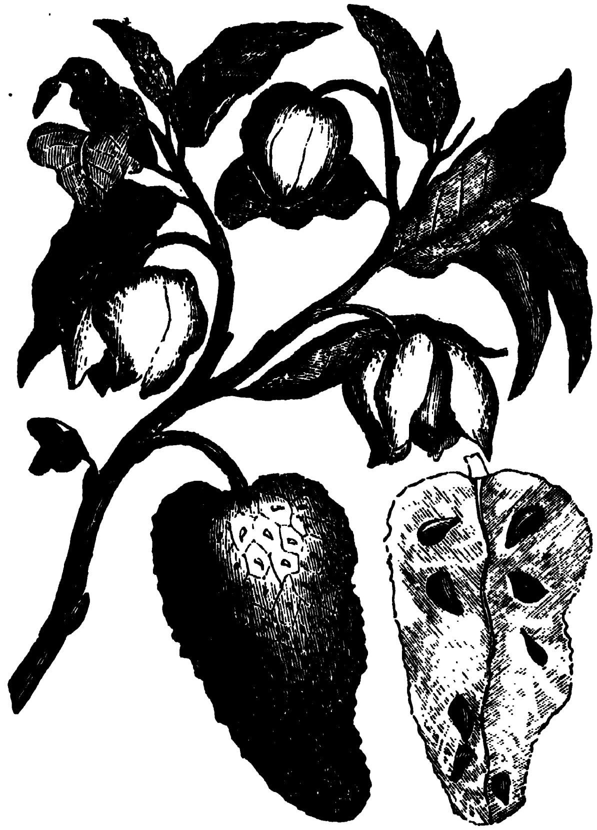
1, A calyx opened, the petals having fallen away, showing the arrangement of the stamens and carpels in the inside of the flower; 2, a stamen; 3, a seed; 4, the same cut in half, to show the ruminated albumen; 5, the embryo; 6, a ripe fruit, much less than the natural size (the projections on its surface are the points of the carpella which grow together into one fleshy mass, as in the raspberry); 7, a view of the same fruit cut in half.

The Custard-Apple (*Anona reticulata*) is an inferior kind, resembling the foregoing, but forming a larger tree, and having a much larger dark-brown fruit, the surface of which is netted all over. The bulb is yellowish or reddish, and of about the consistence of custard.

The Sour Sop (*Anona muricata*) forms in the West Indies a picturesque small tree, resembling a large bay-tree. The flowers are yellow, and have an unpleasant odour. The fruit is often as heavy as 2 lb., or even 3 lb.; it is covered all over with weak prickles; its skin is yellowish-green, and very thin; its pulp is more like pith, is as white as milk, and is sweet mixed with a most agreeable acid.

The Cherimoyer (*Anona Cherimolia*), is easily known from the preceding by its leaves not being shining and bright green, but hoary, with short down, and very blunt. It forms a small tree about 12 or 14 feet high, and is exceedingly valued in Peru, where it is cultivated on account of the excellence of its fruit. The flowers are very fragrant. The fruit heart-shaped, grayish-brown or black, when ripe, with a scaly rind; it is white, sweet, and ri[illegible]

A. sylvatica is called *Araticu do Mato* in Brazil. Its wood is used for light turnery, and its fruit is good for the dessert. The root of *A. palustris* is used for making corks in Brazil.



Fruit of Sour Sop (*Anona muricata*).

Sour Sop (*Anona muricata*).

ANOPLOTHE'RIUM (from ἀ privative, ὅπλον, and θὴρ, that is, a beast without offensive arms or tusks), in Fossil Zoology, a genus of extinct Pachydermatous Quadrupeds, discovered and characterised by Baron Cuvier. The bones of these singular inhabitants of a former world, occur in great quantities, mixed with those of the *Palæotherium,* another extinct genus of the same order, likewise described by M. Cuvier, in the gypsum-strata or plaster-quarries in the neighbourhood of

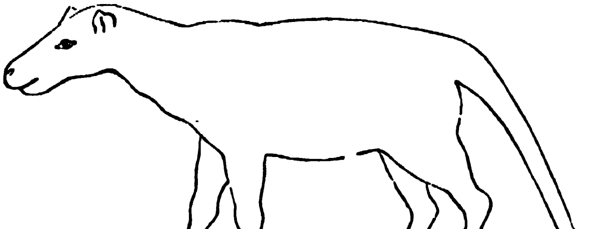
Paris, and they are occasionally, though more rarely, met with in the neighbourhood of Orleans and Genoa. Remains also of this genus have been found in the fresh-water deposits at the Seafield quarries in the Isle of Wight.

The first character in which the *Anoplotheria* differ essentially from all other Pachydermata, whether extinct or recent, is found in the number and arrangement of their teeth, which consist of 6 incisors, 2 canines, and 14 molars in each jaw, making in the whole 44 teeth. These, as in the human subject, are arranged in a continued and uninterrupted series, without any vacancies between the molars or incisors and the canines, a circumstance peculiar to this genus of animals among the Pachydermata, and which, besides man, it shares only with the shrews and hedgehogs—Mammalia in all other respects widely different. The canines moreover are perfectly similar in form and appearance to the incisors, and might easily be mistaken for lateral teeth of this description, did not their situation in the jaw, beyond the maxillary suture, prove their real nature. The four posterior molars resemble those of the Rhinoceros and Palæotheria; that is to say, they are quadrangular in the upper jaw, and marked in the lower with a double or triple crescent of enamel, which penetrates their substance and shows itself on the crowns in the form of salient ridges.

This formation of the organs of mastication, intimately connected as these organs necessarily are with the food and alimentary canal, demonstrate most unequivocally that these animals fed upon vegetable substances, and that, in all probability, they differed but little in this respect from the Tapirs and Rhinoceroses at present existing.

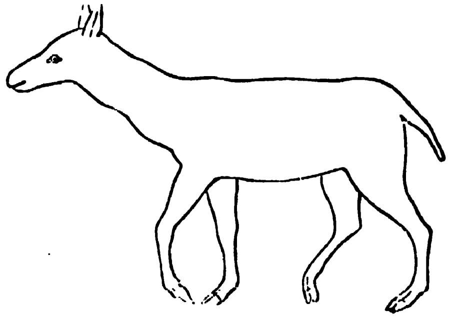
The second important character of the *Anoplotheria* which must have exercised a very decided influence upon their habits, arises from the conformation of the extremities. These, as in Ruminating Animals, were terminated by two toes, enveloped in small hoofs, sometimes without accessory or false hoofs behind, as in the Camels and Llamas, sometimes with one or even two small lateral toes of this description, as in the Peccaries; but the bones of the metacarpus and metatarsus respectively corresponding to these two toes were not united into a single canon, as they invariably are among the Ruminantia, and this is in reality the principal difference between the extremities of the latter animals and those of the *Anoplotheria*. The structure of the carpus and tarsus is precisely the same in both genera; the scaphoïd and cuboïd bones, which are soldered together into a single piece in all the other Ruminantia, being separate in the Camels and Llamas, as they invariably are in the *Anoplotheria* and other Pachydermata. These analogies prove that the *Anoplotherium*, which its teeth have already shown to have been essentially a Pachydermatous quadruped, approached in many of its characters to the Ruminantia of the existing creation, partaking on the one hand of the characters of the Camels and Llamas, and on the other of those of the Rhinoceroses and Peccaries. In the less prominent details of organisation however, the different species of *Anoplotheria* present peculiarities which have induced Baron Cuvier to distribute them in three sub-genera. In all, the prolongation of the nasal bones clearly shows that the *Anoplotheria* were not furnished with trunks like the Elephants, Tapirs, and Palæotheria; and their head altogether, judging from the form of the skull, appears to be intermediate between that of the Horse and that of the Camel. The first subdivision comprehends those species which M. Cuvier calls—

Anoplotheria proper. They are distinguished by having all the lower molars marked by double or triple crescents in a longitudinal direction, without salient tubercles; and by a third or supernumerary hoof on the fore-feet. This division comprehends two species, differing from one another principally in point of size, the one (*A. commune*) being about the size of the ass, and the other (*A. secundarium*) about that of the hog. Both these species have been found in the Isle of Wight. These animals were low on the limbs, probably like the Tapirs, but their long and powerful tail, equalling the body itself in length, made them still more essentially aquatic animals. The great size of their members, the depressed and heavy proportions of their bodies, and their long tails compressed horizontally at the base, must have given them much of the external form of the otter; but they resorted to the lakes and marshes of the antediluvian world, not for the purpose of preying upon other animals, but in search of aquatic plants, whilst the depressed form of their tails shows that they must have swum and plunged with as much ease and facility as either the Tapir or Hippopotamus. Like these animals their ears were probably short and erect, and their bodies sparingly covered with hair, as in all the existing Pachydermata.



Anoplotherium commune.

The sub-genus *Xiphodon* differs from that just described in having the inferior molars tuberculous, and being without the additional or false hoof on the fore feet. It contains but a single species (*A. gracile*), which, judging from the length and smallness of its limbs, and the elevation of the tarsus, must have presented in every respect a complete contrast to the *A. commune*, exhibiting the light form and graceful proportions of the gazelle. Its course must necessarily have been rapid, and probably unembarrassed by a long tail; and, instead of resorting habitually to the rivers and ponds, like the former species, it must have been confined to the dry land, and, probably like the gazelles and antelopes, fed upon dry aromatic herbs, and was provided with long moveable ears to warn it of the approach of danger.



Anoplotherium gracile.

The third sub-genus, *Dichobunes*, contains three species, all established from the observation of detached bones, and of the actual forms of which it is consequently impossible to give a correct idea. They differed from the species contained in the two former subdivisions, principally by having a small additional or false hoof both on the fore- and hind-feet; and this character is so well marked in all the sub-genera of M. Cuvier, that, besides other considerations, it would suffice, among existing animals, to distinguish three separate genera, and perhaps should do so in the present instance. The *Dichobunes* were all of small stature: the largest of the three known species (*A. leporinum*) was about the size of a hare; the other two (*A. murinum* and *A. obliquum*) about that of the guinea-pig, were in all probability the smallest of hoofed quadrupeds. M. Cuvier supposes them to have been the hares and rabbits of the preadamite world, but their whole structure seems to approximate them more correctly to the musks of the present time, and they probably differed little from these animals either in form or habits. Another species of this genus was discovered by Mr. Pratt, in the Eocene deposits at Brinstead in the Isle of Wight, and has been described by Professor Owen under the name of *D. cervinum*.

(Cuvier, *Ossemens Fossiles*; Owen, *British Fossil Mammals.*)

ANOPLURA, a family of Insects, including the *Aptera* of Linnæus, and the various forms of *Pediculus* [PEDICULUS] and Parasitic Insects of other authors. The researches which were commenced on this family by Dr. Leach have been carried on by Mr. Denny, and resulted in the discovery of a vast number of new forms. The result is that it has been found that every animal is infested with, or, for some wise purpose is accompanied by, one or more creatures belonging to this family, having a peculiar form in each species. Nearly 500 different forms of these curious insects, all formed on the type of the common human louse, have been described by Mr. Denny, in the catalogue of the specimens which at present exist in the British Museum. In most cases but one species of the parasite exist on one species of animal, but there are instances, as in the eagles and gulls, in which a species of the bird is attacked by five species of *Anoplura*. The best series of illustrations of these insects which exist are contained in Denny's 'Anoplura Britannica,' published in 1842.

ANORTHITE, a mineral found at Monte Somma, and, according to the analysis of Rose, containing:—

Silica	44·9
Alumina	34·46
Lime	15·68
Magnesia	5·25
Oxide of Iron	0·74

It occurs crystallised, and has the primary form of a doubly oblique prism. The colour and streak are white. The lustre is vitreous, inclining to pearly on the cleavage surfaces. It is translucent and transparent. The specific gravity is 2·65.

ANSER, the Goose, a genus of birds which M. Brisson separated from the genus *Anas* of Linnæus. Brisson has been followed in this by Baron Cuvier, Vieillot, Lesson, Drapiez, and Fleming; while Latham adheres to Linnæus, and Temminck confines *Anser* to a section of *Anas*. [GOOSE.]

ANT (*Formica*), a well-known genus of insects, which has attracted attention from the earliest ages, on account of the singular economy and extraordinary industry manifested by the different species. In the present article we shall confine ourselves to a brief but methodical outline of their natural history. In tracing the history of most insects, it is best, perhaps, to begin with the eggs; but in the case of the ant, the laying and hatching of the eggs could not be well understood without an acquaintance with their singular manner of pairing, with which, therefore, we shall begin.

Pairing of Ants.—It may be necessary to premise here, that, similar to bees, a community of ants, whatever the species may be, consists of males, which have always four wings; of females, much larger in size than the males, which only possess wings during the pairing season; and of a sort of barren females, which have been variously termed neuters, workers, or nurse-ants, and which, so far as we know, have never been observed to have wings in any stage of their existence.

If an ant-hill be examined any time after midsummer up to the close of autumn, there may be seen, mixed with the wingless workers, a number of both males and females furnished with white glistening wings. These however are neither kings nor queens in the state, at least so far as freedom of action is concerned, for they are not allowed to move without a guard of workers to prevent their leaving the boundaries, and if one straggles away unawares, it is for the most part dragged back by the vigilant sentinels, three or four of whom may, in such cases, be seen hauling along a single deserter by the wings and limbs. The workers, so far from ever facilitating the exit, much less the departure of the winged ones, more particularly the females, guard them most assiduously in order to prevent it; and are only forced to acquiesce in it when the winged ones become too numerous either to be guarded or fed. There seems indeed to be a uniform disposition in the winged ones to desert their native colony: and as they never return after pairing, it would soon become depopulated in the absence of females. The actual pairing does not seem to take place within the ant-hill, and we have observed scouts posted all around, ready to discover and carry back to the colony as many fertile females as they could meet with. Nay, we are quite certain that whole colonies have been thus dispersed; and when they did not find fertile females near their encampment, they have gone farther and farther till they found them, and, if they had gone very far, never returned, but commenced a number of new establishments, according to their convenience. It is probable that, soon after pairing, the males die, as do the males of bees and other insects; for, as the workers never bring any of them back, nor take any notice of them after leaving the ant-hill, they must perish, being entirely defenceless, and destitute both of a sting and of mandibles to provide for their subsistence. The subsequent proceedings of the females are very different, and of curious interest. It was supposed by the ancients that all ants, at a certain age, acquired wings; but it was reserved for the younger Huber, in particular, by means of his artificial formicaries, to trace the development of the wings in the female from the first commencement, till he saw them stripped off and laid aside like cast clothes.

This curious process, which was first hinted at by Gould in his interesting account of 'English Ants,' we have repeatedly witnessed—the females extending their wings, bringing them over their heads, crossing them in every direction, and throwing them from side to side, till at length they are disjointed from the body and fall off.

Foundation of Colonies.—Some of the females are, after pairing, usually captured by the working ants, and conducted back to the parent community; and others are laid hold of by straggling parties of from two to a dozen workers, who do not return to the parent community, but commence small colonies on their own account. This explains the common occurrence of a great number of small colonies being formed in the immediate vicinity of each other, while sometimes the parent community is thereby quite broken up, and the hill deserted. This happens frequently in the case of the Red Ant (*Myrmica rubra*) and the Ash-Coloured Ant (*Formica fusca*), both very common species in fields and gardens. In the case of the Yellow Ant (*F. flava*) again, and the Wood-Ant (*F. rufa*), this rarely occurs, the parent community often remaining in the same spot for years together.

When a female, after pairing, does not chance to fall in with any scouting parties of workers, she proceeds without their assistance to found a colony herself in the same manner as is always done by the females of the social wasps and humble-bees every spring. We have repeatedly verified this fact, both by confining a single female after pairing, and witnessing her proceedings, and by discovering in the fields single females occupied in laying the foundations of a future city for their progeny. We have met with these single females when they have just begun to form the first cell for the reception of their eggs; when the eggs have just been laid; when the eggs have been hatched; and also when a few workers had been reared to assist in the common labours.

Contrary to what takes place in most insects, the eggs of ants are not, when laid, glued to any fixed place, but are found in parcels of half a dozen or more loosely attached, so that they can be removed at pleasure during the hatching. It has been shown in the 'Penny Magazine' (vol. i., p. 60), by a series of minute observations, that the female earwig moves her eggs with the utmost care from a place which she judges too dry, to one which is sufficiently moist; and in the same way the female ant, when she founds a colony without assistance, or the nurse-ants in a community, change the situation of the eggs according to the state of the weather or of the day and night—a circumstance first observed by Dr. King in the reign of King Charles II. Heat being indispensable to their successful hatching, the eggs are carefully placed during the day near the surface of the ant-hill, but so sheltered from the direct influence of the sun as to prevent the too rapid evaporation of their moisture. During the night, or in cold weather, the eggs are not placed so high, to prevent the escape of the heat which they naturally possess. The attention to the state of temperature occupies much of the assiduity of the female and the nurse-ants.

When the eggs are at length hatched (and during this process we have already seen that they enlarge in size), the young grubs are similarly treated with respect to temperature, but greater care is now taken to preserve them from too great heat, which might prove more injurious than before hatching.

The grubs are fed by the nurse-ants when any of these are in the colony, and by the mother when she is alone, by a liquid disgorged from the stomach, as is done in a similar way by wasps, humble-bees, pigeons, and canary birds. It consequently requires no little industry on the part of a solitary female to procure for herself sufficient food to supply nutriment for a brood of perhaps a dozen or twenty grubs, which are insatiably voracious.

When the grubs are full grown they spin for themselves cocoons of a membranous texture, and of a brownish-white colour, not unlike barleycorns in appearance, and indeed mistaken for these by early observers—a mistake which led to the unfounded notion that ants store up corn for winter provision, though, from their always becoming torpid in the winter, they could have no need of this; and even were this not so, they never feed on corn, and would probably starve rather than taste it. The authority of Scripture, which has been supposed to countenance the popular notion, is shown by the Rev. Dr. Harris, Messrs. Kirby and Spence, and others, to have no foundation in the sacred text.

The cocoons are treated precisely like the eggs and the grubs with regard to exposure to heat; and the anxiety of the nurse-ants to shelter them from the direct rays of the sun is taken advantage of on the Continent to collect the cocoons (popularly and erroneously called ants'-eggs) in quantity as food for nightingales and larks. The cocoons of the Wood-Ant are the only species chosen; and in most of the towns in Germany one or more individuals make a living during summer by the business.

In the case of moths, ichneumons, and other insects which spin themselves up in cocoons, the included insect, when the time of its change arrives, is enabled to make its own way through the envelope; but though it would appear, from some observations made by Swammerdam, that ants may, when forced thereto, effect their own disengagement, this is not the usual process. It is the nurse-ants that cut a passage for them with their mandibles, as was first minutely described by Baron de Geer and the younger Huber.

Labours of the Working Ants.—We have already seen that workers or nurse-ants have to labour assiduously in placing the eggs, the grubs, and the cocoons in due degrees of temperature; that they have to feed the grubs by a liquid disgorged from the stomach, and have to disengage the insect at its period of change from the envelope of the cocoon. They have also to perform the task of forming streets, galleries, and chambers for the habitation and protection of the colony, and they exhibit in the work such perseverance and skill as must excite the admiration of every observer. Many of their processes, indeed, it is not a little difficult to account for and explain, though these have been very carefully investigated, particularly by the younger Huber, in whose work, and in the 'Library of Entertaining Knowledge—Insect Architecture' (p. 254 *et seq.*), may be found copious details of the mining, masonry, and carpentry of various species. We shall here give an instance of each of those operations.

Mining.—There is an interesting species called the Sanguinary Ant (*F. sanguinaria*, Latreille), reported to have been seen near London, but which is certainly very rare, if it is found in England. In the summer of 1832 we discovered several colonies of this ant on the brow of the heath above Godesberg, on the Rhine; and being desirous of taking a number of them alive to England for the purpose of observing their singular manners, we waited till the beginning of October, when they had ceased to work, and had retired for the winter to their galleries underground. After uncovering the thick coping of dry heath-twigs and grass-stems which was placed over the subterranean city of the colony so as to defend it from rain and cold, we found several covert-ways dug into the clay, wide enough to allow two or three ants to walk abreast; but not an individual now made its appearance, though some weeks previously we had observed thousands in all the bustle of industry; and we began to fear the whole had migrated elsewhere. Being anxious, however, to see the interior structure, we dug in the direction of the covert-ways to the depth of about six or nine inches, when we came upon a number of chambers communicating with each other by galleries, and from an inch to two or three inches in extent, in each of which a number of ants were lying along the floor in a half torpid state, being so sluggish that they could not be brought to run with their usual agility even when irritated.

The point which we wish to call attention to here is, that the whole of the apartments which we laid open, amounting to a dozen or more —and there were probably as many more to which we did not penetrate—must have been dug out of the solid clay by the jaws (*mandibula*) of these little miners. We deemed it singular that we could see none of the rubbish lying about, which must have been cleared away from the interior; and we can only account for this by supposing the colony long established, and the rubbish battered into the grass by the weather.

In other instances of mining, such as in the case of the Turf-Ant (*F. cæspitum*), the clay taken from the interior is built up on the outside, using the herbage for buttresses to support the walls thus formed. In the case of the Sanguinary Ants, however, we observed nothing of this kind, and do not think they ever employ any exterior masonry.

Masonry.—The most common of our English ants which employ masonry is the Yellow Ant (*F. flava*), whose hills are so usually found built up in old pastures, a foot or more in height, and from 6 inches to 2 feet in diameter. For the materials of their building they are wholly indebted to the soil below, which they quarry out with great assiduity; but as they have no means of tempering the clay when it is dry, they are always forced to execute their principal works in rainy weather. "I was," says Dr. J. R. Johnson, "in the habit of visiting, almost daily, for a month, an extensive nest of Red Ants, of which a large flat stone formed the roof. During my visits for the first three weeks, scarcely a drop of rain had fallen, and the nest seemed considerably injured by the continual falling in of loose earth, which these little creatures with amazing industry removed, whenever it happened any of the avenues were blocked up. No attempt was ever made towards reparation; but what was my surprise, on visiting my little friends after a two days' heavy rain, to find that the repairs were already completed, and that the upper surface of their habitation presented as smooth a surface as if a trowel had been passed over it; yet all their work they had industriously effected by kneading with the rain-water the loose earth into a sort of paste. From the nest being situated in the midst of an extensive heath, where there could be no supply of water, and from its remaining unrepaired during the dry weather, it amounts to a full conviction that ants employ no other cement than water in the construction of their varied habitations.

"I have often been surprised at the ingenuity of these little creatures, in availing themselves of contiguous blades of grass, stalks of corn, &c., when they wish to enlarge the boundaries of their abode. As these are usually met with in the erect position, they are admirably calculated for pillars; they therefore coat them over with a fine paste of earth, giving them, by additional layers, the solidity they judge necessary for the work on which they are engaged; they then leave them to be consolidated by the wind, and afterwards spring a number of arches, from pillar to pillar, and thus form an extensive saloon. Should they be at any time in want of small apartments, they have only to prepare a quantity of moistened earth, and by placing this between the pillars, and carrying it up to the roof, leaving here and there an aperture for entrance, their object is completely attained."

It is remarkable that the greater part of these masonic labours are performed during the night, or at least in gloomy weather.

Carpentry.—The coping which we have already described as placed over the subterranean abode of the Sanguinary Ants, and which is still more remarkable in the colonies of the Wood-Ant (*F. rufa*), cannot be referred to any sort of carpentry, for the small sticks and straws of which it is composed are not cut into fitting lengths, but collected in the vicinity of the hill and laid on it after the manner of thatch. The term carpentry, however, will apply most justly to those species which form excavations in the interior of trees, of which the following is an instance observed in 1832.

We had brought into our garden in the beginning of June, a large piece of a willow tree, which had been very curiously worked out by the species usually called the Emmet (*F. fuliginosa*, Latreille). The tree indeed from which it had been taken, appeared to have been destroyed in a great measure from the extensive excavations of these little carpenters. Yet the portion of the tree alluded to seemed to be singularly strong, when the great number of the cells and their peculiar structure was taken into consideration. The walls of these cells were literally as thin as writing-paper, though not quite so smooth and even, and they were seldom quite parallel, but arranged, some perpendicularly, and others slanting in various directions, worked out, it would appear, upon no previous design, but beginning at any given point, and only limited in extent by the worker discovering his approach to one adjacent. The tact with which they chisel away the wood with their jaws, so as to come so near the next cell without actually cutting into it, cannot well be accounted for on any of the common principles of human mechanism. It cannot be the result of vision, from the worker-out looking along the level of the plane, as one of our carpenters would do, and thence working so as not to cut through it; for the wall has, in most instances, though not in all, no free edge along which such a level could be taken by the eye. Hearing might assist them however, supposing workers to be engaged in chiselling on each side of the partition, but it would appear to be more from touch, or rather that modification of it denominated tact, which enables them to feel, as it were, when they have nearly penetrated the wall, and which consequently warns them to stop.

It is not a little remarkable, that all the wood which is worked out by these ants is tinged of a black colour, giving all their streets and lanes somewhat the appearance of having suffered from fire or of being smoked. M. Huber the younger did not succeed in ascertaining the cause of this black colour. We should conjecture it to arise from iron contained in the saliva of the ants acting on the gallic acid of the wood, in a similar way as the same wood becomes black when cut with a knife. The fine glossy black of the ants themselves may originate from the same chemical principle, and this is rendered more probable from the excavations made by other species, such as the Dusky Ant (*F. fusca*, Latreille), not being tinged with this black colour. Neither are the excavations of the latter so regular in the form of the cells; and the delicately thin partitions do not occur. We have seen several colonies of the Yellow Ant (*F. flava*, Latreille) established in trees, though their usual habits lead them to prefer a hedge-bank, the dry ridge of a field, or a small knoll on a common. In none of these however had the workers much trouble in making their excavations, the trees being in every instance far gone with the dry rot, and the chambers were consequently as easy to construct as in a knoll of sand. In the instance of the Black Carpenter-Ant (*F. fuliginosa*), on the other hand, the wood of the tree selected for their colony is always hard and tough, the easiness of working it being apparently considered a disadvantage rather than a recommendation. We have usually seen these colonies, therefore, in growing trees, the oak seeming to be preferred to all others; the honeycomb-like work does not seem to stop the vegetation, the tree continuing to put forth leaves and shoots as before it was excavated for the use of the colony. In the instance which gives rise to these remarks, the willow tree was indeed dilapidated and shorn of its leaves and branches, yet was it untouched with dry rot, and the wood was hard and tough.

Food of Ants.—Some species of ants are carnivorous and will eat insects, fruits, and almost anything eaten by other animals; but honey is the most universal favourite among all the species, particularly the excretion of the various species of Aphides, called Honey-Dew. It is on this account that, wherever Aphides abound, we are always certain to meet with ants carefully attending their motions and greedily drinking the honey-dew, which becomes so injurious to plants when it increases in quantity so as to obstruct the pores of the leaves. It is stated by Huber and some other authors, that during winter the ants imprison some Aphides in their cells, or, at all events, take advantage of individuals of the Grass Aphis (*Aphis graminum*) in the vicinity of their hills to obtain honey-dew. We strongly suspect there must be some fallacy in this statement; for among numerous colonies which we have carefully examined during winter, we always found the whole population torpid or nearly so, and not inclined to touch even honey when we offered it to them. In the case of the Sanguinary Ants in Germany already mentioned, we have seen that they had become torpid as early as October, when the weather was still fine and far from being cold. We are therefore of opinion that the statement will be found as void of accurate foundation as that which represents ants as storing up corn for the winter.

Migrations.—We have already seen, under the head of pairing, one principle in operation for spreading around a parent ant-hill a number of young colonies. This indeed may be considered the main principle of migration; but besides this, the whole of a populous ant-hill which has been established for several years will, from some cause beyond our means of tracing, though most probably on account of more convenient forage, at once desert their homes and march to a new station. Among the Yellow Ants, the Emmets, and the Wood Ants or Pismires, this is by no means common; but it is an every-day occurrence among the Red Ants, the Ash-Coloured Ants, the Turf-Ants, and others whose colonies never become very populous, and are consequently both more easily moved and more easily provided with lodging.

"Immense swarms of ants," to use the words of Dr. Roget, "are occasionally met with, and some have been recorded of such prodigious density and magnitude as to darken the air like a thick cloud, and to cover the ground to a considerable extent where they settled." Mr. Gleditsch describes, in the 'History of the Berlin Academy,' for 1749, shoals of a small black ant which appeared in Germany, and formed high columns in the air, rising to a vast height, and agitated with a curious intestine motion, somewhat resembling the aurora borealis. A similar flight of ants is spoken of by Mr. Acolutte, a clergyman of Breslau, which resembled columns of smoke, and which fell on the churches and the tops of the houses, where the ants could be gathered by handfuls. In the German 'Ephemerides,' Dr. Charles Rayger gives an account of a large swarm which crossed over the town of Posen, and was directing its course towards the Danube. The whole town was strewed with ants, so that it was impossible to walk without trampling on 30 or 40 at every step. And Mr. Dorthes, in the 'Journal de Physique' for 1790, relates the appearance of a similar phenomenon at Montpellier. The shoals moved about in different directions, having a singular intestine motion in each column, and also a general motion of rotation. About sunset all fell to the ground, and, on examining the ants, they were found to belong to the *Formica nigra* of Linnaeus.

Wars and Expeditions to capture Slaves.—In the same way as the bees and the wasps of different hives manifest inveterate hostility when they meet, ants also of the same or of different species assail one another when they meet during their foraging excursions. Besides the individual skirmishes which thence occasionally arise, pitched battles are sometimes fought between the whole or nearly the whole force of populous adjacent colonies. We have never ourselves witnessed any very extensives battles of this kind, such as Huber describes, in which thousands of combatants were engaged, but we have seen as many as 50 of the Wood-Ants fighting most pertinaciously within the area of a few inches on what were supposed to be the boundaries of their several territories. Their bite is so sharp, and the acrid [illegible] which they infuse is so deleterious, that many are thus disabled or killed outright. Huber witnessed on such occasions very extensive carnage.

Besides these skirmishes and battles which occur among all the species, there are whole communities of warrior-ants, as was first discovered by Huber, whose history is so extraordinary as almost to exceed belief. The details indeed have hitherto been credited chiefly, if not solely, on the well-known veracity of Huber; but in the autumn of 1832 we had an opportunity of verifying them both in the Black Forest and in Switzerland, with respect to the species which he terms the Amazon Ant (*F. rufescens*, Latreille), and on the Rhine with respect to the Sanguinary Ant.

Both of these species make war on the ants of a different species from themselves, particularly the Dusky Ant (*F. fusca*), not for the purpose merely of gratifying a propensity to combat, but to make slaves of the vanquished to do the drudgery of the conquerors at home. The manner in which they proceed in this affair manifests, so far as we can judge, deep design, such as might be ascribed to the counsels of a cunning diplomatist. They do not capture the adult ants and carry them into slavery, but make booty of the eggs and cocoons, which, after the contest is decided—and the warriors are always conquerors—are carried off to the Amazonian citadel, and being hatched there, the poor slaves are most probably not aware but that it is their native colony. Huber repeatedly witnessed such expeditions for the purpose of capturing slaves; but though we were not so fortunate, we witnessed, in a great number of instances, the slaves at work for their warlike captors.

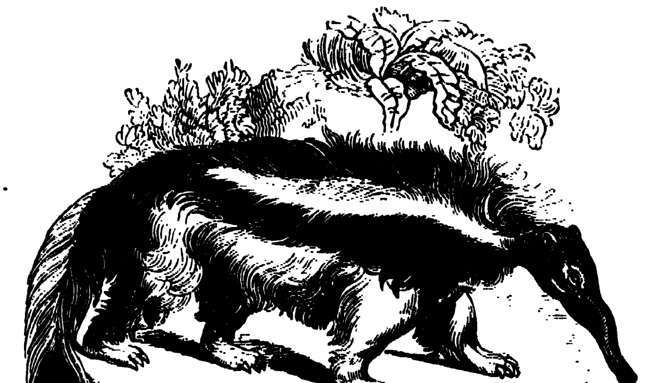
The Amazons have not hitherto been found in Britain, and we were unsuccessful in our attempt to bring over from the Black Forest a nest of live ones with their slaves which we had placed in a box for the purpose.

ANT-BEAR, the name commonly given to the *Myrmecophaga jubata* by the English at Demerara. [ANT-EATER.]

ANT-EATER (*Myrmecophaga*, Linnæus), a genus of *Edentata*, distinguished by their total want of teeth and their hairy covering. The latter circumstance separates them from the Pangolins (*Manis*), or Scaly Ant-Eaters of Africa and Asia, which they resemble closely in other respects, as well in their general anatomy as in their food and habits. These two genera form a small but very distinct family of Cuvier's order *Edentata*, differing from the common animals comprised in that singular group, as well as from all other known mammalia, by their entire deprivation of the organs of mastication, and acquiring an additional interest by the light which their osteological conformations throws upon the structure and organisation of the *Megatherium*, *Megalonyx*, and *Mylodon*, those extraordinary animals whose fossil remains have attracted so much of the attention, not only of the professed naturalist, but likewise of the public at large. The osteology of the skulls and trunks of these extinct animals presents the closest analogies with that of the corresponding parts in the Sloths; so the whole construction of their extremities appears to have been formed after the same model as that of the corresponding organs of the Ant-Eaters. The head of these latter animals, indeed, is altogether different from that of the Sloths: not only does it want the organs of mastication, of which they are deficient only in the incisors, but the bones of the face, which in them are short and round like those of apes and monkeys, are prolonged in the Ant-Eaters, particularly in the Great Ant-Eater (*M. jubata*), to double the length of the skull. This singular conformation arises from the form of the maxillary or jaw-bones, and those of the nose, which form together a kind of long tube, very small in proportion to its length, and almost cylindrical. This prolongation of the muzzle is not carried to so great an extent in either of the other two known species of Ant-Eaters; but even there the construction here described differs only in degree, and presents, on a more contracted scale, all the characteristics of the *Myrmecophaga jubata*.

It is in the construction of the anterior extremities however that these animals offer the greatest singularities, and become most important in their relations to the fossil species. The phalanges or joints of the toes, particularly the last, which bear the claws, are formed in such a manner as to permit them to be bent inwards only, as in the Sloths; and for this purpose they are provided with very powerful ligaments, which keep them, in a state of repose, bent in along the sole of the foot, and never permit the hand to be completely opened, but only half extended, as we sometimes see in gouty or rheumatic people. The toes themselves are of very unequal size, and even differ in number in different species. The Great Ant-Bear and Tamandua have four on the anterior and five on the posterior extremities, whilst the smallest species, called, from that circumstance, *M. didactyla*, has only two on the fore feet and four on the hind. The toes themselves, as in the Sloths, are united closely together as far as the claws, and are consequently incapable of any separate or individual motion, but the disadvantages arising from this circumstance are more than counterbalanced by the increased strength which it produces, and the consequent adaptation of the organ to the peculiar purposes of these animals' economy. The claws are all large and powerful, especially that of the middle toe, of which the dimensions are quite enormous. Nor do the Ant-Eaters, in walking, tread flatly upon the sole of the foot like the generality of mammalia: on the contrary, they rest entirely upon its outer edge, which is provided with a large callous pad for that purpose, whilst their toes being bent inwards along the palms, the sharp points of their powerful claws are preserved from being injured by the friction of the hard ground. In other respects the Ant-Eaters are remarkable for their long cylindrical tongues, covered with a glutinous saliva, by means of which they entrap and devour the insects upon which they live, and from which they derive their names, both among naturalists and common observers—*Myrmecophaga* literally signifying Ant-Eater. This tongue is protractile, and capable of being extended to a surprising distance beyond the snout; it is nearly twice the length of the whole head and muzzle together, and when not extended is kept doubled up in the mouth with the point directed backwards. The eyes are particularly small, the ears short and round, the legs robust and amazingly powerful, but so unfavourably formed for locomotion, that the pace of these animals is almost as tardy as that of the sloths themselves, their greatest exertions not enabling them to surpass the ordinary walk of a man. The tail is always long: in the great species lax and thickly covered with very long flowing hair, in the other two, strongly prehensile, and naked underneath. These species consequently climb trees and reside principally among their branches, feeding upon the wild bees and termites which inhabit the same situations. The Great Ant-Bear, on the contrary, never quits the surface of the earth, and confines its depredations entirely to the numerous species of large ants which inhabit its native regions, and furnish him at all times with an abundant and easily-procured nutriment. The whole genus is confined to South America, and contains three distinct and well-defined species.

1. The Great Ant-Eater (*M. jubata*, Linn.), called Tamandua by the Portuguese, and Ant-Bear by the English and Spaniards, is a large animal which measures, when full grown, four feet and a half from the extremity of the snout to the origin of the tail. The tail itself is 3 feet 3 inches in length, reckoning to the extremity of the hair, or measured only along the stump, 2 feet 4 inches; the head, 13½ inches from the snout to the base of the ear, and 10¼ inches to the anterior angle of the eye; its circumference immediately before the eyes, where it is the thickest, is 14 inches, but from this part it gradually diminishes to the end of the muzzle, where it measures only 5¼ inches. The height of the animal at the shoulder is 3 feet 3 inches, and at the croup only 2 feet 10 inches, because, being perfectly plantigrade, it necessarily stands lower on the hind legs than before, as may be observed in the common bear, the badger, and other species which partake of the plantigrade formation of the extremities. The ear is short and round, being an inch and a quarter broad at the base, and only an inch in length; the eye is remarkably small, deeply sunk in the head, and with a naked eyelid; the head and snout, as already observed, are prolonged to a remarkable degree; they are in form almost cylindrical, and end in a small truncated muzzle, having



Great Ant-Eater (*M. jubata*).

the nostrils and mouth placed at its extreme end; the latter is so small that its whole width scarcely exceeds an inch, and the jaws are of equal length. The tongue is almost cylindrical, fleshy, extremely flexible, and capable of being protruded to the distance of 16 or 18 inches. The toes of the anterior extremities, four in number, are of unequal length, the innermost being the smallest and weakest of all; the second measures 2½ inches in length, and is provided with a powerful crooked claw nearly 2 inches long, sharp-pointed, and trenchant on its under surface; the third, which is the largest of all, has a similar claw 2½ inches in length; and the fourth, or exterior toe, is provided with a smaller and weaker claw, like that of the innermost. All these claws, when in a state of repose, are kept bent inwards, and only extended, or rather half-extended (for the animal cannot open the fingers farther), when used for defence, or for breaking through the hard external crust of the ant-hills.

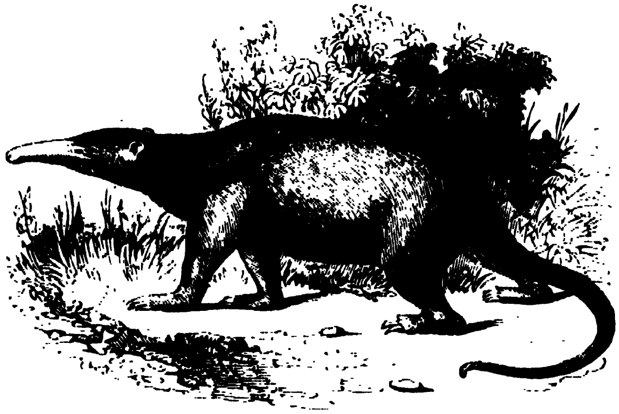
The prevailing colour on the head, face, and cheeks of the Ant-Bear is a mixture of gray and brown; that on the upper parts of the body and tail is a deep brown, mixed with silvery-white. A broad black band, bordered on each side with a similar one of a white or light grayish-brown colour, commences on the chest, and passes obliquely over each shoulder, diminishing gradually as it approaches the loins, where it ends in a point. The sides, arms, and thighs are silvery-gray, with a slight mixture of brown, marked with two deep black spots, one on the carpus, and the other on the toes; the hind-legs are almost perfectly black, and the breast and belly of a deep brown, almost equally obscure.

The habits of the Great Ant-Bear are slothful and solitary; the greater part of his life is consumed in sleeping, notwithstanding which he is never fat, and rarely even in good condition. When about to sleep, he lies upon one side, conceals his long snout in the fur of the breast, locks the hind and fore claws into one another, so as to cover the head and belly, and turns his long bushy tail over the whole body in such a manner as to protect it from the too powerful rays of the sun. The female bears but a single young one at a birth, which attaches itself to her back, and is carried about with her wherever she goes, rarely quitting her, even for a year after it has acquired sufficient strength to walk and provide for itself. This unprolific constitution, and the tardy growth of the young, account for the comparative rarity of these animals, which are said to be seldom seen, even in their native regions. The female has only two mammæ, situated on the breast, like those of apes, monkeys, and bats.

In its natural state the Ant-Bear lives exclusively upon ants, to procure which it opens their hills with its powerful crooked claws, and at the moment that the insects, according to their nature, flock from all quarters to defend their dwellings, draws over them his long flexible tongue, covered with glutinous saliva, to which they consequently adhere; and so quickly does he repeat this operation, that we are assured he will thus project his tongue and draw it in again covered with insects twice in a second. He never actually introduces it into the holes or breaches which he makes in the hills themselves, but only draws it lightly over the swarms of insects which issue forth alarmed by his attack. "It seems almost incredible," says Azara, "that so robust and powerful an animal can procure sufficient sustenance from ants alone; but this circumstance has nothing strange in it for those who are acquainted with the tropical parts of America, and who have seen the enormous multitudes of these insects, which swarm in all parts of the country, to that degree that their hills often almost touch one another for miles together." The same author informs us, that domestic Ant-Bears were occasionally kept by different persons in Paraguay, and that they had even been sent alive to Spain, being fed upon bread and milk, mixed with morsels of flesh minced very small. Like all animals which live upon insects, they are capable of sustaining a total deprivation of nourishment for an almost incredible time.

The Great Ant-Bear is found in all the warm and tropical parts of South America, from Colombia to Paraguay, and from the shores of the Atlantic to the foot of the Andes. His favourite resorts are the low swampy savannahs, along the banks of rivers and stagnant ponds, also frequenting the humid forests, but never climbing trees, as falsely reported by Buffon, on the authority of Laborde. His pace is slow, heavy, and vacillating; his head is carried low, as if he smelled the ground at every step, whilst his long shaggy tail, drooping behind him, sweeps the ground on either side, and readily indicates his path to the hunter; though, when hard pressed, he increases his pace to a kind of slow gallop, yet his greatest velocity never half equals the ordinary running of a man. So great is his stupidity, that those who encounter him in the woods or plains may drive him before them by merely pushing him with a stick, so long at least as he is not compelled to proceed beyond a moderate gallop; but if pressed too hard, or urged to extremity, he turns obstinate, sits up on his hind-quarters like a bear, and defends himself with his powerful claws. Like that animal, his usual and indeed only mode of assault is by seizing his adversary with his fore-paws, wrapping his arms round him, and endeavouring by this means to squeeze him to death. His great strength and powerful muscles would easily enable him to accomplish his purpose in this respect, even against the largest animals of his native forests, were it but guided by ordinary intelligence, or accompanied with a common degree of activity. But in these qualities there are few animals indeed which do not greatly surpass the Ant-Bear; so that the different stories handed down by writers on natural history from one another, and copied, without question, into the histories and descriptions of this animal, may be regarded as pure fictions. For this statement we have the express authority of Don Felix d'Azara, an excellent observer and credible writer, from whose 'Natural History of the Quadrupeds of Paraguay' we have derived the greater portion of the preceding account of the habits and economy of this extraordinary animal. The flesh of the Ant-Eater is esteemed a delicacy by the Indians and negro slaves, and, though black, and of a strong musky flavour, is sometimes even met with at the tables of Europeans.

2. The Tamandua (*M. Tamandua*, Cuvier), is an animal much inferior to the Great Ant-Bear in point of size, being scarcely so large as a good-sized cat, whilst the other exceeds the largest greyhound in length, though, from the shortness of its legs, it is much inferior in height. The head of the Tamandua is not so disproportionately long and small as that of the Great Ant-Bear. It is however of the same general cylindrical form, and equally truncated at the extremity, having the nostrils and mouth situated in the same position, and equally minute, when compared with the size of the animal. Its whole length, from the extremity of the muzzle to the root of the ear, is 5 inches, and to the anterior angle of the eye, 3 inches; the body, from the muzzle to the origin of the tail, measures 2 feet 2 inches, the tail itself being 1 foot 4½ inches more; the height at the shoulder is 1 foot 3 inches, and at the croup an inch lower; the length of the ear is 1¼ inch, its greatest breadth an inch, and the greatest circumference of the head—that, namely, taken immediately in front of the ears—8¼ inches. The conformation of the extremities, and the number of the toes both before and behind, are in every respect the same as in the Great Ant-Eater; but the Tamandua differs from this animal particularly in the prehensile power of its tail, which makes it essentially an arboreal quadruped, and altogether changes the most striking traits of its habits and economy. The hair over the entire body also is of a very different texture; instead of being long, harsh, and shaggy, as in the Great Ant-Bear, it is short, shining, and of a consistence something between the qualities of silk and wool; standing out from the body like the latter, and of the same uniform length in every part. The colours of this species, however, are by no means so uniform and invariable as those of the species already described; on the contrary, they differ more in the Tamandua, according to the individual, than perhaps in any other known animal in a state of nature. Accordingly many eminent naturalists are disposed to consider them as forming distinct species, rather than mere varieties of the same; and it is not improbable that, when we come to be better acquainted with this animal in its native woods, their opinion may be at least partly confirmed.



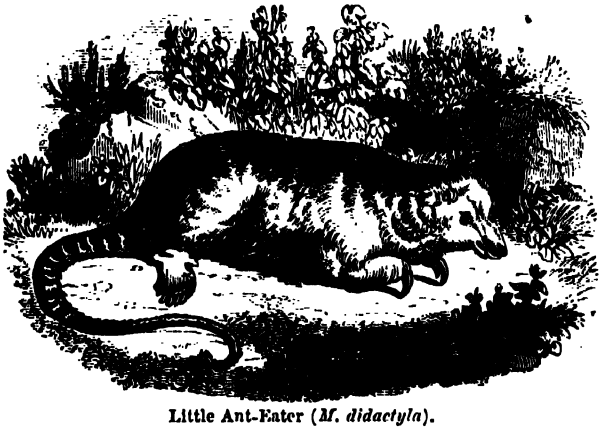
Tamandua (*M. Tamandua*).

The eyes of the Tamandua are minute; the ears small and round; the body long and cylindrical; the legs short and robust; the tail round and attenuated, covered with very short hair throughout its greater part, but naked underneath towards the point, and strongly prehensile. There are several varieties of the Tamandua, chiefly distinguished by differences of colour.

The Tamandua is an inhabitant of the thick primeval forests of tropical America; it is never found on the ground, but resides exclusively in trees, where it lives upon termites, honey, and even, according to the report of Azara, bees, which in those countries form their hives among the loftiest branches of the forest, and, having no sting, are more readily despoiled of their honey than their congeners of our own climate. When about to sleep it hides its muzzle in the fur of its breast, falls on its belly, and letting its fore-feet hang down on each side, wraps the whole tightly round with its tail. The female, as in the case of the Great Ant-Eater, has but two pectoral mammæ, and produces but a single cub at a birth, which she carries about with her, on her shoulders, for the first three or four months. The young are at first exceedingly deformed and ugly, and of a uniform straw-colour.

This animal has a strong disagreeable odour, which is so powerful that it may be perceived at a very great distance, particularly when the animal is irritated. Tamandua is the name by which it is known to the Portuguese of Brazil; the French call it Fourmillier and the English the Little Ant-Bear.

3. The Little or Two-Toed Ant-Eater (*M. didactyla*, Linn.) is easily distinguished from the other two species, not only by its size, which does not exceed that of the common European squirrel, but likewise by the number of its toes, four on the posterior and only two on the anterior extremities. The form and general proportions of its body resemble those of the Tamandua, only on a very reduced scale. Its whole length, from the snout to the origin of the tail, is but 6 inc[illegible], that of the head not quite 2 inches, and of the tail 7¼ inches. This organ is consequently rather longer than the body; it is thick at the root, and covered with short fur, but tapers suddenly towards the point, where it is naked and strongly prehensile. The muzzle is not so long, in proportion, as in the other two species; the tongue also is shorter, and has a flatter form; the mouth opens farther back in the jaws, and has a much larger gape, the eye being situated close to its posterior angle; the ears are short, rather drooping, and concealed among the long fur which covers the head and cheeks; the legs are short and stout, and the hair very fine and soft to the touch, three-quarters of an inch in length on the body, but much shorter on the head, legs, and tail. The general colour is that of straw, more or less tinged with maroon on the shoulders, and particularly along the median line of the back, which usually exhibits a deep line of this shade. This species is said to have four mammæ, two pectoral, as in those already described, and two others on the abdomen. It is reported, nevertheless, to have but a single cub at a birth, which it conceals in the hollow of some decayed tree. The native countries of the Little Ant-Eater are Guyana and Brazil, beyond which it appears not to extend farther towards the south, since Azara is not only unacquainted with it, but imagines from Buffon's and Daubenton's descriptions that it must be the young of his Tamandua. The habits and manners of this little animal are thus described by Von Sack, in his 'Narrative of a Voyage to Surinam':—



Little Ant-Eater (*M. didactyla*).

"I have had," says he, "two Little Ant-Eaters or Fourmilliers, which were not larger than a squirrel: one was of a bright yellow colour, with a brown stripe on the back; the other was a silvery-gray and darker on the back; the hair of each was very soft and silky, a little crisped; the head was small and round, the nose long, gradually bending downwards to a point; it had no teeth, but a very long round tongue; the eyes were very small, round, and black; the legs rather short; the fore-feet had only two claws on each, the exterior being much larger and stronger than the interior, which exactly filled the curve or hollow of the large one; the hind-feet had four claws of a moderate size; the tail was prehensile, longer than the body, thick at the base and tapering to the end, which, for some inches on the under side, was bare. This little animal in Surinam is called Kissing-Hand, as the inhabitants pretend that it will never eat, at least when caught, but that it only licks its paws, in the same manner as the bear; that all trials to make it eat have proved in vain, and that it soon dies in confinement. When I got the first, I sent to the forest for a nest of ants, and, during the interim, I put into its cage some eggs, honey, milk, and meat; but it refused to touch any of them. At length the ants' nest arrived, but the animal did not pay the slightest attention to it either. By the shape of its fore-paws, which resemble nippers, and differ very much from those of all the other different species of ant-eaters, I thought that this little creature might perhaps live on the nymphæ of wasps, &c.; I therefore brought it a wasps' nest, and then it pulled out with its nippers the nymphæ from the nest, and began to eat them with the greatest eagerness, sitting in the posture of a squirrel. I showed this phenomenon to many of the inhabitants, who all assured me that it was the first time they had ever known that species of animal to take any nourishment. The ants with which I tried it were the large white termites, upon which fowls are fed here.

"As the natural history of this pretty little animal is not much known, I thought of trying if they would breed in a cage; but when I returned from my excursion into the country, I found them both dead, perhaps occasioned by the trouble given to procure the wasps' nests for them, though they are here very plentiful: wherefore I can give no further description of them than that they slept all the day long curled together, and fastened by their prehensile tails to one of the perches of the cage. When touched they erected themselves on their hind-legs, and struck with the fore-paws at the object which disturbed them, like the hammer of a clock striking the bell, with both paws at the same time, and with a great deal of strength. They never attempted to run away, but were always ready for defence, when attacked. As soon as evening came they awoke, and with the greatest activity walked on the wire of the cage, though they never jumped, nor did I ever hear their voice."

ANTAGONIST MUSCLE (from ἀντὶ, against, and ἀγωνίζομαι, to strive), a muscle the action of which is opposed to that of some other muscle. Muscles are the instruments by which, in the animal body, motion is effected. The object of each muscle is to produce some specific motion. Among the various motions which are needed in the animal economy, it necessarily happens that some are directly opposite to others, and the muscles which accomplish these directly opposite movements are said to be with relation to each other Antagonists.

ANTELOPE. [ANTILOPEÆ.]

ANTENNÆ, horn-like members placed on the head, and peculiar to Insects and Crustaceous Animals. Their functions are not well understood, and have given rise to several different opinions among naturalists. The term is derived from the Latin *ante*, 'before.' In insects they are uniformly two in number; but in crabs and lobsters there are more than two. They are connected with the head, always near the eyes, by means of a ball (*bulbus*) and socket (*torulus*). They are composed of minute cylinders or rings successively added to each other, to the number of 30 in some butterflies, and thus forming a tube which incloses nerves for sensation, muscles for moving, as well as air-pipes and cells.

The form of the antennæ is exceedingly various, some being simple and some feathered, clubbed, comb-shaped, in endless diversity. In moths, the female is distinguished from the male by the antennæ being more simple. In some moths and beetles the antennæ are very long compared with the length of the body, whereas in the house-fly, and some other two-winged flies, they are very short. Their length does not depend on the number of joints, for they may be long when composed of only three or four pieces, and short when composed of ten or more pieces.

With respect to the functions of the antennæ, it is the most common opinion, sanctioned by such authorities as Linnæus and Bergmann, that they are organs of touch, and are on that account often termed feelers; "but," as M. Straus-Dürckheim justly remarks, "this conjecture is founded upon facts imperfectly investigated, if not altogether false. I have made numerous researches on this subject, and I have never been able to satisfy myself that insects examine objects by feeling them with their antennæ. On the contrary, I have rarely observed these animals touch anything with these organs, and when this did happen, it appeared to be only by accident, and not at all from design. Many insects, besides, have their antennæ so short, that they would be obliged to stand erect upon their heads in order to come at the bodies which they might thus wish to explore, and for this their feet are certainly much better adapted.

"Since," continues M. Straus-Dürckheim, "almost all Articulated Animals possessing a solid skin (*peau*) have antennæ, which are furnished with nerves of an extraordinary thickness in proportion to their own size, there cannot remain a doubt that they are organs of some sense, and that too a very acute one.

"I have said that insects are proved, by observation, to be furnished with an organ of hearing. The solidity of the envelope of antennæ renders these organs well adapted to undergo the same vibrations as the air, in the same manner as the strings of an Æolian harp vibrate and emit various sounds according as they are differently struck by the air. In this view, however, we might infer that nature would have made antennæ in the form of rods, consisting of a single piece, in order that they might be more susceptible of vibrations; but it ought to be considered, that these organs would, by such a conformation, have been much exposed to breaking, while, in consequence of their jointed form, they have the advantage of regulating the degree of vibration at pleasure, as may indeed be observed when insects listen with attention; I mean, that the joints of the antennæ perform the same functions as the chain of small bones in the chamber of the human ear, inasmuch as they form a similar chain, and transmit the vibrations of the air to the auditory pulp."

Professor Bonsdorff of Abo in Finland, and other naturalists, though opposed to the views of Linnæus and Bergmann, have adopted the same opinion, and regard the antennæ as organs of hearing.

There is one other subject connected with the antennæ which requires notice. The younger Huber has attributed to ants the use of certain signs made with these organs, which he terms 'antennal language,' understood not only among ants themselves, but also among the aphides, on which they depend for the excretion popularly termed honey-dew. The motions of the antennæ, however, to which he refers in proof of his views, do not, so far as we can judge, authorise us to conclude that they are used in the way of language, any more than to theorise in the same way upon the bills of nestling birds which are opened to receive food, or their wings which are opened and vibrated rapidly while they receive it. That there is nothing peculiar in this alleged antennal language, so far as the aphides are concerned, any one who chooses may prove by taking a pin or a camel-hair pencil and gently touching the aphis, when it will eject the honey-dew as readily as in consequence of being touched with the antennæ of an ant. This we deem to be quite fatal to M. Huber's conclusions.

(*Insect Miscellanies*, vol. iv., in the *Library of Entertaining Knowledge.*)

ANTENNULARIA, a genus of Sertularian Zoophytes. [SERTULARIADÆ.]

A'NTHEMIS is the genus of plants which includes the useful herb Chamomile. It belongs to the order *Compositæ*, and is distinguished by having the scales that surround its flower-heads membranous at the border, like those of a *Chrysanthemum*, from which genus it, in fact, differs chiefly in the receptacle of the flowers being furnished with little chaffy projections.

Anthemis nobilis, or Chamomile, is frequent in a wild state on many of the commons near London, where it adds a peculiar richness of colour and fragrance to the turf. It is a dwarf plant, with finely-cut leaves; its flower-heads are white in the ray, but deep yellow in the disk. All the parts are intensely bitter, but especially the little yellow flowers of the disk: for this reason the wild blossoms are far more efficacious than those of the cultivated sort, in which there is scarcely any disk, the flowers of the ray having almost entirely usurped their place. Besides the bitter principle for which Chamomile is so celebrated, it has been found by chemists to contain camphor and tannin, and also a volatile oil of a beautiful blue colour.

There is another wild plant, called *Anthemis Cotula*, or Mayweed, which must not be confounded with Chamomile, to which it bears great resemblance: it may be distinguished by its being an erect branching plant, with an exceedingly disagreeable and powerful odour.

Anthemis tinctoria is used in France by the dyers for the sake of a brilliant yellow tint, which is obtained from it.

ANTHER, in Botany, the upper part of the stamen which contains the pollen-cells, the function of which is to aid in the development of the embryo in the ovule. [STAMEN.]

ANTHERI'DIA, in Botany, organs found in many of the tribes of Cryptogamic or Flowerless Plants. They have been observed in the Characeæ, Horse-Tails, Ferns, Mosses, and Algæ, and are supposed to represent the anthers in Phanerogamic or Flowering Plants. In the cells of which they are composed certain moving filaments are observed, which have received the name of *Phytozoa* or *Spermatozoids*. Many of these phytozoa move by cilia attached to their surface. For the nature of their functions, development, and forms, see REPRODUCTION, VEGETABLE.

ANTHOLI'THES (Brongniart). Some Fossil Plants thus designated occur in the Coal-formations of Shropshire and Northumberland.

ANTHO'PHYLLUM (Schweigger), a Fossil genus of *Madrephylliœa.* [MADREPHYLLIŒA.]

ANTHO'SIDERITE, in Mineralogy, an impure silicate of iron.

ANTHOSPE'RMEÆ (from ἄνθορ, flower, and σπέρμα, seed), a tribe of plants resembling *Anthospermum* (the Amber-Tree), belonging to the natural order *Cinchonaceæ*. It consists of the genera *Coprosma*, *Phyllis*, *Galopina*, *Ambraria*, and *Anthospermum*. They possess diœcious or hermaphrodite flowers; a rotate corolla; styles separating to the base, ending in an elongated hispid or plumose stigma; the fruit consists of 2 indehiscent 1-seeded mericarps, or nuts; the albumen of the seed is fleshy. The species are small herbs or shrubs, with opposite or verticillate leaves, and small 1-3-toothed stipules, which are adnate to both sides of the petioles.

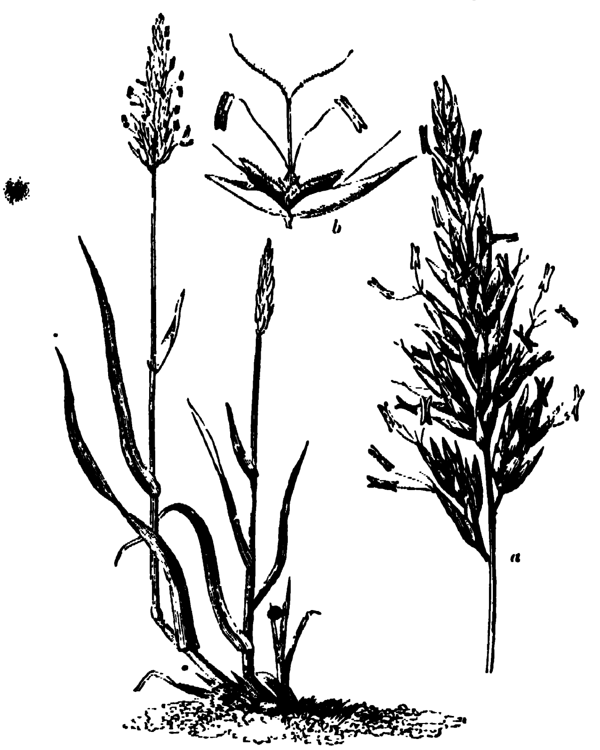
None of the species are used in the arts or medicine; the tribe is however interesting as forming a link between the opposite-leaved *Cinchonaceæ* and the verticillate *Rubiaceæ*. Although most of the *Anthospermeæ* have opposite leaves, yet several species of *Anthospermum* itself, as *A. Bergiainum* and *A. Æthiopicum*, have their leaves subverticillate. In *Phyllis* the leaves occur in whorls of three or four. This genus has but a single species, known by the common name of Bastard Hare's-Ear. It may be cultivated, with other species of the tribe, in a mixture of loam, peat, and sand.

ANTHOXA'NTHUM, a genus of Grasses, one species of which (*A. odoratum*) is well known to farmers under the name of the Sweet Vernal Grass. It is a small annual plant, bearing its flowers in short heads, which are not very compact, and broader at the bottom than the top. The flowerets of which it is composed are a pale yellowish-green; each consists of two sharp-pointed smooth glumes, within which are two other dark-brown hairy paleæ, each having an awn at its back; the stamens are only two in number. This grass is of little importance for its nutritive qualities, but it is much esteemed for the sweet smell of its leaves, which causes much of the well-known fragrance of new-mown hay.

A'NTHRACITE, a black, light, mineral substance, resembling coal; so named from ἄνθραξ, charcoal. It is also called Blind-Coal, because it burns without flame; and Glance-Coal, from the German word *glanz* (lustre), because it has often a shining surface like graphite or blacklead, as it is improperly called, the substance of which pencils are made, and to which it is very closely allied in composition. In some systems of mineralogy it is divided into massive, slaty, and columnar anthracite; but these are mere accidental varieties of structure, and are all of the same chemical composition, when the pure anthracite is separated from the matrix, or from the foreign matter with which it is mechanically mixed. Its specific gravity is about 1400, water being 1000; it is slowly combustible, but without flame, and contains from 70 to 90 per cent. of carbon. Naphtha may be considered as one extremity of the mineral carbonaceous substances, and anthracite as the other; and from the highly-inflammable fluid naphtha we have numerous varieties of mineral tar, or petroleum, bitumen, asphaltum, cannel-coal, caking-coal, slaty-coal, &c., all diminishing in inflammability, until at last we come to the blind-coal, or anthracite. If asphaltum, or indurated mineral pitch, be subjected to distillation, at a certain stage of the process, when it has lost a part of the bitumen which it contains, it resembles caking Newcastle coal; continuing the distillation, it passes into a substance which is identical with anthracite, both in appearance and composition. The following is an analysis of Welsh anthracite :—

Carbon	92·56
Hydrogen	3·33
Oxygen and Nitrogen	2·53
Ash	1·58
	100·00

It is undoubtedly of vegetable origin in common with all coal. [COAL; COAL PLANTS.]



Sweet Vernal Grass (*Anthoxanthum odoratum*).
a, a flower-head magnified. *b*, a floweret more magnified.

ANTHRACOTHE'RIUM (Cuvier), a Fossil genus of Pachyderm Mammals, of which many species occur in Tertiary deposits, especially in the Gypseous and Lignitic strata of Paris and Tuscany.

ANTHRI'SCUS, a genus of plants belonging to the natural order *Umbelliferæ* and the tribe *Scandicineæ*. It is known by possessing little or no calyx, with heart-shaped petals bent down at the point; a fruit narrowed below the short beak, and without any ridges. The beak has five ridges.

A. sylvestris, Wild Chervil, is known by its terminal stalked umbels, and its linear glabrous fruit with a short beak. It is a common weed in hedges and banks throughout Europe.

A. Cerefolium (*Scandix Cerefolium*), the Garden Chervil, is probably an escape from cultivation in England. It is common enough in waste places. [SCANDIX.]

A. vulgaris has the umbels lateral and stalked, and an ovate hispid point. The leaves are slightly hairy. It is common in the waste places of Great Britain. (Babington's *Manual of British Botany.*)

ANTHROPHYLLITE, a mineral, containing, according to an analysis by Gmelin :—

Silica	56
Protoxide of Iron	13
Magnesia	22
Protoxide of Manganese	4
Lime	2
Alumina	3

It occurs in crystalline masses with a fibrous columnar structure. The cleavage is parallel to the lateral planes of a rhombic prism and to both its diagonals. The colour varies from a brown to a yellowish-brown. It has a white streak and an uneven fracture. The specific gravity is from 3·0 to 3·3. The lustre is pearly, and inclining to metallic. It is translucent and transparent on the edges. It is found at Kongsberg and Modum in Norway, in the United States, and in other places.

ANTHRO'POLITES, the name given to Human Fossil Remains. Although at one time it was thought that human remains were often found fossilised, the investigations of modern anatomists have shown that in most of these cases the supposition has been false. Daubenton first demonstrated that some bones which had long been regarded in Paris as the remains of a gigantic human being belonged to a lower tribe of beings. The researches of Cuvier gave a clue by which all cases might be tested, and most of the earlier instances brought forward have been referred to their correct types.

Human fossil bones have, however, been discovered in the Belgian bone-caverns, with bears, rodents, &c., and are figured by Dr. Schmerling, in his interesting work on the bones found in a cavern near Liège.

Dr. Buckland ('Bridgewater Treatise') remarks that frequent discoveries have been made of human bones and rude works of art in natural caverns, sometimes inclosed in stalactite, at other times in beds of earthy materials, which are interspersed with bones of extinct species of quadrupeds. These cases, he thinks, may be explained by the common practice of mankind in all ages to bury their dead in such convenient repositories. "The accidental circumstance," continues Dr. Buckland, "that many caverns contained the bones of extinct species of other animals, dispersed through the same soil in which human bodies may, at any subsequent period, have been buried, affords no proof of the time when these remains of men were introduced. Many of the caverns have been inhabited by savage tribes, who, for convenience of occupation, have repeatedly disturbed portions of soil in which their predecessors may have been buried. Such disturbances will explain the occasional admixture of fragments of human skeletons and the bones of modern quadrupeds with those of extinct species introduced at more early periods and by natural causes. Several accounts have been published within the last few years of human remains discovered in the caverns of France and in the province of Liège, which are described as being of the same antiquity with the bones of hyænas and other extinct quadrupeds that accompany them. Most of these may probably admit of explanation by reference to the causes just enumerated. In the case of caverns which form the channels of subterranean rivers, or which are subject to occasional inundations, another cause of the admixture of human bones with the remains of animals of more ancient date may be found in the movements occasioned by running water."

The same learned author observes that the most remarkable and only recorded case of human skeletons imbedded in a solid limestone rock is that on the shore of Guadaloupe, adding that there is however no reason to consider these bones to be of high antiquity, as the rock in which they occur is of very recent formation, and is composed of agglutinated fragments of shells and corals which inhabit the adjacent water. Such kind of stone is frequently formed in a few years from sand-banks composed of similar materials, on the shores of tropical seas. ('Bridgewater Treatise,' vol. i.) One of these skeletons, described by Mr. König ('Phil. Trans.,' 1814) is in the British Museum. See further as to the rock in which the skeletons are imbedded, 'Linn. Trans.,' 1818, vol. xii.

Dr. Lund published, some years ago, the discovery of human remains with those of *Megatherium*, &c.; and he was of opinion that the former were of the same epoch as those of the latter. The cranium had the peculiar shape which distinguishes the ancient Peruvian.

ANTHUS (Bechstein), the Pipit, a genus of birds separated by Dr. Bechstein from the Linnæan genus *Alauda*, a separation followed by Temminck, Cuvier, Lesson, and Selby, and justly; for though the Pipits have a long hind claw, and are usually coloured, like the larks, their bill is more slender, in consequence of which they never, like them, feed on grain. In the form of the head, in the movement of the tail, and their mode of life, they resemble the Wagtails (*Motacilla*) on the one hand, and on the other the Blue-Breast (*Sylvia Suecica*).

Adhering, then, to the distinction of Bechstein, we characterise the Pipits by the bill being straight, slender, somewhat awl-shaped towards the point, having the base of the upper mandible keeled, the tips lightly bent downwards, and notched. The nostrils, situated at the sides of the base of the bill, are oval, and partly concealed by a membrane: feet, with the shank (*tarsus*) generally exceeding the middle toe in length; toes, three before and one behind, and with the outer toe adhering to the middle one as far as the first joint; the hind claw rather long. The wings have the first quill very short; the third and fourth the longest in each wing.

A. pratensis, the Meadow-Pipit, known also by the names Titlark, Titling, Common Titlark, and Moss-Cheeper, is a common British bird, occurring on the coasts as well as the interior of the country, and frequenting wet meadows, moors, commons, and pasture-land. It usually builds its nest on a grassy bank or beside a tuft or turf. It is to this species that the young of the cuckoo are most frequently consigned.

A. arboreus, the Tree-Pipit, Meadow-Lark, or Short-Heeled Field-Lark, is a larger bird than the last. It is only a summer visitant in the British Islands, arriving at the end of April, and departing in September. Its song is superior to that of the last. It frequently perches on trees. It builds its nest on the ground.

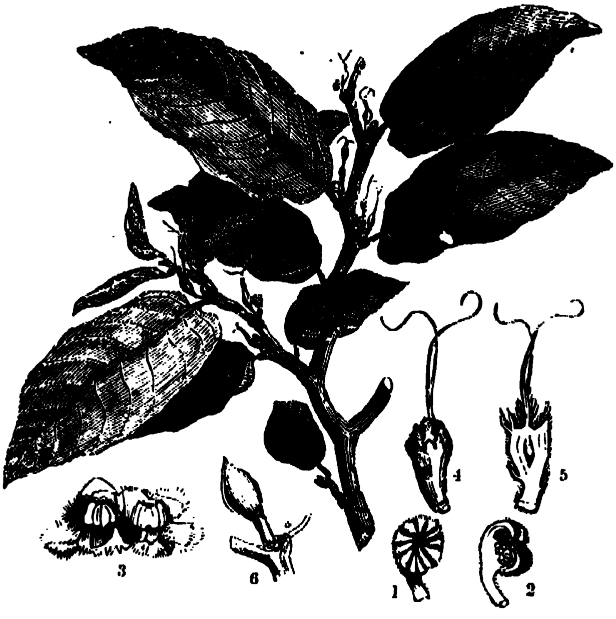
A. obscurus, Dusky or Shore-Pipit, Rock-Pipit, Rock-Lark, Sea-Lark, Dusky Lark, is larger than the last species, has duller tints, and is entirely confined to the sea-shore.

A. Spinoletta, Red-Breasted Pipit, has been observed by Mr. Macgillivray in the neighbourhood of Edinburgh.

A. Richardi, Richard's Pipit, was first described as a British species by Mr. Vigors. (Macgillivray, *British Birds*.)

ANTIARIS is the botanical name of the half-fabulous Upas-Tree, of which so many idle stories were propagated some years since by travellers. It was said to be a large tree, growing in the island of Java, in the midst of a desert caused by its own pestiferous qualities; its exhalations were reported to be so unwholesome, that not only did they cause death to all animals which approached the tree, but even destroyed vegetation for a considerable distance round it; and, finally, the juice which flowed from its stem, when wounded, was said to be the most deadly of poisons. To approach the Upas-Tree, even for the momentary purpose of wounding its stem and carrying away the juice, was stated to be so dangerous, that none but criminals under sentence of death could be found to undertake the task. As is usual in such cases, this fable is founded upon certain natural phenomena which occur in Java. There is such a tree as the Upas, and its juice, if mixed with the blood in the body of any animal, is speedily fatal; and there is also a tract of land in the same island on which neither animal nor plant can exist. But the two circumstances have no relation to each other: the poisoned tract is a small valley completely surrounded by a steep embankment, like the crater of a volcano, and is continually emitting from its surface carbonic acid gas, which is alike fatal to animals and plants; on the other hand, the poisonous Upas-Tree is not an inhabitant of the valley, for nothing can live there, but it flourishes in the woods, in the midst of other trees which are unharmed by its vicinity.

The Upas is a species of the genus *Antiaris*, which belongs to the natural order *Artocarpeæ*, a group of plants all of which abound in a milky juice, and many of which are poisonous. (ARTOCARPEÆ.) *A. toxicaria* is the true Upas. It is not unlike *A. macrophylla*, which has been found on the north coast of Australia.



Antiaris macrophylla.

1, A head of male flowers in the involucrum; 2, the same divided perpendicularly; 3, a couple of the male flowers; 4, pistil; 5, the same divided perpendicularly; 6, a fruit.

ANTICLI'NAL, a term in Geology which expresses the fact that, from a given line, the strata dip in opposite directions.

ANTIGORITE, in Mineralogy, a silicate of lime and magnesia, a variety of Bronzite. [BRONZITE.]

ANTILOPEÆ, in Zoology, a family of Ruminating Mammals, belonging to the Hollow-Horned group, and distinguished by the following characters. The horns conical, bent back, cylindrical, or compressed, and ringed at the base. The knee (or wrist) in the middle of the fore-leg. The occipital plane of the skull forms an obtuse angle with the frontal plane. Core of the horns thin, consisting of dense bone, often with a clear sinus at the base within. Teats two or four. Feet-pits in hind-feet and generally also in the fore ones.

Perhaps the most general character belonging to the Antelopes consists in the form of the horns being round and annulated, or at least never exhibiting the prominent angles and ridges which distinguish those of the Sheep and Goats. In their particular forms and curvatures, however, they vary in almost every different species, as among domestic sheep they do even in different varieties of the same species. Sometimes they form a single bend forwards or backwards, sometimes they are what is commonly called lyrated, or bent first backwards and then point forwards, in such a manner as, when opposed to one another, to assume the figure of an ancient lyre, the brachia or sides of which instrument were frequently made of the horns of the *Dorcas* or Common Gazelle, as appears from the engravings of antique gems still preserved. In many of the smaller species the bony core, or process of the os frontis which is inserted into the hollow sheath of the horn itself, is almost solid, or at least the osseous substance of it is penetrated only by very minute pores.

The possession of 'lachrymal sinuses,' or as they are vernacularly called with reference to the stag and fallow-deer, 'tear-pits,' is another circumstance which distinguishes the greater number of the Antelopes, but which, like all their other characters, is far from being general. Many zoologists suppose these organs to communicate with the nostrils, so as to enable the animals to breathe freely during their long and rapid flights when pursued or frightened. Some even suppose them to be subservient to the sense of smell, and to serve for detecting the noxious qualities of the numerous poisonous plants which grow in the deserts, or spring up among the rank vegetation of tropical climates. It is certainly true that all these animals possess a most delicate sense of smell, and that no known quadrupeds can surpass, and very few equal them in the course. It has been supposed that these organs are used when the animal drinks. The anatomy of the parts demonstrates that no internal communication exists between the lachrymal sinus and the nose, or indeed any other organ. The sinus itself is simply composed of a sac or fold of the skin, of greater or less extent according to the species, but always capable of being opened or shut at the will of the animal, and furnished at the bottom with a gland which secretes an oily viscous substance of the colour and consistence of ear-wax, but which hardens and turns black upon exposure to the air. The precise function of these organs is uncertain; all that we know with certainty at present is, that many of the Antelopes which are most commonly brought to Europe and preserved in menageries, such as the common Indian Antelope and the Gazelle, make continual use of this organ when any strange substance is presented to their notice, particularly if it be odoriferous, and appear to derive great pleasure from protruding the lachrymal sinus and rubbing its interior surface against the odorous body.

It has been already hinted that the Antelopes are not the only ruminants which possess suborbital sinuses: in fact, these organs are more universally found in the deer kind than in the present family; but, on the other hand, as these are the only animals belonging to the hollow-horned family which exhibit this character, it thus becomes sufficiently appropriate, and, as far as it goes, serves readily to distinguish the Antelopes from the Goats and Sheep, with which they are most liable to be confounded. In this respect, as well as in the absence of horns in the females of many species, they form an intermediate link between the rest of the hollow-horned ruminants and the cervine or solid-horned family: so nearly indeed do some species of Antelopes approach to the deer kind in general, and so perfectly similar are they in all their most prominent and essential characters, the horns alone excepted, that it is often next to impossible to distinguish the hornless females of the one genus from those of the other.

Besides the suborbital sinus, a few species of Antelopes possess a different gland, which runs lengthwise between it and the mouth, in a direction for the most part parallel to the plane of the chaffron or face and nose, and secretes a dark oily substance; it is, however, entirely external, and has no internal opening like the lachrymal sinus, nor are its uses better known than those of that organ. The former fact, if it can be relied upon, proves at least that it is a separate organ, and not a mere modification of the lachrymal sinus; and, consequently, it may be fairly presumed that its function, whatever it may be, is likewise different. Another character, but much more generally found to distinguish the Antelopes than even the suborbital sinus itself, is derived from the inguinal pores, which are sacs or deep folds of the skin, situated in the groin, opening inwards, and secreting a glutinous substance similar to that of the glands already mentioned.

In the form of the upper lip, an important character among animals which seek their food on the ground, and in which the lips and tongue constitute the only organs of touch and prehension, the Antelopes are as variable and inconstant as in the other characters already described. In some species it forms a broad naked muzzle, as in the ox; in others it is hairy and attenuated, like that of the goat; and finally, it sometimes assumes an intermediate form, and presents a modification of both these characters. The females are furnished with either two or four teats, forming a small udder; they usually bring forth but one at a birth, in a few instances two, and the period of gestation differs from five to eight months according to the species.

The hair of the Antelopes is generally short and smooth, and of an equal length over every part of the body; some however have manes along the neck and on the shoulders, composed of long bristly hair, either growing upright or reversed towards the head as in the Oryx; and a very few species, like the Gnu, are furnished with a beard on the chin and throat. The ears are commonly long, narrow, and pointed, smooth on the outside, and filled internally with long white hair growing in five longitudinal lines, with four naked black spaces between, and forming the appearance which, in describing these animals, is usually denominated *striated*. The tails are generally short, round, and tufted at the extremity, and many species are furnished with little tufts of long black hair, called *scopæ*, or knee-brushes, upon the upper part of the anterior canons, immediately below the carpal joint.

Generally speaking, the Antelopes are gregarious, and unite in large herds, either permanently or at particular seasons of the year, but only for the purpose of migrating in search of more abundant and grateful pasturage; some species, however, reside in pairs or small families, consisting of an old male and one or more females, with the young of the two foregoing seasons. They are always extremely cautious in guarding against surprise, placing sentinels in various directions about their feeding ground, to warn them of the approach of danger whilst grazing or reposing; and their vision and sense of smell are so acute, that it is only by using the greatest caution and circumspection that the hunter can bring them within range of the gun. The names by which the animals themselves are distinguished in all languages, ancient as well as modern, have a direct reference to this quickness of sight, and to the brilliancy of the large black eyes which form so conspicuous a feature in the Antelopes. Thus the word *Dorcas* (δορκάς), the Greek and Roman name of the Gazelle, or common Barbary Antelope, is derived from the verb δέρκομαι, 'to see.' The common English word Antelope, which zoologists have adopted as the generic name of the group, is a corrupt form of the term ἄνθολοψ, employed by Eustathius to designate an animal of this genus, and literally signifying 'bright eyes;' and, according to the learned Bochart, *Tabitha*, the name of the disciple raised to life at Joppa, is derived from *Tzebi*, the Hebrew name of the common Gazelle, and alludes likewise to the beauty of her eyes. Among the Greeks and Romans also, as we learn from Agathias, and others, *Dorcas*, *Dorcalis*, and *Damalis*, all names of different Antelopes, were common names of women likewise, bestowed without doubt on account of the remarkable beauty of their eyes; and Prosper Alpinus, and more recent travellers, inform us that *Aine el Ghazel*, 'You have the eyes of an antelope,' is the greatest compliment which at the present day an oriental admirer can pay to his mistress.

The Bushmen of the Cape often destroy vast numbers of the antelopes with which their country abounds, by poisoning the springs and reservoirs to which they are known to resort, nor is the flesh ever known to be injured by this mode of slaughter; they also shoot them with poisoned arrows, but in this case the parts immediately around the wound must be cut out before the rest of the body imbibes the poison, which would otherwise penetrate it, and render it unfit for food.

Africa may be considered as the head-quarters of the Antelopes. Australia and Madagascar are, as far as we at present know, completely destitute of Antelopes, as indeed they appear to be of all indigenous ruminants. The precise nature of the habitat frequented by these animals has nothing of a uniform character, but, as might naturally be expected from the different modifications of organic structure observable throughout the genus, differs according to the particular species. Some frequent the dry sandy deserts, and feed upon the stunted acacias and bulbous plants which spring up even in the most arid situations, where the stony nature of the ground gives a certain degree of adherence to the soil; some prefer the open stony plains, the steppes of Central Asia and karroos of Southern Africa, where the grass, though parched, is still sufficient for their subsistence; some again inhabit the steep rocky mountains, and leap from cliff to cliff with the ease and security of a wild goat, whilst others are found only in the thick and almost impenetrable forests of tropical countries.

Although what are popularly called Antelopes were at one time all referred to the genus *Antilope*, their number has so greatly increased as to render it necessary to distribute the various species under different genera. As by far the most extensive and available collection of these animals for the British student is contained in the British Museum, we shall follow in this article the arrangement given of these animals by Dr. J. E. Gray in the 'Catalogue of the Specimens of Mammalia' in that collection, published in 1852.

The family *Antilopeæ* is divided into two great divisions, the *Antelopes of the Fields*, and the *Antelopes of the Desert*. These divisions are recognised by a peculiarity of the nostrils, easily perceived. In the Antelopes of the Fields the nostrils are bald or free from hairs, whilst in the Antelopes of the Desert these organs are bearded within or covered with bristles. There are other distinctions, but these are the most obvious, and readily recognised.

ANTELOPES OF THE FIELDS.

These are again divided into three groups:—

1. *The True Antelopes*, which have a light elegant body; slender

limbs; small hoofs; a short or moderate tail, covered with elongated hairs at the base; lyrate or conical horns, placed over the eyebrows.

2. *The Cervine Antelopes* approaching the deer in character. They have rather a heavy large body; strong slender limbs; a long tail, cylindrical at the base, with the hair longer at the end, often forming a compressed ridge. The muffle is like that of the Cervine Ruminants.

3. *The Goat-like Antelopes*, which have a heavy body; strong legs; large hoofs and false hoofs; very short tail, flat and hairy above; recurved conical horns.

1. *True Antelopes.*

Saiga.

The horns are short, strong, lyrate, annulated, and of a white colour; the nose is compressed, very high, rounded, the nostrils very close together; the crumen distinct; the fur soft; the skull has the nose-opening very large, and extended back over the eyes.

1. *Saiga Tartarica* (*Antilope Colus*, H. Smith), the Saiga and Colus, is the only species of True Antelope which inhabits any part of Europe. The size of the Saiga is about equal to that of the fallow deer, the length being four feet; but the form of the body more nearly resembles that of the sheep, being round and heavy, with a large head and short slender limbs, and the whole proportions of the animal want the usual grace and elegance which commonly characterise the antelope tribes. The nose is large, swollen, and cartilaginous, like that of the elk; it is marked above by deep transverse furrows or wrinkles, and, from its great size and protuberance, compels the animal to go backwards whilst feeding. The nostrils are large and open; the ears of a moderate size; the tail from three to four inches in length; and the lachrymal sinuses much smaller than in the Indian Antelope. The hair is uniformly long and flowing over the whole body, of a grayish yellow colour in summer, and grayish white in winter on the upper parts, and white beneath at all seasons; the knees are furnished with small brushes. The horns of the male are longer than the head, they are semi-transparent and of a light yellow colour, which causes them to be much sought after by the Russians and Chinese for the purpose of making combs, lanterns, and other articles of domestic economy; their form is intermediate between that of the spiral-horned and lyrated groups, being distinctly twisted upon their axis, though without exhibiting the complete spiral threads which characterise the horns of the Indian Antelope.

The Saiga is mentioned by Strabo (vii., 312. ed. Casaub.) under the name of *colus* (κόλος). The Polish name of the animal, *Sulak*, appears to bear some resemblance to the name in Strabo. The Tartars call it *Akkak* and the Turks *Akim*, which come so near to the Hebrew word *Akko*, translated 'wild goat' in our English version of the Scriptures, that we cannot help suspecting that the sacred writers alluded to this animal. In autumn the Saigas unite into large flocks, composed sometimes of many thousand individuals, and migrate southward in search of a milder climate and more abundant pasturage; they return northward in small families about the commencement or middle of spring, and generally keep about the vicinity of lakes and rivers, as they drink a great deal, and, as we are credibly assured, by sucking the water through their large open nostrils. This last fact is also stated by Strabo. They like to feed upon acrid, saline, and aromatic plants, and grow very fat during the summer season; but their flesh acquires a disagreeable taste from the nature of their food, and must be allowed to cool after cooking before it is fit to be eaten. The females are gravid about six months, from the end of November to the end of May; they drop their kids soon after they return northward in the spring, and commonly produce one, rarely two, at a birth. They inhabit the open steppes and deserts from the Danube to the Irtish eastward, and as far north as 54° of N. latitude; and are found in Poland, Moldavia, about the Caucasus, and the Caspian Sea, in Siberia, and in Northern Persia. Their eye-sight is said to be defective from the reflection of the dry arid plains upon which they mostly reside; and, though amazingly swift for a short distance, they are soon exhausted, and easily run down. They are hunted principally for the sake of their horns and skins, the latter of which, particularly those of the kids, are much valued for the manufacture of gloves. The hunters must always take care to approach them against the wind, as their sense of smell is remarkably acute. With all these precautions it is often impossible to get within shot of these animals, as, like many other gregarious species of antelope, they take care, whilst feeding or reposing, to place sentinels in different directions round their encampment to warn them of the approach of danger.

Pantholops.

The horns are elongate, lyrate; the nose (of the males?) has a dilated pouch on each side; the crumen is distinct; the hair close, erect, and spreading; the nose-opening in the skull is large.

2. *Pantholops Hodgsonii* (*Antilope Hodgsoni*, Abel), the Chiru, is believed to be the Unicorn of the Bhotias, and supposed by Colonel Smith to be the animal which Ælian describes under the name of *Kemas*, (see also Homer, 'Iliad,' x. 361.) an opinion founded upon very slight and not easily tenable grounds. The whole length of this animal, from the muzzle to the root of the tail, is about 5 feet, its height 3 feet; the tail is 8 inches long; the head, from the nose to the root of the horns, 9 inches; the ears 4 inches, and the horns measured along the curves, upwards of 2 feet. The horns grow upright from the skull, are strongly compressed on the sides, bent slightly backwards at first, and afterwards point gradually forwards, thus assuming a lyrate form, but less stongly marked than in the common gazelle; they are surrounded, to within 6 inches of the points, with from 15 to 20 annuli, forming prominent knobs in front, but more obscure on the sides and rear; the last 6 inches are smooth and round, and the points rather attenuated. The legs are long and slender; but the symmetry of the head is destroyed by two large fleshy tumours about half the size of a hen's egg, which grow close to the outer margins of the nostrils, as well as by a profusion of bristly hair which surrounds the mouth and nose. The body is furnished with two different kinds of hair, a long external coat of the usual quality, and a short interior one of fine close wool. The prevalent colour of the latter is uniform grayish blue, and the outer coat is likewise of the same colour at the base, but it is tipped with reddish fawn, and thus gives the whole of the upper parts a tawny hue, through which the lower tinge is but faintly visible. The belly and interior of the limbs are white, the nose and face black, and a dark brown band passes down the front of each leg.

The Chiru, according to the information obtained by Mr. Hodgson, inhabits the elevated plains of Tibet, but never approaches the mountains, and is altogether unknown on the Indian side of the great Himalayan chain. It is gregarious, residing in herds of many hundreds on the open plains, extremely shy and difficult to approach, posting sentinels in all directions where the herd feeds or reposes, and flying with astonishing velocity on the first alarm or intimation of danger. When brought to bay, however, the males defend themselves with courage, and in confinement are sometimes mischievous, and should be always approached with a considerable degree of caution. They are very jealous and pugnacious, and in their contests often break off one of their long horns—hence the belief in their being Unicorns. Like most other Ruminants, they are extremely fond of salt, and during the summer months unite in large herds to visit the beds of this mineral, which abound throughout Tibet, advancing under the guidance of an experienced leader, and as usual posting sentinels to prevent surprise.

Procapra.

The horns are lyrate, strong, and black; the tail is tapering; the nose simple, as in the sheep; the muffle and crumen absent; the feet with small feet-pits; the post-corneal sinus large; no inguinal pores; the hair elongated, especially above the head and neck; the knees not tufted; the females are hornless; the teats two; the male has rather a large nose-hole; no suborbital pits, but very large slits; the intermaxillary bones short.

3. *Procapra gutturosa* (*Antilope gutturosa*, Pallas), the Dzeren, the Hoang Yang, Whang Yang, or Yellow Goat of the Chinese, is nearly 4½ feet in length, and 2 feet 6 inches high at the shoulder; the body also is large and corpulent, and the legs shorter than is common to the Antelopes in general; the horns are black, lyrated, and marked to within a short distance of their points with prominent transverse rings; the suborbital sinuses are small; the larynx large and salient, forming, particularly in the old bucks, a prominent lump on the throat; upon the prepuce of the same sex there is likewise situated a bag about the size of a hen's egg, which contains a waxy substance similar to that produced in the analogous organ of the musk animal, but without any kind of odour; the tail is short, and the knees furnished with small bunches of hair, but scarcely sufficiently long and distinct to merit the name of brushes; the summer coat is of a grayish fawn-colour above, and white beneath; that of winter almost entirely white, being tinged but slightly with a grayish yellow shade on the back and sides. The females resemble the males in colour, but are rather of smaller size, and without horns; they want the sac on the abdomen, and have two teats.

The Dzerens inhabit the dry arid deserts of Central Asia, Tibet, China, and Southern Siberia, particularly the great desert of Gobi; and prefer the most sandy and stony plains, feeding upon such scanty herbage as these localities supply, and avoiding water, to which they appear to entertain a marked aversion. They are remarkably swift, take prodigious leaps, and when frightened will occasionally pass over 20 or 25 feet at a single bound. In spring and summer they form small families which live apart from one another, but in the beginning of winter they unite into large flocks, always under the guidance of an experienced old buck. They never run, even when pursued, in a confused crowd, but form single files, and follow closely in the footsteps of their leader. They rarely emit any voice. When taken they are easily tamed, and appear to have rather a predilection for the domestic state, often mixing with flocks of sheep, and approaching human habitations during the severity of the winter season. Their flesh is tender and well tasted, and they are a favourite object of chase with the Moguls and Tartars. The gestation of the females continues from December till the middle of June, and they produce but a single kid at a birth, which grows slowly, and is long in arriving at maturity. During the first year the young males have neither horns nor any appearance of the protuberance on the throat from which the specific name of *gutturosa* is derived; but these organs are gradually more and more developed in proportion as the animal advances in age, till at last, in very old animals, the laryngal protuberance attains the dimensions of 5 inches in length by 3 inches in breadth, and assumes the appearance of a large and deformed goitre. The females differ from the males by the absence of this protuberance as well as by the want of horns. Gmelin denies the antipathy to water which Messerschmid attributes to this species, and affirms that when pursued the Dzerens do not hesitate to throw themselves into the first river they meet with, and that they swim remarkably well. The physical nature of the arid sandy plains which they frequent, in preference to all other situations, may probably have given rise to this presumed antipathy to an element which they seldom encounter, as well as to the marked antipathy to woody localities likewise attributed to them, trees and rivers being equally unknown in the indigenous habitats of these animals.

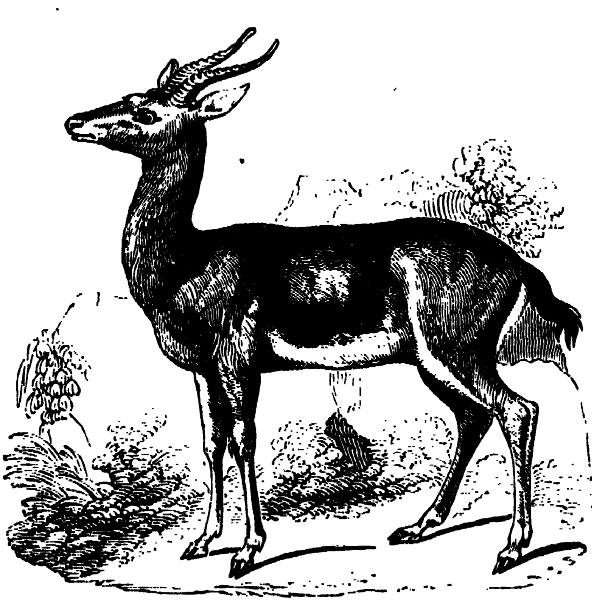
4. *Procapra picticauda*, the Ragoa, or Goa, is an animal described by Mr. Hodgson as an inhabitant of Tibet. It has brown hair with rufous tips; the inside of the ears and limbs white; and tail black. It is perhaps the last species in its summer coat.

Gazella.

The horns black, strong, lyrate; the face conical, tapering; the nose is simple; the females have smaller horns; the fur is short, close-pressed; the skull has a suborbital fissure, and a moderate or very slight fossa suddenly pressed in before the orbit.

Group of Gazelles.

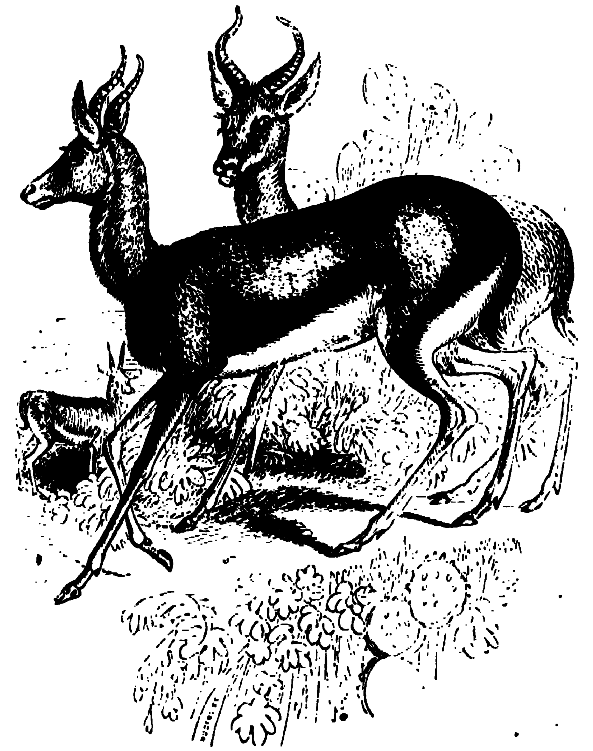
5. *Gazella Dorcas* (*Antilope Dorcas*, Pallas), the Gazelle, the Algazel, the Corinne, is 3 feet 6 inches in length, 1 foot 9½ inches high at the shoulder, and 1 foot 10½ inches at the croup; the head is 6 inches long, the horns 9⅓, the ears 4¾, and the tail, with its terminating tuft, 8 inches. The horns of the old male are surrounded by 13 or 14 prominent rings, complete and close together at the base, more distant, oblique, and interrupted behind, towards the points, the last inch or inch and a half alone being smooth and free from annuli; they rise almost immediately above the orbits, are black, almost cylindrical, at first bent gently backwards, and finally forwards; in the females they are much smaller, seldom exceeding the ears in length, surrounded at the base with a few obscure wrinkles, smooth and polished throughout the rest of their extent, straight to near the tips, and pointing inwards. This is the character of the *Corinne* of Buffon, which is now considered by the best zoologists to be nothing more than the female of this species, and not itself a distinct species, as was formerly supposed. The ears of the Gazelle are long, narrow, and pointed; the eyes large, mild, and black; and the tail round, furnished on its upper surface only with an upright ridge of stiff black hair, and terminated by a little tuft of the same colour; the size of the body is about equal to that of the roebuck, but the legs are considerably longer, and the whole form lighter and more elegant; the face and cheeks are reddish fawn-colour, and the nose has a broad mark of a dark-brown colour, approaching to black; on each side of the face, passing over the eyes from the horns down to the nose, there is a broad white stripe, and beneath this, from the anterior canthus of the eye, a narrower dark stripe, parallel to it and separating it from the fawn-colour of the cheeks; the hind part of the head, the back of the ears, neck, shoulders, back, sides, and croup, are fulvous, of different shades according to the age of the individual; all the under parts are white, and this colour is separated from the fulvous of the sides by a broad dark-brown longitudinal band on the flanks; the knees are furnished with brushes of dark hair, and the ears are filled internally with long white hair arranged in three longitudinal striæ.



The Gazelle (*Gazella Dorcas*).

The Gazelle is found in Egypt, Barbary, and some say also in Asia Minor; but it is very questionable whether the animal of the Levant does not really belong to a different species. It lives in large troops upon the borders of the Tell, or cultivated country, and the Sahara, or desert. When pursued it flies to some distance, then stops to gaze a moment at the hunters, and again renews its flight The flock, when attacked collectively, disperse in all directions, but soon unite; and when brought to bay defend themselves with courage and obstinacy, uniting in a close circle, with the females and fawns in the centre, and presenting their horns at all points to their enemies; yet, notwithstanding their courage, they are the common prey of the lion and panther, and are hunted with great perseverance by the Arabs and Beduins of the desert. When taken young, they are easily domesticated, and soon become familiar. This animal is frequently cut upon the monuments of Egypt and Nubia.

The Kevel of Buffon, the Flat-Horned Antelope of Pennant, the *Antilope Kevella* of Pallas,. have been described from young specimens of this species. The Ariel (*Antilope Arabica*, Hemprich, *A. Cuvieri* of Ogilby, and *A. leptoceros* of F. Cuvier), seems to be a variety only.



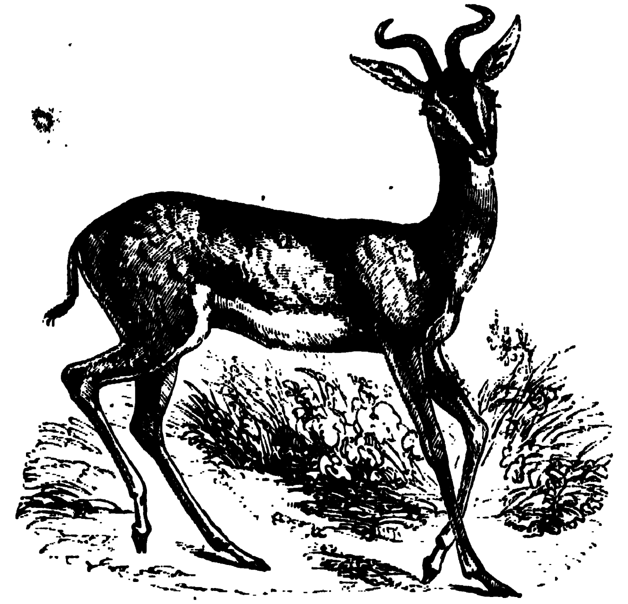
Ariel Gazelle (*Antilope Arabica*).

6. *G. Isabella*, the Isabella Gazelle, has been separated by Dr. J. E. Gray from the last species. He remarks that it may be easily known

from the foregoing by the softness and fineness of the skin, and the lower side-streak being of the same colour as the back, and by having no dark edge to the anal disk. It is a native of Egypt and Kordofan.

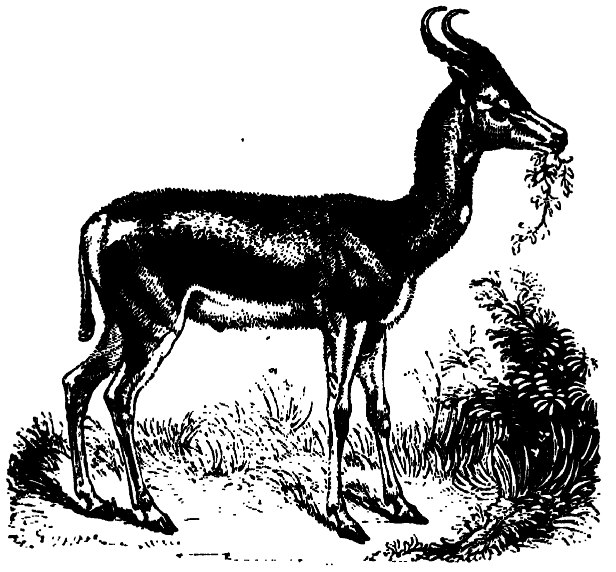
7. *G. subgutturosa* (*Antilope subgutturosa*, Guldenstädt), the Ahu and Jairou, is of a pale brown colour, the upper part of the sides with a broad rather paler streak, the face-streak indistinct; the lower part of the sides, belly, hinder side of fore and front side of hinder limbs, and anal disk, white; the streak on the haunches dark brown; the end of the tail black. It inhabits all the central parts of Asia, Persia, Daüria, the country around Lake Baïkal, and from the eastern limits of Great Bucharia to the shores of the Hellespont. It associates with its own species in extensive flocks, frequents the open uncovered plains and naked hills of moderate elevation, and feeds principally upon the *Absinthium Ponticum.* The flesh is much esteemed, and of an agreeable taste.

8. *G. Sœmmeringii* (*Antilope Sœmmeringii*, Cretzschmar), the Abyssinian Mohr discovered by Cretzschmar in Abyssinia, is considerably larger than the species of *Gazella* hitherto described. The horns are irregularly lyrated, bending boldly outwards towards the points, and then suddenly turning inwards towards one another, with a very sharp and well-defined curve; annulated with 15 or 16 prominent and complete rings, which reach from the base to the inward curvature within about 2¼ inches of the points. The colour of all the upper parts of the body, the neck, shoulders, back, croup, sides and outward faces of the fore arms and thighs, is a beautiful clear isabel or yellowish-dun, the hair being extremely short, and appearing almost as if it had been clipped or shorn. It does not lie close and smooth upon the hide, nor does it all follow the same direction, as in the generality of animals, but is disposed in innumerable small waves, pointing in different directions as if it had been regularly shaded and parted on each side, and appearing glossy or glazed along their ridges with a shining dun shade, more or less intense according to the light in which it is observed. All the under parts of the body are of the most pure and brilliant white, and a large disk of the same colour surrounds the tail, and passes over the rump and croup. The white of the belly also is separated from the yellowish dun of the sides, immediately, without being shaded off. The tail is small and slender, nearly naked at the root, and furnished at the extremity with a tuft of mixed brown and gray hairs. The outsides of the legs are very pale fawn-colour, the insides white, and the knee-brushes white and fawn mixed. The ears are pretty long and brown, with a narrow black border surrounding their outer edge. The face is dark brown in some specimens, and pure black in others, uniform towards the end of the nose, but curiously mixed with wavy red on the forehead; on each side of this a broad white band passes from the root of the horns over the eyes to the nose, and there is an indication of a small black one from the anterior angle of the eye to the corner of the mouth, separating this white band from the cheeks and sides of the lower jaw, which are uniform fawn-colour. The horns of the female have nearly the same curvature as those of the male, and are fully as long, but they are much more slender, and have not such prominent annuli. This is the only external difference observable between the sexes. This antelope frequents hills of moderate ascent and elevation in the eastern provinces of Abyssinia, and is said to live in pairs, and not to unite into large flocks like the Gazelle and Kevel.



The Abyssinian Mohr (*G. Sœmmeringii*).

9. *G. Mohr* (*Antilope Mhorr*, Bennett), the Mohr or Mhorr, is 4 feet 2 inches long from the nose to the origin of the tail, 2 feet 6 inches high at the shoulder, and 2 feet 8 inches at the croup; the length of the head from the nose to the root of the horn is 7 inches; that of the horn 9½ inches on the curve, and 7¼ in a straight line; and that of the tail 7 inches without the terminal tuft. The hair of the body is sleek and of moderate length; on the head and face it is very short and close, except about the root of the horns, where it is slightly tufted; the hair of the limbs is also short, except the tufts below the knees, which are long, and consist of a mixture of dark brown and grey hairs. The horns are thick at the base, and annulated with 11 or 12 prominent and complete rings, which occupy about two-thirds of their entire length; they are round, smooth, and attenuated towards the tips, which point directly forwards, and are but moderately sharp. The ears are narrow, erect, and pointed; the eyes large, dark, and lively; and the tail long, naked at the base, and furnished at the extremity with a tuft of long black hair. The colour of all the upper parts of the body, of the neck, back, shoulders, sides, fore-arms and thighs, as well as of the whole throat except a square spot on the larynx, is a deep brownish-red; and a narrow stripe of the same colour is continued down the outer face of the legs, both anterior and posterior, from the shoulders and thighs respectively to the hoofs and pasterns: the belly, buttocks, posterior face of the thighs and inner face of the extremities are pure white, as well as the spot on the larynx above referred to; and this colour, after spreading round the entire region of the tail, is continued forwards on the hip in a pointed stripe on each side, about half way between the croup and the knee-joint, and reaching nearly over the whole hip. It contrasts strongly with the surrounding colour, and has a very singular effect. There is no dark band on the flanks, the light colours of the under parts being abruptly separated from the darker shade above without any blending or intermediate colour. The head and cheeks are light fawn-colour, intermixed, in front of the horns, with dark brown and gray hairs, and marked below the opening of the suborbital sinuses with a small dark spot, representing the black band which passes in some other species of the last division from the anterior canthus of the eye to the corner of the mouth: the whole line of the nose and chaffron are likewise dark brown, mixed with gray in old specimens, and the back of the ears is fawn-coloured, tipped with black.



The Mohr (*G. Mohr*).

It is a native of Western Africa. The species is not found in the empire of Marocco, but individuals are occasionally brought from the opposite confines of the desert; the animal is much sought after by the Arabs on account of producing the bezoar-stones so highly valued in eastern medicine. These stones are commonly called in Marocco, Baid-el-Mhorr, or Mhorr's Eggs.

The Nanguer (*Antilope dama*, Pallas) was originally described and figured by Buffon from materials brought by Adanson from Senegal; since that time the animal has not been seen by any naturalist, and as the description of Buffon is imperfect, doubt may be entertained whether it be not in reality the young of the Mohr.

10. *G. ruficollis* (*Antilope ruficollis*, H. Smith), the Andra, is a beautiful species of Eastern Africa, discovered on the barren wastes of Nubia by Rüppel, and in Senaar and Dongola by Hemprich and Ehrenberg. The whole length of this species is 5 feet 4 inches, its height at the shoulder 3 feet; the length of the head is 8 inches, that of the horns 12½ inches, and that of the tail 9 inches. The horns are precisely similar to those of the Mohr already described, as are likewise the general form and proportions of the body. This species is gregarious, and resides in flocks on the desert between Nubia, Dongola, and Kordofan.

11. *G. rufifrons*, the Korin, is of a bay-brown colour, the sides above

paler, with a broad dark streak below; the chest, belly, inside of the legs, back edge of tarsus, and underside of feet and anal-disk, white; the face bright bay, with a broad white side-streak. Dr. Gray says, "The Kevel figured by M. F. Cuvier well represents this species. The Corinne of the same author, also from Senegal, well represents the young animal." The Corinne and Kevel of Buffon belong to *G. Dorcas.*

Tragops

Has short, black, lyrate horns; a tapering face; ovine nose; no muffle or crumen; the fur short, pressed down; the sides without any dark streak; the knees tufted; the feet with large feet-pits; the inguinal pits distinct. The female has slender horns and two teats.

12. *Tragops Bennettii* (*Antilope quadricornis*, Blainville), the Chikara, Ravine-Deer, Goat Antelope, Kalsiepie, or Black-Tail, is of a bay-brown colour, and has the end of the nose and tail black; the face streaked; chest, belly, and inside of limbs, white; the feet are black or brown.

The Kalsiepie, or Black-Tail, so called by the Mahrattas on account of the deep black colour of the tail, and distinguished by the name of the Goat Antelope by the Europeans, is found on the rocky hills of the Deccan, and, according to the report of Colonel Sykes, differs from many other antelopes in not being gregarious, there being rarely more than three or four found together in the same company, and not unfrequently a solitary individual.

Antidorcas

Has lyrate, short, black horns; a tapering face; a simple nose; the crumen moderate, distinct. On the back it has an extensive white fold or streak; the hair is pressed close; the knees are not tufted. The female has small horns, but the number of its teats are not known.

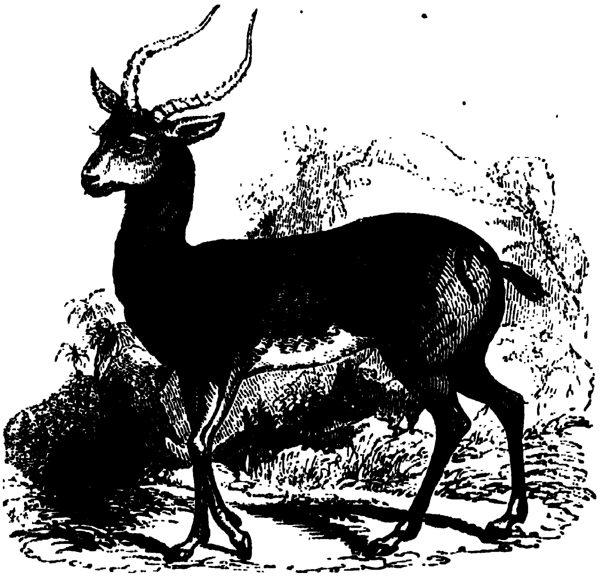
13. *A. Euchore* (*Antilope Euchore*, Forster), the Tsebe, or Spring-Boc, Prong-Boc, or Showy Goat, is perhaps the most graceful in its proportions, and beautifully varied in its colours, of all the antelope tribe. Imagination cannot conceive a quadruped more light and airy in form, more delicate in its proportions, or whose movements are executed with more natural ease and grace, than the Spring-Boc, or, as the English colonists now universally denominate it, Spring-Buck. In point of size it is nearly a third larger than the Dorcas. The horns of the Spring-Buck are rather irregularly lyrated, like those of the species last described; they are round, black, annulated very regularly till within a short distance of the points, spreading first backwards and widely outwards, and finally turning inwards, and with an almost imperceptible twist on their own axis backwards. The hair is long on the upper parts of the body, particularly on the back and croup, but smooth, sleek, and shining: it is of a beautiful light cinnamon-colour on the shoulders, neck, back, sides, and thighs; and of a pure snowy white on the breast, belly, and inner sides of the limbs, these two colours being separated on the flanks by a broad longitudinal band of a deep vinous-red colour, larger and more distinct than in any other species of Antelope. The whole head, face, cheeks, and chin are white, with a broad brown band on each side from the eyes to the corners of the mouth, and a mark of the same colour on the centre of the face, commencing in a narrow point on the muzzle, and enlarging as it proceeds upwards till it joins the reddish fawn-colour of the body on the crown of the head. The eyes are large, lively, and of a brown colour; the ears long, small, and cylindrical at the root, then widening in the middle, and ending in an attenuated point. The neck is long, slender, and slightly compressed on the sides; the hoofs are small, black, and triangular; the legs remarkably long and slender; and the tail small, round, and naked, except a ridge of stiff black hair which fringes it along the upper surface, and forms a small tuft at the extremity. But the most remarkable and distinctive character of this species consists in two longitudinal foldings or duplications of the skin on the croup, which commence above the loins, or about the middle of the back, and run in a straight line from thence to the tail. The interior of those folds is lined with long hair of 9 or 10 inches in length, and of the most brilliant and snowy whiteness; they are likewise under the complete command of the animal's volition, and are opened and shut at pleasure. When closed, which they always are when the animal is at rest, their lips form a narrow line along the top of the loins and croup, which, being covered by the long cinnamon-red hair of the back and hips, is scarcely distinguishable, or only as a narrow white streak; but when the animal leaps or runs, these folds are expanded, and form a broad circular mark of the purest white, which extends over the whole croup and hips, and produces a most remarkable and pleasing effect.

The Spring-Buck is so called from its remarkable habit of jumping almost perpendicularly upwards, apparently without any other motive than for its own amusement. It resides, in almost innumerable flocks, on the dry arid plains and karroos of the interior of South Africa, seldom approaching the inhabited districts of the colony, unless in seasons of peculiar drought, when the pools and pastures of the interior are dried and burnt up by the excessive heat, and these animals are compelled to migrate in search of a more abundant supply. On these occasions they are said to unite into flocks which often consist of from 10,000 to 50,000 individuals, spreading over the face of the whole country like a swarm of locusts, devouring every vegetable substance that they meet with, and scarcely deviating from their direct path to avoid the men and dogs which endeavour to turn them into another direction. These vast flocks, according to Mr. R. G. Cumming, will continue streaming along in an unbroken compact phalanx for two or more hours. This migration is called at the Cape a *Trak Bokken.* So great are their numbers in these migrations that those which happen to get into the rear of the troop are lean and half-starved before the migration is concluded, from the advanced ranks cropping the scanty pastures almost bare, and thus leaving them nearly destitute of food; but when the journey is concluded, and the troop begins to retrace its steps northward, those which formed the van during the advance are necessarily in the rear returning, soon lose their plump condition, and are in their turn subjected to want and starvation. During these migrations they are closely followed by lions, panthers, hyænas, and wild dogs, which destroy great numbers of them. There is perhaps no object in nature finer than a flock of these beautiful antelopes enlivening the dreary brown karroos of South Africa with their graceful motions; now leaping perpendicularly upwards to the height of six or seven feet, displaying at the same time the snowy-white marks on their croups, and anon flying over the desert with the speed of a whirlwind. It is only when disturbed or otherwise excited that they make those extraordinary springs from which they have derived their name; nor do they ever display the white mark on their rump except on these occasions. They are said to be particularly affected by the change of the weather, and are observed to leap more than usual before the setting in of the south wind, which, at the Cape of Good Hope, generally betokens stormy weather, and is always violent and tempestuous. When tak[illegible] young, the Spring-Buck is easily tamed, and soon displays all the petulance and familiarity of the Common Goat, butting at every stranger that approaches it, and warding off stones or other objects thrown at it with its horns.

Æpyceros

Has black lyrate horns, elongate, wide-spreading, curved outwards from the base, then backwards and upwards at the tip; the face tapering; the nose simple; no tear-bag; the knees not tufted; the feet with a tuft of black hair near the pasterns; the female has two teats.

14. *Æ. melampus* (*Antilope melampus*, Lichtenstein), the Pallah, or Rooye-Buck, the Betjuan of the Kaffirs, is a magnificent species of South Africa, discovered by Professor Lichtenstein during his travels in Kaffraria, and since found in the Betchuana country on the elevated plains of Latakoo, by Trutell, Somerville, and Burchell. It is upwards of 4½ feet in length from the nose to the origin of the tail, and 3 feet high at the shoulder; the horns have an irregular lyrate tendency, bending first forwards and very much outwards, then with a large circular sweep inwards, and finally pointing forward again, approaching within three inches of one another at the tips, after being nearly a foot distant in the middle: they are about 20 inches long in adult animals, and surrounded for two-thirds of their length with irregular rings, often splitting into two, and forming prominent knobs on the front of the horn, but frequently obliterated, and always less strongly marked on the sides, which are slightly compressed. In the beautiful drawing of this animal given in Daniel's 'African Scenery,' the horns are represented with an unnatural angular bend, which has misled many describers, and caused even Colonel Smith to describe them as forming an obtuse angular bend, though he has himself given an accurate drawing of the pair which we have here described, and which certainly exhibit no appearance of the sudden angle attributed to them; which probably arose from the particular position in which Mr. Daniel's figure was drawn. The horns for a third of their length towards the points are black, smooth, and polished. The head, back, flanks, and outer surface of the legs and tail are of a deep rufous colour; the lips, eye-brows, interior of the ears, breast, belly, interior



The Pallah (*Æ. melampus*).

of the thighs and arms, and the region below the tail, white; the back is marked longitudinally by a band of deep shining black, which divides on the croup, and passes down along each hip in the form of a crescent, separating the pure white of the buttocks and interior of the thighs from the general rufous colour of the upper parts; the outside of the knee and heel are likewise marked by brilliant black spots, which contrast strongly with the general rust-colour of the extremities, and from which the animal derives its specific name of *melampus*. The ears are very long, particularly in the females, which are without horns, and of a smaller size than the males, but similar in other respects; the ears are covered on the outside with short red hair, bordered and tipped with black, and the knees are without brushes. We are as yet very imperfectly acquainted with the characters of this magnificent species of antelope, so that it is not without considerable doubt, and only on the authority of Colonel Smith, that we venture to include it in the present group.

The Pallah inhabits Kaffraria and the country of the Bachapins or Betchuanas, never descending farther south than the Koosges valley in the one direction and the Kamhanni Mountains in the other. They reside on the open plains in families of six or eight individuals, run with amazing swiftness, and occasionally leap like the Spring-Buck, which, according to Mr. Burchell, they much resemble in their general habits and manners. They are extremely numerous on the elevated plains in the neighbourhood of Latakoo, and constitute a favourite object of the chase with the natives, as their flesh, though deficient in fat, is well-tasted and wholesome. *Pallah* or *Phaala* is the Bachapin name of the animal; but the mixed Hottentots, who travel into that country from the Cape, distinguish it by the Dutch term *Rooye-Boc* or Red-Buck, on account of the prevailing colour of its hair.

Antilope

Has elongate, subspiral, erect, diverging horns; a tapering face; a simple nose; a large crumen; the male with a small suborbital fissure, and a very large suborbital pit; the tubercles and median grooves of the basi-occipital bone well developed.

15. *A. Bezoartica* (*A. cervicapra*, Pallas), the Sasin, or Common Antelope, is remarkable for the form and beauty of its horns, which compose a spiral of two or more turns, according to the age of the animal. This beautiful animal is, when full grown, about 4 feet in length, and 2¼ feet high at the shoulder; the head, measured from the nose to the root of the horn, is 7 inches long, the ears 5¼ inches, and the tail, without the hair, 6 inches. The legs are long and delicate; the body round, but light, and well formed; the head small; the eye large, lively, and expressive; the ears long and cylindrical, the suborbital sinus particularly developed, and in continual motion; and the horns forming a complete spiral of two or three turns, wrinkled at the base, distinctly annulated in the middle, and smooth for a couple of inches next the points. The females, and young males for the first three years of their age, are of a uniform tawny-brown on all the upper parts of the body, with a light silvery band passing longitudinally [illegible] the shoulder to the hips, about six inches below the spine, on either side; the breast, belly, and interior of the fore arms and thighs are white; as is likewise the under surface of the tail, which is rather broad, and furnished with a small tuft of black hairs at the extremity. After their third year, the males begin to assume the adult colours of their sex, and gradually darken on all the upper parts of the body, till they finally become almost entirely black above and white beneath; the nose, lips, and a large circle round each eye being likewise white, but the light bands of the sides completely obliterated. The hair is uniformly short and close over the whole head, body, and extremities, except on the knees, which are furnished with tufts of long bristles, forming small knee-brushes.

The Sasin, or Common Antelope (*A. cervicapra*).

The Sasins are so swift that it is useless to slip greyhounds after them; as, unless taken by surprise, which their extreme precaution seldom allows, it is impossible to overtake them, and experience has convinced the Indian sportsmen that the dogs are more likely to be injured in the chase than the game. The bounds also which these animals occasionally take, either for their own amusement or over the long grass when pursued, are said to be almost inconceivable. Captain Williamson, in his splendid work on the 'Wild Sports of the East,' assures us that he has seen an old buck Antelope lead a herd of females over a net at least 11 feet high, and that they frequently vault to the height of 12 or 13 feet, and pass over 10 or 12 yards at a single bound. They reside on the open plains of India, where they can see to a great distance in every direction, live in large families of from 5 or 10 to 50 or 60 grown females to a single male, and when they feed, or lie down to ruminate, detach a number of the young bucks to a distance of 200 or 300 yards on every side to watch over the common safety. Nothing escapes the notice of these careful sentinels; every bush or tuft of grass that might be suspected to conceal an enemy is strictly and attentively examined, and on the first alarm the whole herd betakes itself to flight, following closely in the footsteps of the old buck, and is soon beyond the reach of pursuit. The venison is dry and unsavoury, and being held in small esteem, consequently holds out no inducement either to the occasional sportsman or to the professional Indian hunter. The species extends over every part of India, from the borders of Persia to the most eastern parts of which Europeans have any distinct knowledge. It is found on rocky open plains, avoids woody localities and the thick cover of the forest; nor is there any certainty of its existing beyond the limits of India, though many zoologists, from Ray to Hamilton Smith, are of opinion that it likewise inhabits some parts of Africa. The fakirs and dervishes polish the horns, and form them into a kind of offensive arms by uniting them at the base; these they wear at their girdles instead of swords and daggers, which their vows and religious character prevent them from using.

Tetracerus

Has the muffle large; the crumen large, longitudinal; four horns, the front pair very short, placed over the orbits, the hindmost, which are conical and straight on the back edge of frontal bone. The skull is like that of *Cephalopus*, with the nasal bones not expanded. The suborbital fossa large, shallow, occupying nearly the whole of the cheek. It has no knee-tufts; and the females are hornless.

16. *T. quadricornis* (*Antilope quadricornis*, Blainville), the Chousingha, is about 2 feet 9 inches in length from the muzzle to the root of the tail; the tail itself is 5 inches long, and the height at the shoulder about 1 foot 8 or 9 inches. The superior or common horns are about 3 inches long, smooth, black, pointed, erect, and moderately divergent, bending very slightly forwards, and without the least indication of annuli. The spurious or additional pair of horns are placed in front of these, immediately between the orbits, and consist of short, erect, blunt stumps, about three-quarters of an inch in length, 1½ inch in circumference at the base, and of the same smooth and black appearance as the real horns. The head is 7½ inches long, the ears 4¾ inches, erect and pointed; the general colour of the upper parts is uniform bright bay, and that of the under parts silvery white, more or less mixed with sandy-coloured hairs; the lips are bordered with black. The females differ from the males by the absence of horns, and likewise by being of a lighter colour, which character is conspicuous at a very early age, and continues throughout life.

This species, as well as *Tragops*, called Chikara by the Hindoos, is common in all the wooded parts of India, particularly in Bengal, Bahar, and Orissa; it is monogamous, and lives in pairs in the forests and thick jungle, being exceedingly wild and active, and rarely suffering a state of confinement unless taken young. During the rutting season the male becomes particularly mischievous, and it is then dangerous to approach him, as he butts at everything within his reach; the female produces two young at a birth, but the period of gestation has not been recorded. Baron Cuvier supposes, and apparently with reason, that the ancients were acquainted with this species, and that the Four-Horned Oryx of Ælian refers to the modern Chikara.

17. *T. Iodes*, the Rusty-Red Chousingha, is an Indian species described by B. H. Hodgson, Esq.

18. *T. paccervis*, the Full-Horned Chousingha, is another Indian species.

19. *T. subquadricornutus*, the Jungliburka, is distinguished by its front pair of horns being rudimentary and tubercular. It is a native of Bombay, and there are four specimens, two male and two female, in the collection of the British Museum.

Calotragus

Has the muffle large; the crumen arched, transverse; the horns subulate, elongate, erect; the hoofs triangular, flattish beneath, acute in front; the false hoofs small or none; the crown of the head smooth; the tail very short; the ears elongate; the knees not tufted; the females hornless; the teats four.

20. *C. campestris* (*Antilope Tragulus*, Lichtenstein), the Stein-Boc is one of the most graceful and elegant of the antelope tribe. Its

legs are longer and smaller in proportion to its bulk than in any other species; its body is compact and well made; its head small, pointed, and ending in a well-formed naked muzzle, and its tail reduced to a mere tubercle, scarcely perceptible among the long hair of the croup and buttocks. The whole length, from the muzzle to the root of the tail, is about 3 feet 4 or 5 inches; that of the head, from the muzzle to the base of the horns, 4 inches, and from the same point to the root of the ear 6 inches, the tail being 1½ inch long, and the horns 4 inches. The height at the shoulder is 1 foot 7 inches, and at the croup 1 foot 9 inches. The colouring of this species is altogether peculiar, and alone sufficient to distinguish it from all other ruminants. In general, it is a reddish fawn-colour on the upper parts of the body; but this seems to be glazed or as it were overlaid on the shoulders, back, sides, and hips, with a light dun or silvery-brown hue, arising from the hairs in these situations being tipped with that colour; the nose and legs are dark brown, the breast, belly, and interior of the fore arms and thighs white; the hair of the forehead is long and of a deep red colour, and a remarkable black line passes from the root of each horn backwards, uniting between the ears, and forming an obtuse angle equally as conspicuous in the hornless females as in the horned males, and affording an excellent criterion by which to distinguish the species. The horns of the male are small and round, furnished at the roots with a few faintly marked wrinkles; but smooth and polished throughout the greater part of their length, and ending in extremely sharp points, almost imperceptibly bending forwards. The ears are extremely large for the size of the animal, being nearly half as long again as the horns, and broad in proportion. But perhaps the most remarkable character of the species, and certainly that which most definitely distinguishes it from all the other ruminants with which it is at all likely to be confounded, though it has hitherto escaped the notice of observers, is the total absence of spurious hoofs, both on the fore and hind feet, a character which exists also in the Prong-Buck, and which, as far as we are aware, no other ruminating animals of the hollow-horned family possess.

The Stein-Boc resides in pairs on the stony plains and mountain valleys of South Africa, not however frequenting very elevated or rocky localities, as its colonial name of Stein-Boc, or Stone-Buck, would seem to imply. On the contrary, it prefers the dry open flats, covered here and there, it is true, with large rocks and boulder stones, but likewise interspersed with clumps of stunted bushes and underwood, which furnish it with cover. This is the general character of the South African plains in the neighbourhood of Cape Town, as well as of the gorges of the moderate hills and mountains, and it is in such situations that the Stein-Boc is most commonly found. This animal is, moreover, remarkably shy and timid, runs with extraordinary swiftness, and when pursued will frequently bound over a space of 12 or 15 feet at a single leap. When closely pressed, and without any further means or power of escape, it will hide its head in the first hole or corner it happens to meet with, and thus patiently resign itself to its fate. Though it cannot be called a rare animal at the Cape, it is nowhere particularly common, being much hunted on account of the delicacy of its flesh, which furnishes excellent venison, and great numbers of the young being destroyed by eagles and other birds of prey. Colonel Smith has described the young of the Stein-Boc as a different species, by the name of *A. rufescens*; and the *A. pallida*, or *A. pediotragus*, of Afzelius, appears to differ in no respect from the adult of the present animal, the really distinctive characters of which have been hitherto very imperfectly reported.

21. *C. melanotis* (*Antilope melanotis*, Lichtenstein), the Grys-Boc is a species closely allied to the Stein-Boc, but rather lower on the legs and more heavily made. The whole length of the body is nearly 3 feet, that of the head, from the muzzle to between the ears, 6 inches; the height at the shoulder is 1 foot 5½ inches, and at the croup 1 foot 7¼ inches; the horns are 2½ inches long, and the ears 5 inches. The head, as in the Stein-Boc, contracts suddenly before the eyes, and ends in a pointed muzzle; the horns are situated immediately above the orbits, straight, upright, pointed, and shining, with two or three small annuli at the roots; the ears are long, wide, and open; and the tail, almost tuberculous, is concealed among the long hair which passes backwards over the hips. The hair of the body is universally long, particularly on the hind quarters; on the head and extremities it is, on the contrary, remarkably short. All the upper parts are of a deep crimson red colour, thinly but regularly intermixed with long coarse hairs of the purest white, giving the whole animal a hoary appearance, expressed by its colonial name of Grys-Boc, or Gray-Buck, and forming altogether a character not easily mistaken. The inferior parts are uniform light sandy-brown or red, the head and extremities fawn-colour; the muzzle, the openings of the lachrymal sinuses, and an obscure circle about the eyes, as well as a mark upon the occiput of some specimens, are black, as are likewise the backs of the ears, which are nearly naked, with a few very short gray hairs thinly scattered over them.

The habits of the Grys-Boc are in most respects similar to those of the Stein-Boc. It lives in pairs upon the plains, never unites into troops or flocks, and conceals itself in clumps of underwood, whence it is not easily driven, lying close like a hare in her form, and seldom moving till almost trodden on. It is common in most parts of the colony at the Cape, and being less swift than the Stein-Boc is more easily captured. Its venison is much esteemed, though, like the generality of antelopes, destitute of fat.

Scopophorus

Has the muffle small and bald; tear-bag (crumen) transverse; the horns subulate, elongate, acute, and slightly recurved at the tips; the knees largely tufted; the inguinal pores distinct and bearded; the ears of moderate size, with a naked spot on the outside of their base; the hoofs triangular, and false hoofs distinct.

22. *S. Ourebi* (*Antilope scoparia*, Schreber), the Ourebi, called Bleek-Boc, or Pale-Buck, by the Dutch colonists at the Cape, according to Professor Lichtenstein, is a much smaller species than the Nyl-Ghau, and differs from all the other species of the present section by the large brushes which, in common with many other antelopes, it has upon the upper end of the canons, immediately below the knees, and from which it was called by Schreber *A. scoparia*. It measures 3 feet 8 inches in length from the muzzle to the root of the tail; the length of the latter is 3½ inches, that of the head is 7½ inches from the muzzle to the root of the horn; of the horns themselves 5¼ inches; and of the ears 3¾ inches. The height at the shoulder is 1 foot 10 inches, at the croup nearly 2 feet, and the size of the animal, as well as its general form and proportions, are nearly those of the Roebuck, only that the head is longer and more slender. The horns are awl-shaped, sharp, slender, nearly straight, and bending almost imperceptibly to the front; they are surrounded at the base with a few obscure wrinkles, succeeded by five or six well-defined rings, but are smooth and black throughout the greater part of their length, and end in very sharp points. The general colour of the upper parts is a uniformly pale yellowish-brown, darker in some individuals than in others; all the under parts, as well as the chin, lips, and a longitudinal streak over the eyes in the form of eyebrows, are white, and this colour likewise spreads over the posterior surface of the hips. The tail is covered with long bushy hair of a jet black colour, forming a marked and prominent contrast with the white of the buttocks; the ears are edged with a narrow border of dark brown, and immediately beneath their opening at the root there is a remarkable bald or naked spot of an oval form on each side of the head.

The Ourebi inhabits the open plains of South Africa, and without being positively gregarious, is fond of the society of its own species. It is found chiefly in the eastern districts of the Cape Colony towards Kaffraria; and its flesh, though dry and destitute of fat, is esteemed one of the best vensions of the country. Great numbers of these animals are found on the plains about Zwartkops Bay. When feeding they straggle confusedly over the plain, and appear to be in company rather accidentally than by intention; when alarmed also they do not fly together, but each runs off by itself in whatever direction it thinks most secure from danger for the moment.

23. *S. montanus* (*Antilope montana*, Rüppell), the Gibari, is very like the former, but is of a gray-brown colour, and the temporal spot much larger, deeper, more distinct and bald, both when alive and in the skin. It was found in Abyssinia by Rüppell, and the late Earl of Derby received a specimen from Gambia.

Oreotragus

Has the muffle large; the crumen arched and transverse; the horns subulate, elongated; the hoofs squarish, high, compressed, much contracted, concave beneath; the false hoofs large, blunt; the crown of the head smooth; the tail very short; the hair thick, goat-like, spread out. The female is hornless, and has two teats.

24. *O. Saltatrix* (*Antilope Oreotragus*, Forster), the Kainsi or Klippspringer, is an Antelope which inhabits the most barren and inaccessible mountains of the Cape, and appears to supply in South Africa the place of the Chamois and Ibex. The entire length of this animal, from the muzzle to the root of the tail, is 3 feet 2 inches, its height 21 inches at the shoulder, and about an inch more at the croup; the horns are 3½ inches long, the ears 4¼ inches, and the tail 3 inches. The head is short and small, compressed on the sides, and suddenly contracted immediately in front of the orbits, ending in a small, round, naked, black muzzle; the lachrymal sinuses open by a moderately-sized circular aperture; the horns of the male are perfectly straight and smooth throughout the greater part of their length, having three or four small but distinct annuli surrounding their roots; the ears are large, open, and rounded at the points; the eyes large and dark; and the tail appearing externally only by a brush of hair which clothes it. There are neither inguinal pores nor knee-brushes, but in place of the latter the knees of some specimens exhibit a naked callous patch, probably occasioned by rubbing against the rocks. The general colour of the animal on all the upper parts of the body is a lively and pleasing mixture of yellow and green, resul[illegible] from each hair being individually surrounded by alternate rings of these two colours; the under parts of the body are light sandy-red, tinged with yellow: the interior of the ears is filled with long white hair, a narrow black border surrounds their edges, and the eyes are encircled by the same colour. The hair of the body is long, padded, and stands perpendicularly out from the hide; that of the head and extremities is shorter, and lies in the usual direction; in quality the latter also resembles the hair of common animals, but the texture of the hair which covers all the upper surface of the body and neck is altogether peculiar, being similar to that of the Prong-Buck already described. It is round and hollow internally, and so fragile

that it breaks with the slightest touch, crushing like straw when pressed between the fingers, and so deficient in elasticity that it never regains its original form. The tail is covered with a small bush of hair of the same description, but so short as to be scarcely perceptible among the long hair of the hips. The legs are more robust than in most other species of Antelope; and the hoofs, instead of being pointed and flat beneath, are perfectly round and cylindrical, being worn only at the tips, upon which alone the animal treads. This peculiarity of structure in the hoof, and the riged form of the pastern-joints, which are perfectly stiff, and in a straight line with the canons, account for the amazing agility which the Klippspringer displays in bounding among the most dangerous rocks and precipices.

The peculiar habitat of this species makes it impossible to hunt it with dogs, but it is easily shot as it exposes itself upon the naked rocks; and great numbers of the young are destroyed by eagles and other birds of prey which inhabit the same localities. In consequence of this the animal is by no means common, and is becoming every day more scarce in situations where it most abounded formerly. The excellence of its venison and the value of its hair, which is held in great estimation for stuffing saddles and mattresses, hold out a powerful inducement to its destruction.

Nesotragus

Has the muffle large and bald; the crumen large, deep, and arched; the face and forehead not crested; the ears large; the horns nearly straight, elongated, strong, many-ringed, incumbent, nearly parallel in the direction of the facial line; no false hoofs; the tail very short; the females hornless.

25. *N. moschatus* is the only species. It is an inhabitant of the island of Zanzibar. It was first described by Von Duben. Male and female specimens exist in the Stockholm Museum.

Neotragus

Has no muffle; the nose ovine; the nostrils close together; the crumen roundish; the horns short, conical, and recumbent; the tail very short; the crown crested; females hornless.

26. *N. Saltiana* (*Antilope Saltiana*, Blainville), the Madoqua. This is perhaps the smallest of all horned animals, being scarcely the size of a good English hare. It measures 2 feet in length from the nose to the root of the tail, and about 14 inches in height at the shoulder, the height at the croup being about an inch more. The length of the head from the nose to the ear is 5 inches, that of the horns 3 inches; the ears are 2¾ inches long, and the tail 1½ inch. The horns of the male are situated in the plane of the forehead; they are very sharp-pointed, almost insensibly bent outwards and forwards, provided on the inner anterior margin with a prominent sharp ridge, which runs from the base to within a quarter of an inch of the points, and annulated for about two-thirds of their length from the roots. The females are without horns, but have, in common with the males, a tuft of long stiff hair standing upright from the crown of the head, and forming a small crest, particularly remarkable in the females, from their not being furnished with horns; the hair on all other parts of the body is short, close, and smooth, except on the hind side of the hips and thighs, where it is rather longer, and radiates outwards and round the tail, its pure white colour contrasting agreeably with the colours of the croup and thighs; the face, forehead, and legs, as well as the tuft of long hair between the horns, are of a bright and deep red, as are likewise the backs of the ears; the neck, shoulders, flanks, rump, and outsides of the thighs, are of a clear gray colour, like that of the American gray squirrels, each hair being annulated with alternate rings of black and white; the back, from the shoulders to the rump, is a deep reddish-brown; and the breast, belly, interior of the fore arms and thighs, and hinder surface of the hips, of the most pure unmixed white, forming altogether a variety, clearness, and brilliancy of colouring rarely met with among quadrupeds. The tail is very short, being in fact little more than a mere stump; the ears are round and nearly the length of the horns; the hoofs small, well-formed, and, like the horns, of a deep black colour; the forehead is perfectly flat, and the head is compressed suddenly below the eyes, and tapers to a small and attenuated snout; the legs are long in proportion to the weight of the body, and so small that they scarcely equal the little finger in thickness.

The Madoqua (*N. Saltiana*).

The Madoqua is found in all parts of Abyssinia, where it was originally noticed by Bruce, who discovered it in the country about the sources of the Abai, or eastern branch of the Nile. Mr. Salt afterwards procured specimens in the mountains of Tigré, and sent the horns and legs to the British Museum, where they were observed by De Blainville, and described under the specific name of *Antilope Saltiana*, in compliment to the distinguished traveller who procured them. More recently complete specimens have been brought to Europe by Rüppell, and Hemprich and Ehrenberg, and the species has been well described and beautifully figured both by these travellers and in the 'Darstellung Neuer oder Wenig-Bekannter Säugethiere' of Professor Lichtenstein. Little is known regarding the habits of this species. It is said to live in pairs in mountainous districts; and Pearce informs us that many of the Abyssinians object to eat its flesh, from a superstitious belief of its being often found in the society of monkeys and baboons.

Cephalopus

Has a large muffle; the tear-bag absent, but it is replaced by a naked glandular line formed of two series of pores on the side of the cheek; the crown crested, forming a tuft between the horns; the horns short, conical, placed far back on the hinder edge of the frontal bone, and inclined backwards. This genus contains several species.

27. *C. quadriscopa* (*Antilope quadriscopa*, Hamilton Smith), the Four-Tufted Antelope, is known only from Colonel Smith's description and figure of a male specimen formerly exhibited at Exeter Change. The individual from which Colonel Smith's description was taken was brought from Senegal.

28. *C. Grimmia* (*Antilope Grimmia*, Desmarest), the Impoon, Duyker, or Duyker-Boc, is of a yellowish-brown colour, and grayish in winter. The hair is yellowish, with black tips. The forehead yellowish-bay; the inside of the ears, chin, throat, abdomen, inside of fore and hind legs, and under side of tail, white; the feet, streak on the nose and up the legs, and upper part of the tail, black; the ears elongated, nearly as long as the head, acute; the horns black, elongated, slender; the base rugose, subangular in front; the skull small and short.

The Duyker-Boc, or Diving-Goat, so called by the Dutch of South Africa from its habit of plunging under the bushes in its passage through the woods, instead of leaping over them like the generality of other Antelopes, is a common animal in Kaffraria and in all parts of the Cape Colony which abound in forest and underwood, from the cover of which it seldom ventures, unless occasionally at night to steal into a neighbouring garden. It is found alone or in pairs, makes its way readily among the thickets and low bushes, and when pursued will from time to time stand up on its hind legs to look round it, then dive under the branches to reappear again at some distance; and thus alternately continuing its flight, and standing up at intervals to watch the motions of its pursuers. The peculiar nature of the humour secreted by the maxillary glands of this animal has given origin to a common saying among the Dutch colonists, that it carries the gall-bladder under the eyes. This species is most probably the animal of which the female was long since imperfectly described by Grimm, and which has been admitted into systematic catalogues under the name of *Antilope Grimmia*. The *A. Platous* of Colonel Smith likewise appears to be identical with, or at most a casual variety of the Duyker-Boc, the characters upon which the separation is made being by no means constant, and some of them even of doubtful authenticity. The *Capra sylvestris* (*Africana* of Grimm), is probably this species. *Fitomba* or *Philatomba* appears to be the Kaffrarian name for all the Bush Antelopes or species of *Cephalopi*.

29. *C. Campbelliæ* (*Antilope Campbelliæ*, Gray), the Black-Faced Philatomba. This species differs from the Duyker by being much darker and more distinctly grisled or dotted, and the under side being much whiter. It is possible that it is only a variety of that species.

30. *C. Burchellii* (*Antilope Burchellii*, Smith), Burchell's Bush-Boc. This species is easily known from the two former by its darker colour, and by the under sides and inside of the legs being nearly of the same colour as the back, and not white; and also by the shortness of the intermaxillary bones, and the width of the nose-hole. It inhabits the districts more or less covered with underwood in Kaffirland, and the country north of the Orange River. When interrupted or pursued by dogs, it springs with considerable activity over such bushes as may stand in its course, and endeavours to plunge into the closest bushes for concealment.

31. *C. Madoqua* (*Antilope Madoqua*, Rüppell), the Abyssinian Bush-Goat, is of a yellowish-brown colour, slightly punctulated with black; the neck is yellowish, the limbs blacker; the face-streak and feet black; the hair rather close-pressed, reddish-gray at the base;

upper part polished, yellow-brown, with dark tips; the forehead is reddish. This species inhabits Abyssinia, and is the Madoqua of Bruce.

32. *C. coronatus* (*Sylvicapra coronata*, Sundevale), the Red-Crowned Bush-Buck, is a species found in Western Africa, and is very distinct from the last, its colour being lighter, and the fur less rigid and close-pressed.

33. *C. sylvicultrix* (*Antilope sylvicultrix*, Afzelius), the White-Backed Bush-Buck, the Bush-Goat, and Bush-Antelope, is about 5 feet in length from the muzzle to the root of the tail, 3 feet high at the shoulder, and 3 feet 2 inches at the croup: the head, measured from the muzzle to the base of the horns, is upwards of 10 inches long, the horns and ears each 4 inches, and the tail with the hair half a foot. The circumference of the horns at the base is 3 inches, and their distance at the points 5 inches; they grow entirely in the direction of the forehead; are pointed, black, shining, nearly straight, with a slight inclination backwards, and diverging gradually towards the points. For about half an inch from the base they are finely marked with a number of small transverse striæ, then covered for about an inch with little depressions and inequalities, and smooth from thence to the points. The ears are situated rather close to the horns; they are about the same length as these organs, broad, open, rounded at the top, and nearly naked; the eye-lids are bordered with thick black lashes; the tail is bushy and pendent; the buttocks nearly naked; the limbs short and slender; the knees unprovided with brushes; and the female furnished with two teats. The hair is in general remarkably short, sleek, and shining, of a deep brown colour, rather paler on the neck and flanks, mixed with gray on the thighs, almost yellow on the throat, dun on the cheeks and sides of the jaws, clear brown on the face, nose, and backs of the ears, and chestnut-brown on the legs and feet. A tuft of long hair surrounds the base of the horns, and along the middle of the back is a longitudinal line of silvery gray which expands upon the croup, and is provided with hair considerably longer than that on the rest of the body. The tail is black, covered with moderately long hair, and without a terminal tuft.

The proportions of this species are heavy and ungainly, and bear a considerable resemblance to those of the Hog-Deer of India. The legs are short and slender, and appear disproportioned to the size of the body, which is large and heavy; the head, too, is thick and clumsy, though much attenuated towards the muzzle; the neck short and thick; the croup depressed; and the back very much arched. This species inhabits the west coast of Africa, about Sierra Leone, and the sources of the Pongas and Quia rivers. It frequents the thickets and underwood of the upland plains and moderate mountain declivities, keeping close to the cover during the day-time, and quitting it only at early dawn for the purpose of feeding in the neighbouring meadows. It is at this time that it is pursued by the hunters, who station themselves on the margin of the woods, and shoot it as it comes out to graze. It is a slow heavy runner, as might be anticipated from the size and corpulent make of its body, and the shortness of its legs. It affords excellent venison, and is much sought after on that account. It has long maxillary glands, but no appearance of lachrymal sinuses.

34. *C. Ogilbii* (*Antilope Ogilbii*, Waterhouse), the Black-Striped Bush-Buck, is of a pale bay-brown colour, with a deep black dorsal streak, pale beneath; the crown and haunches brighter bay; the neck, withers, and side of the dorsal line varied with deep brown hairs; the streak up the fore legs, upper part of hock, feet above the hoofs, and end of the tail, black. The horns are short, thick, conical, very rugose on the inner front edge of the base. This species is a native of Fernando Po, and was named by Mr. Waterhouse after Mr. Ogilby, the late secretary of the Zoological Society, and the author of the article 'Antelope' in the 'Penny Cyclopædia.'

35. *C. badius*, the Bay Bush-Buck, is very like the last species, but is of a darker bay colour; the legs are blackish; and the neck bright bay, and not blackish-bay as in *C. Ogilbii*. It is a native of Sierra Leone.

36. *C. dorsalis*, the Bay Bush-Goat, is of a dark-bay colour, with shoulders and legs darker. The hair is brown, a few hairs on the haunches tipped with white; the crown and nape, and a broad dorsal stripe, black; a spot over each eye, the lips, sides of chin, front of chest, under side of tail, and inside of the thighs, pale brown. It is a native of Sierra Leone.

37. *C. niger*, the Black Bush-Buck, is a native of the coast of Guinea, distinguished by its sooty-black colour.

38. *C. Natalensis* (*Antilope Natalensis*, A. Smith), the Natal Bush-Buck, or Rhoode-Boc, is of a bright red-bay colour, and has short conical horns. It inhabits the forests about Port Natal and the country to the eastward, living in the thick brushwood which fills up the intervals of the larger trees. It feeds on grass, the young shoots of trees, and the delicate twigs of smaller shrubs. It occupies the same position at Natal that the little Blue Antelope does at the Cape.

39. *C. rufilatus* (*Antilope Grimmia*, H. Smith), the Coquetoon, is of a deep reddish-bay colour; the legs, nape, streak on the nose to the crown, and broad streak on back, blackish-gray; the ears blackish; the crest and upper part of tail black; the cheeks rather paler; the inside of ears whitish; the horns conical, rather elongated, obscurely annulated, and slightly recurved. This is the Grimme of Buffon and F. Cuvier. It is a native of Western Africa.

40. *C. Maxwellii* (*Antilope Maxwellii*, H. Smith,) the Guevei, is of a gray-brown or sooty-black colour. It has a rather rigid fur, and the abdomen and front of the thighs white. It is the Guevei of Buffon, the Royal Antelope and Pigmy Antelope of Pennant and Shaw. It is a native of Senegal and Gambia.

41. *C. pygmæa*, (*Antilope perpusilla*, H. Smith), the Noumetzi, Cape Guevei, or Kleene-Boc, is about 1 foot high at the shoulder; the horns 1½ inch long in the male, three-quarters of an inch in the female, and the tail about 2½ inches. The horns are small, erect, black, slightly inclined backwards and towards one another at the points, and very sharp, with seven or eight minute annuli at the base; the ears about the same length as the horns, perfectly round at the tips, and nearly naked within; the head is long and pointed; the maxillary glands not parallel to the plane of the face, but nearly in the same line with the greater axis of the orbits, or rather in lines parallel to them; the forehead and nose are brown, bordered on each side by a narrow line of a sandy-red colour passing from the root of the horns down to the muzzle; the upper parts of the body are of a uniform dark slaty-brown colour; all the inferior parts, including the region under the chin, the breast, belly, interior of the fore arms and thighs, and under-surface of the tail, ashy-gray, inclining to white in some specimens, particularly in young individuals; the legs are reddish-brown; and the hoofs small, narrow, and pointed.

Kleene-Boc (*A. perpusilla*).

This species, called by the Dutch colonists of the Cape Kleene-Boc. Kleene Blauw-Boc, Blauw-Bokje, all signifying Little Goat or Little Blue Goat, inhabits South Africa, and lives singly or in pairs among the bushes. It is extremely active, and of a mild and timid disposition; but from the nature of the thick bushes in which it resides is not often seen even in those districts where it abounds most plentifully. It is said to exhibit considerable sagacity in eluding pursuit, and when domesticated soon becomes familiar, and learns to distinguish those about it, and to answer to its name. This species is also the *A. cærulea* of Colonel Smith and the *A. pygmæa* of M. Desmarest, who confounds it with the last species.

42. *C. melanorheus*, the Black-Rumped Guevei, is of a gray colour, with the rump and upper part of the back of a black colour. It is a native of Fernando Po.

43. *C. punctulatus*, the Grisled Guevei, is a native of Sierra Leone, and is of a dark fulvous-brown colour.

44. *C. Whitfieldii*, the White-Footed Guevei, is of a yellowish ash colour; the streak over the eyes, cheeks, throat, belly, inside of the limbs, and ring round the feet above the hoofs, ashy white. It is a native of Western Africa.

Nanotragus

Has very short conical horns; small rounded ears; slender legs; a subpectinate tail, and small triangular hoofs.

45. *N. perpusillus* (*Capra perpusilla*, Linnæus), the Royal Antelope, the Guinea Musk, and Pigmy Musk, is a native of Guinea. It is of a fulvous colour, and has the throat, belly, edge of the thigh, and tip of its tail, white.

Pelea

Has conical, erect, scarcely diverging horns, bent forward at the tips; the face narrow and elongated; the nose swollen; the muffle large, extended far behind the nostrils; the fur soft and woolly; the hoofs and false hoofs rather large; the inguinal pores distinct; the teats four.

46. *P. capreola* (*Antilope capreolus*, Lichtenstein), the Reh-Boc

or Peele, is nearly 5 feet in length, and 2½ feet high at the shoulder; the head is 6 inches long from the muzzle to the root of the horns; the ears and tail, without the hair, about the same length; and the horns of the old male from 9 to 12 inches. The head is long, and tapers gradually to the muzzle, which is small, round, and of a black colour; the horns are perfectly smooth and without any appearance of wrinkles or annuli for the two-thirds of their length next the points, but exhibit a few obscure wrinkles at the base; they are remarkably slender, long, straight, parallel, and so sharp at the points that the Hottentots and Bushmen use them in place of needles and bodkins; the ears also are long, very broad at the base, and attenuated towards the points; the tail long and bushy; the hair, or rather fur, is of a woolly quality, and of a uniform ash colour on the neck, shoulders, sides, croup, and thighs, and white or light gray on the breast, belly, and inner side of the arms and thighs. In young individuals it is beautifully frizzled or curled into distinct locks, and its colour is much clearer than in the adults, which have it straight, loose, and often tinged with a sandy-brown hue on the upper parts of the body. The hair of the legs in the young animal is likewise long and curly like that of a young lamb, but in aged specimens the legs are covered with short close hair of the common quality, and frequently with more or less of a dark brown colour. The hair of the head, face, and cheeks is always short, crisp, and close; it is brown on the nose, light fawn on the forehead and cheeks, and white about the margins of the lips and underneath the chin; the tail is slaty-gray above, and white below, and at the tip; and there is a conspicuous black spot at the angle of the mouth on each side. The hairs individually are obscurely annulated with alternate rings of a gray and light rufous-brown colour, the latter becoming more conspicuous as the animal advances in age, and communicating to the general colour of the fur the light rufous shade already mentioned.

The Reh-Boc or Rhee-Boc is of a lighter and more graceful form than the generality of the other antelopes included in the present section. The body is long and small, the neck particularly so, and the legs slender and well-proportioned. Its pace, consequently, is proportionally swift; it runs with great velocity, keeping close to the ground, and moving by long strides, and with a motion so rapid and uniform that it seems to glide rather than run. The Reh-Bocs live in small families of five or six individuals, consisting of an adult male and three or four females with their young. The males are pugnacious, and compel the young of their own sex to separate themselves from the family as soon as they become adult. Their general residence is on the sides of moderate hills, among stunted trees and underwood, or in the rocky glens and mountain-passes, in the vicinity of the little pools of water which remain after the winter-torrents have ceased to flow. Wherever such situations are found, the Rhee-Boc is not an uncommon animal in South Africa. Its flesh is dry and insipid, and esteemed less than that of any other of the numerous Cape Antelopes. The female produces but one at a birth, which grows rapidly, and, if caught at an early period, is readily domesticated.

Eleotragus

Has the horns conical, thick, diverging, bent back and then bent forwards at the tip; the face broad; the muffle rather large; the fur harsh, and that of the back more or less whorled; the hoofs and false hoofs rather large; the inguinal pores distinct; four teats.

47. *E. arundinaceus* (*Antilope Eleotragus*, Schreber), the Inghalla Riet-Boc, or Reed-Buck, so called from its habit of frequenting the reedy banks and beds of dry water-courses, is 4½ feet in length, and 2 feet 9 or 10 inches high at the shoulder. The head is 10 inches long from the muzzle to the base of the horns; the horns 10½ inches in a straight line, and 13 inches along the curves, and the tail 11 inches. The horns are round, annulated at the base, with prominent sharp rings and beautifully striated between, smooth and sharp at the points, and curved forwards with a bold and regular sweep, so as to form almost the segment of a circle. The ears are long and pointed, filled internally with a profusion of whitish hair, and beneath them, on each side of the head, there is a remarkable bald spot of an oval form and shining black colour, which is very characteristic of the species, and readily distinguishes it from all the other antelopes with which it is likely to be confounded. The hair over every part of the neck and body is long and rough, of a uniform dull ashy-gray colour, sometimes tinged with red on the upper parts, and silvery-gray on the throat, breast, belly, and interior of the fore arms and thighs. The tail is long and remarkably bushy, being covered with a profusion of long woolly hair, for the most part of a white or gray colour, with a narrow brown line running down the middle of the upper side. The females are in all respects similar to the males, excepting that they are without horns, and of rather smaller stature.

The Riet-Boc is not found in the immediate vicinity of the Cape, but farther in the interior of the country it is by no means uncommon, living in pairs or small families, and, as already observed, frequenting the reeds and rushy banks of mountain-streams which flow only during the winter season, and are dried up by the summer heats. Sometimes also it is found in woods along the banks of rivers, but always in the neighbourhood of water; and a variety, if not a distinct species, is even said to inhabit the plains. This is of a very deep reddish fawn-colour, and has been described by Afzelius and Hamilton Smith as a distinct species under the denomination of *A. fulvo-rufula*. Excepting in the redder shade of its colour, however, and the name of *Roode Rhee-Boc*, or Red Roe-Buck, by which it is said to be distinguished among the Dutch colonists at the Cape, it does not appear to differ materially from the common variety, and the slight shades of variation which it does present, are most probably the effects of its difference of habitat and other accidental circumstances. The same may be said of the *A. Isabellina*, or Cream-Coloured Antelope of these authors, which does not appear to present any characters sufficiently marked or peculiar to be considered as indicative of a specific distinction.

Rietboc (*E. arundinaceus*).

48. *E. redunca* (*Antilope redunca*, Pallas), the Wonto, or Nagor, known only from the description of Adanson and the figure of Buffon, is a species so nearly resembling the Riet-Boc that some naturalists have not hesitated to unite them. It is 4 feet long from the muzzle to the origin of the tail, 2 feet 4 inches high at the shoulder, and 2 feet 6 inches at the croup; the head [illegible] inches long, the horns 5½ inches, and the ears 5 inches. The horns have one or two annuli at the base, but are smooth and shining throughout the remainder of their length; they are erect, parallel, and almost straight till within a short distance of the points, where they curve forwards. The colour was uniform fawn or pale red, without any white about the breast or belly, and the hair was long, rough, and undulating, and did not lie smooth or close to the body—characters which all tend to approximate the animal to the Riet-Boc, and more particularly to the variety which is said to inhabit the plains. It is found in the neighbourhood of Goree, on the west coast of Africa.

Dr. J. E. Gray refers the Bohor (*Antilope Bohor*, Rüppell) as a variety to this species. He says, "When in Frankfort I observed that the male *Antilope Bohor* from Abyssinia was rather larger than the male of *A. redunca* from Senegal, in the same collection, and the horns more slender; the female was darker and browner than the male: both sexes have more black in the carpus and tarsus than the specimen of *A. redunca* in the same museum."

The genus *Raphicerus*, of Colonel Hamilton Smith, appears to be a very doubtful one. Dr. J. E. Gray says that the author formed it "from two pairs of horns on part of the frontal bones in the College of Surgeons, which he called *Raphicerus acuticornis* and *R. subulata*." The figures are not sufficient to identify the species, and we now know that the horns differ greatly in individuals of the same species, and during the growth of the same specimen. *R. acuticornis* may be the horns of the Duyker-Boc (*Cephalopus Grimmia*).

2. *Cervine Antelopes.*

These Antelopes have rather a heavy body; an elongated tail, with short hair at the base, and a tuft of longer hair at the tip; the horns elongated and generally of a large size.

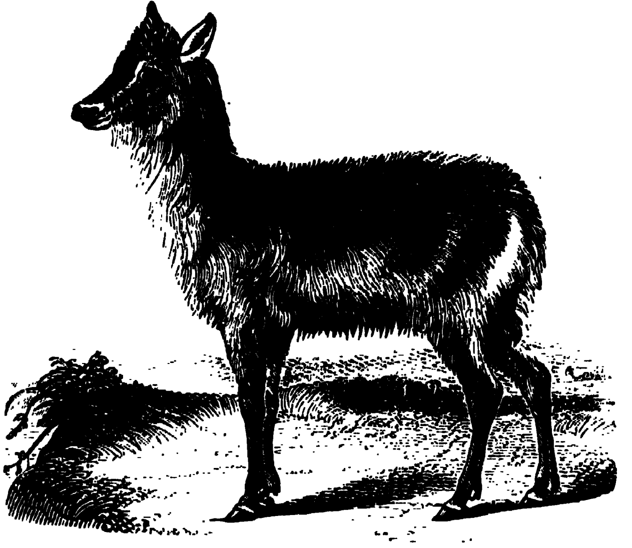
Adenota

Has a cervine muffle, cordate, and moderate; the nose hairy between and over the nostrils; the horns sublyrate, ringed, when young recurved; no tear-bag, or covered by a tuft of hair; the hair of the back whorled, and the hair of dorsal-line and back of head reversed; the tail elongated and hairy.

The only species of this genus is very like the species of *Eleotragus*, but has a smaller and more cervine muzzle and lyrated horns. It differs from the next genus in the form of the tail and absence of the mane, and from it and *Eleotragus* in having a tuft of hair in front of the orbit.

49. *A. Kob* (*Antilope adenota*, H. Smith), the Æquitoon, or Kob, is of

a pale brown colour. The end of the nose, the inside of the ears, the chest, belly, and inside of the legs and thighs, tip of tail, and end-band above the hoofs are white; the front of the fore and hind legs, and the end of ears and tail, black; the hair of dorsal-line reversed, with a whorl on the shoulder and loins. There has been a good deal of confusion about this species. The figure that we have given was referred by Mr. Ogilby, in the 'Penny Cyclopædia,' to a new species which he named *Antilope Koba*. His description of the animal, however, refers to the *Antilope Sing-Sing* of Bennett, the *Kobus Sing-Sing* of the British Museum Catalogue. On this species Dr. Gray makes the following observations:—



Equitoon (*Adenota Kob*).

"A fine pair has been at Knowsley some years. Thinking them new I described them as *A. annulipes*. Mr. Ogilby has called it the Nagor; but it is scarcely the Nagor of Buffon. An adult male noticed by Mr. Ogilby as the Kob is now in the museum of the Zoological Society. Its horns, like the male at Knowsley, are much worn down. They whistle like a stag. Buffon ('Hist. Nat.,' 12—219, 267, t. 32, pl.) figures a skull with horns brought from Senegal, by Adanson, under the name of Kob, which is also called the *Petit Vache Brune*. Erxleben gave this figure the name of *A. Kob*, and Pennant called it the Gambian Antelope ('Syn.' i. 39).

"The figure somewhat resembles the head of a half-grown male of this species, but the horns are longer and have more rings than the specimen in the British Museum; but I am inclined to agree with Mr. Ogilby in believing that it was intended for this species. In the Jardin des Plantes they called the Sing-Sing the Kob of Senegal. This may be a mistake for the Koba. I may remark that the horns of the Koba, in the same plate of Buffon, are represented with more rings than are mentioned in the description.

"Colonel Hamilton Smith describes two figures, a male and female specimen, which were alive in Exeter Change; and figures the male and its skull and horns under the name of *A. adenota*, which well agrees with this species, and has the peculiar distribution of its hair —hence its name: but he says, 'It has a long open suborbital slit, and small black brushes on the knees;' but this I suspect must be a mistake, as he himself observes that no lachrymal cavity was found in the skull. He might have mistaken the tuft of hair for the gland, at the distance at which he saw the specimens.

"He also ('G. A. K.' iv. 221) described a specimen which was in Exeter Change, which he regarded as the Gambian Antelope of Pennant, and calls it *A. forfex*. His characters agree in most particulars with this species, but he says, it had 'a long lachrymal sinus, and had small brushes on the knees.' If there was not some mistake in transcribing these descriptions, both these animals should be *Gazellas*, but I have never seen any which agreed with them.

"The young male in the British Museum shows the development of the horns of these animals. The upper rings of the growing horn falls off in large thick flakes as the horn increases in size beneath: this explains how the extent of the smooth tapering part of the horns increases in length as the horn grows; and how the number of rings are found to be nearly the same in the various ages and different individuals of the various species. Mr. Whitfield informs me that the scrotum is rarely developed or dependent externally in different kinds of antelopes before they have completed their first year."

50. *A. Lechée*, the Lechée. This animal is nearly as large as the Water-Buck. It is of a pale-brown colour. The orbit and lower part of the body is whitish; the front of the legs is dark brown; the horns are elongate and strongly knotted in front; the withers have a small roundish whorl of hair. It is a native of South Africa on the banks of the river Zouga, lat. 21°. There is a male specimen in the British Museum.

Kobus

Has the horns elongated, sublyrate, bent back, and then forward at the tip; the muffle cervine; no tear-bag or inguinal pores; the hair rough and elongated; the neck covered with longer diverging and drooping hair; the tail rather elongated, depressed, hairy on the sides and below. The females are hornless and have four teats.

51. *Kobus ellipsiprymnus* (*Antilope ellipsiprymna*, Ogilby), the Photomok, or Water-Buck. The following is Mr. Ogilby's description of this animal in the 'Penny Cyclopædia:'—The whole length of the animal from the muzzle to the root of the tail was 7 feet 3½ inches; its height at the shoulder nearly 4 feet, and to the top of the horn upwards of 7 feet; the horns measured 30 inches upon the curves, the ears were upwards of 8 inches long, and the tail, with its terminal tuft, 1 foot 9 inches. The horns are very thick and heavy; they spread widely outwards, are nearly straight for the first half of their length, and then turn forwards with a gradual and uniform curvature. They are surrounded with 24 prominent annuli, forming large knobs in front and deeply striated between, but nearly obliterated behind; the last six inches are smooth, and the points blunt. Next to the character of the horns, this species is most readily to be distinguished by a ribbon of pure white, which passes over the croup and down each hip, uniting between the thighs, and forming a perfect ellipse, having the root of the tail in one of its foci, and contrasting most singularly with the dark rusty iron-gray of the surrounding parts. It is to this mark, which is so peculiarly characteristic of the species, that the name of *Ellipsiprymnus* refers. This animal is a native of South Africa, from whence it was originally brought by Mr. Steedman and exhibited with other specimens of South African animals in the Colosseum, Regent's Park. It has got the name of Water-Buck from its habit, when alarmed, of rushing into and crossing very rapid rivers. It lives in small herds on the banks of rivers, and has not been known to occur south of 26°. The flesh is not regarded as good for food, as it has a rank pungent smell, and disagreeable taste.

52. *K. Sing-Sing* (*Antilope Koba*, Ogilby), the Sing-Sing. This species differs in the tints of its colouring as well as the length of its hair at different seasons of the year. The following are the characters of the species. The colour is reddish or yellowish-gray brown, rather grayer on the shoulders; the nose, lips, hinder-parts of the thighs, under the neck from the ears to the gullet, a streak over the eye, and ring above the hoofs and false hoofs, white; the belly and legs, end of tail and legs, from shoulder to hock, black. The females are grayer and have the belly and upper part of the legs paler.

This animal is called Sing-Sing by all the negroes. They do not think that their flocks will be healthy or fruitful unless they have a Sing-Sing with them, just as a fancy is entertained by some persons in England for having a goat in a stable. The English on the Gambia call it a Jackass-Deer from its appearance, and it is called Koba and Kassimause by the negroes at Macarthy's Island. Its flesh is strong, and not pleasant eating. As far as can be judged by recollection and description, the adult specimen at Knowsley, the young male and adult female in the British Museum, the male and female at Frankfort, and the adult male in the Paris menageries, are the same species.

Buffon figured ('Hist. Nat.,' 210, 267, xii. t. 32, f. 2,) under the name *Koba*, a pair of horns which were in the library of St. Victor at Paris. He described them as larger and more curved above than those of the *Kob*, 18 inches long, and 5 inches in circumference at the base; and he refers them to an animal which Adanson says is called Koba in Senegal and the Great Brown Cow by the French colonists. Pallas refers these horns to *A. Pygargus*, and the figures and description agree in many particulars with the horns of that species, but they are rather longer and have more rings. Pennant ('Syn. Mam.' 38) gave the name of Senegal Antelope to Buffon's short account and figure, but has added to it the description and figure of the head of a skin which came from Amsterdam, and appears to be *A. Caama* of South Africa. Cuvier ('Dict. Sci. Nat.' ii. 235,) only translated Pennant's name to *A. Senegalensis*. Erxleben ('Syn.' 293) and Zimmermann ('Zool.' 345) have translated Pennant's description of his skin from Amsterdam of *A. Caama*, and called it *A. Koba*, referring to Buffon's description and Daubenton's figure. Fischer, Hamilton Smith, and M. Sundwall regard the Koba of Buffon the same as the Korrigum of Denham and Clapperton; but the horns of that species are considerably larger and much thicker at the base than those described by Daubenton, and the annulations of the horns are higher and more regular. It should be remarked that Buffon describes his horns as having 11 or 12 rings, but figures them as having 17 or 18. Mr. Ogilby ('Penny Cyclopædia' and 'Proceedings of Zoological Society') considers Buffon's Koba to be the Sing-Sing, from the length of the horns, and in the number, disposition, and form of the rings. His figure more nearly agrees with the horns of that species than of that of the *A. Pygarga*, to which Pallas first referred it; but the horns, according to Dr. Gray, are represented much more lyrated than any horns of the Sing-Sing; indeed, not one of the specimens which had come under his observation had had any inclination to assume that form; but as this is the only West-African species which in any way agrees with Buffon's figure, perhaps it is best to adopt Mr. Ogilby's suggestion. The name of Koba or Kob appears to be common to many species. Schinz erroneously considers *Damalis Senegalensis* (*Antilope adenota* and *A. forfex*, H. Smith), as synonyms of this species. (Gray, 'British Museum Catalogue,' Mammalia, Part III., p. 101.

Ægocerus

Has conical, elongate, recurved, rather compressed, ringed horns, arising immediately above the orbits; the nape with a linear, erect, reversed mane; the tear-bag covered with a tuft of hair. The female is horned, and has two teats.

53. *Æ. leucophæus* (*Antilope leucophæa*, Pallas), the Etaac or Blauw-Boc is 6 feet in length, and 3 feet 7 inches high at the shoulder; the head is 9 inches long from the muzzle to the base of the horns; these are 2 feet 2 inches, measured along the curves; the length of the ears is 8 inches; and that of the tail, with its terminating tuft, 1 foot. The horns are round, uniformly curved backwards, and marked with from 20 to 30 prominent and complete rings, the last six inches being smooth, and the points very fine and sharp. The hide of this animal is perfectly black, and it is this colour reflected through the ashy-gray hair that communicates the dark-blue shade which has given rise to the name of Blauw-Boc, or Blue-Buck, by which it has long been known among the Dutch at the Cape of Good Hope.

The Blauw-Boc (*Æ. leucophæus*).

The Blauw-Boc lives in pairs or small families of five or six individuals on the open plains of South Africa, north of the Kurrichane. It is dangerous when wounded, and during the rutting season in particular is said to attack indiscriminately every animal that comes in its way. It is exceedingly swift. The flesh is eaten, but is not pleasant.

Antilope barbata, H. Smith, the Takhaitze, beautifully figured by Mr. Daniell in the 'African Scenery,' is a variety of this species, and differs from the Blauw-Boc by its long flowing mane, copious beard, and superior size. This animal inhabits the country in the vicinity of Latakoo, and is called Takhaitze by the Betchuanas. It is said to be so wild and ferocious that the natives are afraid to attack it openly with the assagai, or spear, as they do other game, but take it generally in pitfalls covered over with sticks and earth. It is commonly found in pairs upon the open plains, but when disturbed makes for the wooded heights, which are thickly covered with the common mimosa, upon which both this animal and the Giraffe delight to feed. The name Takhaitze signifies a fierce or wicked beast, and expresses the dread with which the resolution and prowess of this powerful animal inspire the Betchuanas, who seldom venture to approach it openly.

A. equina of Geoffroy is also a variety of this species.

Another probable variety is the Docoi, or White-Mouth of the Mandingos, the Kob or Koba of the Joliffs, the Vache Brune of the French in Senegal. Mr. Whitfield, who has brought several pairs of horns of this animal to England, says that the flesh is very good to eat.

54. *Æ. niger*, the Black-Buck, is black, with the face white, having a dark streak. The female and young are brown. This species is known from the description and specimens of Captain Harris, and also specimens in M. Sundevall's collection.

Oryx

Has elongate subulate horns, ringed at the base, straight or slightly arched, placed on a line with the face; the neck maned above and below; a subcervine nose, the nose only margining the nostrils; the hoofs narrow in front, and false hoofs large.

55. *O. Gazella* (*Antilope Oryx*, Pallas), the Kookaam or Gems-Boc. This is the Oryx of Cuvier, the Papan of Buffon, and the Egyptian Antelope of Pennant. It is a heavy stout animal, about 5 feet in length, and 3 feet 2 inches high at the shoulder; the length of the horns is from 2 feet to 2½, that of the ears 7 inches, and that of the tail 13 or 14 inches. The horns are almost perfectly straight, very little divergent, and situated in the plane of the forehead; they are obscurely annulated for half their length, black, and blunt in the male, but very sharp-pointed in the female. The ears are large and pointed, and the tail pretty uniformly covered with long black hair, forming a large switch. The general colour of the body is dark rusty-iron gray on the upper parts, and white on the under, the two being separated on the flanks by a broad longitudinal band of dark brown or black; and the hair of the back and neck reversed. The head is white, and is marked with two transverse bands of deep black, rising from the root of the horns and passing down the face, then encircling the eye, and uniting under the lower jaw with those of the opposite side. From this point a black band passes down the throat upon the chest, where it divides into four, one pair of which pass along the flanks and divide the colours of the upper and under parts of the body, the other pair encircles the fore arms; the thighs are likewise black, whilst all the rest of the limbs is white, except a black mark on the canons. On the upper surface, the black line passes down the neck and back, and expands into a broad disk on the rump. These colours are all boldly separated from one another, and the harshness of their contrast produces a very singular effect upon the appearance of this animal.

Gems-Boc (*Oryx Gazella*).

The *Oryx* inhabits the karroos of South Africa. It is never found in the woods, but keeps on the open plains, and lives in pairs or small families of four or five individuals. It is extremely dangerous to approach when wounded, if not completely disabled, making vigorous use of its long powerful horns, and it is said being not unfrequently the first to commence the assault. We are even assured that the lion himself is afraid to attack this powerful and courageous animal, and that sometimes when, pressed by famine, he has ventured to do so, he has been beaten off with disgrace, or even paid for his temerity with his life. Captain Cumming says that it eats the bulb of the Water-Root, a Liliaceous plant.

56. *O. Beisa* (*Antilope Beisa*, Rüppell), the Beisa. Two specimens of this species exist in the Frankfort Museum, obtained in Abyssinia. They differ from the last species in having no bunch on the throat; the mane of the nape is small and indistinct, and they have no dark mark on the rump.

57. *O. Leucoryx* (*Antilope Leucoryx*, Pallas), the Oryx. This species, also referred to in various writers under the names of the Milk-white Antelope, the White Antelope, and the Algazel, is known to the Arabs by the name of Abu-hard, Jachmur, and Yazmur, and to the Persians as El-Walrugh-el-Bukras. It is perhaps the most celebrated of all the Antelope genus, being the species which is generally supposed to have given rise to the fabulous Unicorn of the ancients. It is indeed, properly speaking, the *Oryx* of ancient writers, but many modern authors have followed the example of Pallas in bestowing that name upon the *Oryx Gazella* of Southern Africa, with which it is impossible that the ancients could have been acquainted, whilst the present species has received the name of *Leucoryx*, from an epithet bestowed upon it by Ælian on account of its white colour. The horns are at first directed in the plane of the forehead, and have a single gradual and moderate curvature throughout their whole course, forming, as it were, the segments of a very large circle; they are small in proportion to their great length, annulated about half way up, gradually attenuated, and very sharp at the points. The ears are long, erect, and pointed; and the tail is terminated by a very copiously furnished tuft of long hair of a mixed black and gray colour, which reaches below the hocks. The hair on the head, body, and extremities, is universally short, and lies smoothly along the hide, except upon the ridge of the back, where it is rather longer, and reversed, or turned towards the head in a direction contrary to that on the other parts of the body, and forming a short reversed mane from the middle of the back to the occiput. The head is

white, with a brown mark descending perpendicularly from each orbit, and expanding over the cheek, and a similar stripe passing down the centre of the face from the horns to the muzzle; the whole neck also, on the throat as well as on the upper part, is of a uniform rusty brown colour, but, with these exceptions, all the rest of the body, as well as the legs and tail, are milk-white.

The Oryx (*Oryx leucoryx*).

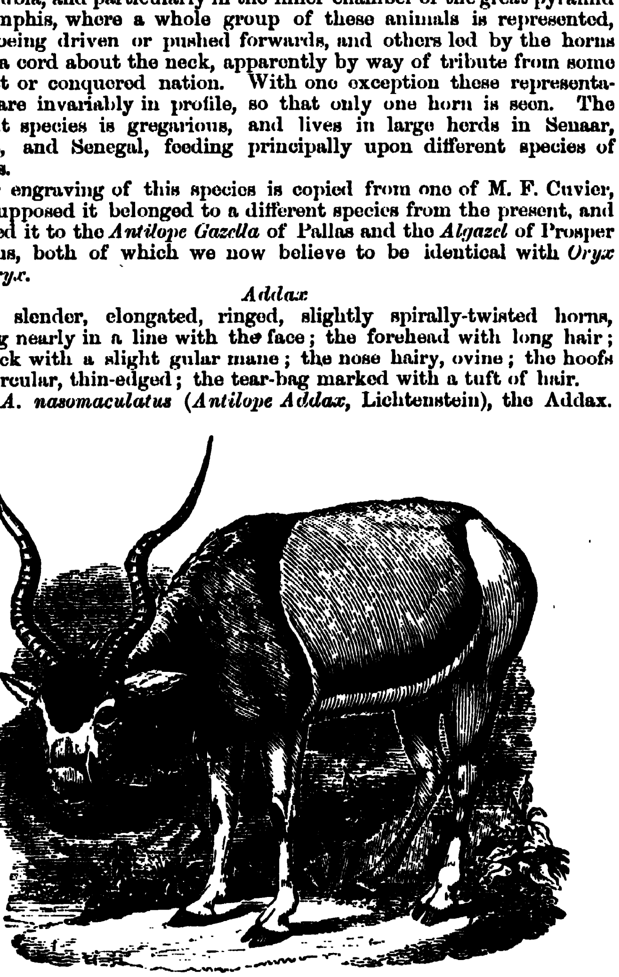
This species is frequently represented on the monuments of Egypt and Nubia, and particularly in the inner chamber of the great pyramid at Memphis, where a whole group of these animals is represented, some being driven or pushed forwards, and others led by the horns or by a cord about the neck, apparently by way of tribute from some subject or conquered nation. With one exception these representations are invariably in profile, so that only one horn is seen. The present species is gregarious, and lives in large herds in Senaar, Nubia, and Senegal, feeding principally upon different species of acacias.

Our engraving of this species is copied from one of M. F. Cuvier, who supposed it belonged to a different species from the present, and referred it to the *Antilope Gazella* of Pallas and the *Algazel* of Prosper Alpinus, both of which we now believe to be identical with *Oryx Leucoryx*.

Addax

Has slender, elongated, ringed, slightly spirally-twisted horns, sloping nearly in a line with the face; the forehead with long hair; the neck with a slight gular mane; the nose hairy, ovine; the hoofs semicircular, thin-edged; the tear-bag marked with a tuft of hair.

58. *A. nasomaculatus* (*Antilope Addax*, Lichtenstein), the Addax.



Addax (*Addax nasomaculatus*).

The Adax is mentioned by Pliny under the name of *Strepsiceros*, which, says he, the Africans call Addax (or it may be Addas, for the accusative *addacem* is the word used in the passage referred to, and it may be derived from either of these forms in the nominative). From the time of Pliny the only information which we had about this animal till a very recent period was derived from a figure and description of the skull and horns sent by our celebrated countryman Caius to his friend Gesner, and inserted in the great work of that early naturalist: the travellers, Rüppell, Hemprich, and Ehrenberg, re-discovered this species, and what is singular enough, under the ancient African name ascribed to it by Pliny, the Arabs still denominating it Akasch, Akas, or Addas, with the addition of the syllable *Abu* (father), which they bestow upon many other animals, as Abu-Hannis (Father John) for the Ibis, &c.

The length of the full-grown Addax is 6 feet from the muzzle to the root of the tail, and its height at the shoulder 3 feet; the horns, measured along the curves, are 3 feet long, the ears 6 inches, and the tail, with its terminating tuft, 1 foot. The animal is therefore about the size of a large ass, of which it has likewise much of the make and proportions, the heavy head, thick neck and legs, and switch tail. The horns are round, rather slender in proportion to their length, twisted outwards and describing two turns of a wide spiral, annulated to within five or six inches of the points, which are smooth and sharp; the form of the horns of the female does not differ from that of the male, but in the young they are almost straight. The ears are pretty long and proportionally broader than in most of the smaller antelopes; the tail reaches almost to the hock, and is terminated by a switch of long, coarse, gray hair. The whole head and neck, both above and below, are of a deep reddish-brown colour, except a transverse mark of pure white across the lower part of the forehead, between the orbits, which expands on the cheeks and half surrounds the eyes; a patch of black curly hair surrounds the root of the horns, and there is a scanty beard of the same colour on the larynx; all the rest of the animal, including the entire body from the neck backwards, as well as the legs and tail, are grayish-white; the hoofs are black, and remarkably broad, to enable the animal to pass more easily over the fine and loose sands of the deserts in which it resides.

These animals live in pairs on the sandy deserts of Central Africa and appear to extend over the greater part of the continent. Hemprich and Ehrenberg found them in Dongola; and a pair of horns were brought from Bornou by Denham and Clapperton, and deposited in the British Museum.

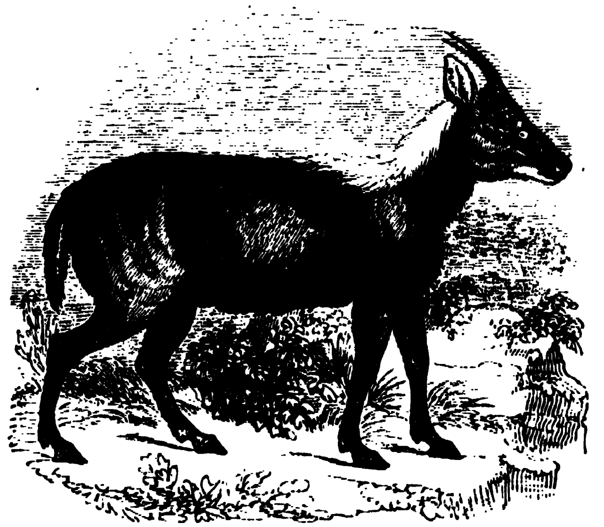
3. *Goatlike Antelopes.*

Those Antelopes have a heavy body; strong legs; the hoofs and false hoofs large; the tail very short, flat, and hairy above; the horns conical and recurved.

Capricornis

Has short, strong, conical, inclined, recurved horns, arising behind the orbit; the nose cervine; the muffle moderate; the tear-bag and interdigital pores large.

59. *C. Sumatrensis* (*Antilope Sumatrensis*, Desmarest), the Cambing Outan, or Sumatran Antelope, first noticed by Mr. Marsden in his 'History of Sumatra,' is about 4½ feet in length, and 2 feet 3 inches high at the shoulder. The horns are 6 inches long, very thick at the base and much attenuated, slightly and uniformly curved backwards. The muzzle is distinct and well formed; the lachrymal sinuses open by a small circular aperture, and between them and the muzzle, on each side, is a long linear space, nearly two inches in length by a quarter of an inch broad, naked, and covered with a soft black integument, which represents the maxillary gland, and secretes a particular humour. The ears and tail are of moderate length, the hoofs very large, the limbs short and stout, and the whole form of the animal robust and powerful. The body is thickly covered with a coat



The Cambing Outan (*C. Sumatrensis*).

of long hair, of a dark-brown colour, almost black, excepting along the nape of the neck, on the shoulders, and inside the ears, where it is white, and under the lower jaw, which is of a deep straw-colour. The white hairs of the neck and shoulders are much longer than on other parts of the body, and form a kind of flowing mane; the hair on the head and limbs, on the contrary, is much shorter than elsewhere, the knees are without brushes, and the tail, which is rather shorter than the ears, is covered throughout its whole extent with hair of moderate and equal length, and of the same dark-brown colour as that on the body.

The Cambing Outan, or Wild Goat, so called by the Malays, inhabits the hilly forests of Sumatra, and is described by Mr. Marsden as being of a wild character, extremely active and sure-footed, with much of the habits and character of the Common Goat and Ibex, of which it has the roving fearless eye and bold undaunted bearing.

60. *C. Bubalina* (*C. Thar*, Ogilby), the Thaar, Thar, Serow, or Imo, is of a gray, brown, blackish washed colour, with the crown and dorsal streak black; the nose, chin, inside of ears, lower part of mane and legs below the hooks, whitish. It is a native of Nepaul, and is principally known by the drawings and specimens presented by B. H. Hodgson, Esq., to the British Museum.

The Thar inhabits the central region of Nepaul, at an equal distance from the snows of the Himalayan range on the one hand, and the sultry heats of the low plains of India on the other. It is the most common of all the wild ruminants which are found in that country, and its chase is the favourite exercise and amusement of the hill tribes. Its flesh is indeed coarse, but there is plenty of it—and these rude people are easily satisfied on the score of quality, provided the quantity be sufficient. Its habits are wild and solitary; it is seldom found in herds, however small; the grown males especially live apart in the mountains, and never seek the society of their species except during the rutting season. As might be supposed from its heavy make and short stout limbs, it is a slow runner, and is soon brought to bay; but it leaps well, and makes its way over broken ground with greater ease than in open level situations. It is found from the eastern confines of Nepaul to the banks of the Sutlege, but abounds especially towards the east. The Thars differ from the Antelopes in being stout clambering animals, but they are not allied to the Ox-Tribe.

61. *C. crispa*, the Japanese Goat-Antelope, has a harsh crisp brown or brownish fur, with whitish sides, white cheeks, and legs black-brown. It is a native of Japan.

Nemorhedus

Has short, conical, inclined, recurved horns, arising from behind the orbits; the nose ovine, hairy; the fur short.

62. *N. Goral* (*Antilope Goral*, Hardwicke), the Goral, is of a gray-brown colour, minutely dotted with black; cheeks, chin, and upper part of throat, white.

The Goral was first described by General Hardwicke in the 'Linnæan Transactions.'

This animal inhabits the kingdom of Nepaul, and lives in large herds upon the elevated plains which crown the lower ridges of the Himalayan Mountains. It is wild and fleet, and when pursued flies to the rocky hills, where it easily escapes the hunter, and is indeed rarely taken except by stratagem. Its flesh is considered excellent venison. It is entirely confined to the cold upper regions of Nepaul, and is incapable of bearing the sultry heat of the plains of Hindustan.

Mazama

Has small, conical, round, nearly erect horns, slightly inclined backwards, and recurved at the tip, ringed at the base; the nose ovine, hairy; the fur double, the outer very long, hairy, and dependent, the under short and woolly.

63. *M. Americana*, the Mazame, or Spring-Buck. The colour of this creature is white; the horns and edge of the nostrils black. It is the Mountain Sheep-Antelope of Bennett, the Rocky-Mountain Sheep of Jameson. It inhabits the Rocky Mountains of North America.

Rupicapra

Has elongate slender round horns, nearly erect from above the orbit, and suddenly hooked backward at the tip; the nose ovine, hairy; the fur soft.

64. *R. Tragus* (*Antilope Rupicapra*, Pallas), the Chamois or Gems. It is the only animal of western Europe that partakes in any degree of the characters of the Antelopes. The horns are seldom more than 6 or 7 inches long, and are nearly parallel throughout their whole extent. The entire length of the body is about 3 feet 3 inches, that of the head to the root of the horns 6 inches, that of the ears 4 inches, of the tail 3¼ inches, and the height at the shoulders rather better than 2 feet. The whole body is covered with long hair, hanging down over the sides, of a deep-brown colour in winter and brownish fawn-colour in summer, being in spring slightly mixed with gray: the head is of a very pale yellow or straw-colour, with a dark-brown band on each side passing from the root of the ears to the corners of the mouth, and encircling the eyes and base of the horns; the tail is short and black, and the edges of the hips and interior of the thighs and ears alone white. The face is straight, as in the goat; the ears small, erect, and pointed; and the chin without a beard. In old individuals, particularly during the severe colds of winter, the cheeks chin, and throat turn white, and the breast and belly are at all times of a light silvery brown or yellow. Underneath the external covering there is a short thick coat of fine wool, which lies close to the skin, and protects the animal from the rigours of the cold mountain regions which it inhabits. The colours of both sexes are the same, but the females are rather smaller than the males, and have horns less abruptly hooked backwards. They go five months with young, and kid in March or April, producing one or very rarely two at a birth, which they suckle till the October following. The young are at first of a uniform deep yellowish-brown, with the lower jaw, sides of the head and throat, white; and the same dark bands through the eyes as in the adults only not extending so far back on the head.

The Chamois (*Rupicapra Tragus*).

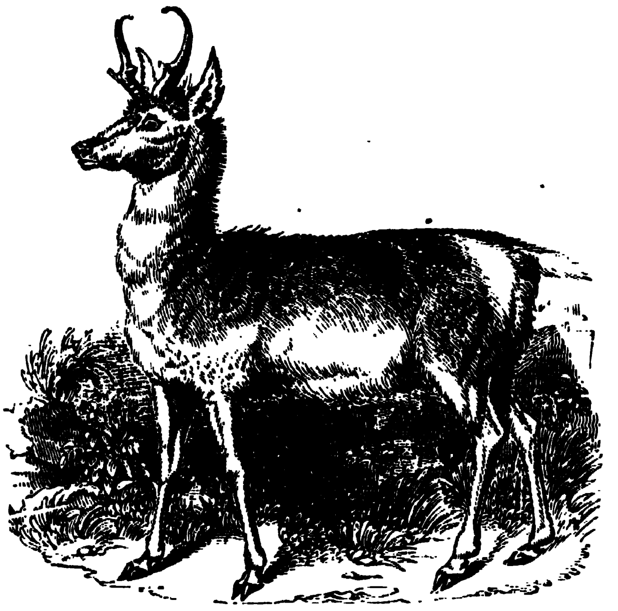
The Chamois, like the Ibex, inhabits the loftiest chains of the primitive mountain ridges, and displays all the vivacity, restlessness, and agility of the common goat. It is extremely impatient of heat, and during summer is only to be found on the tops of the highest mountains, or in deep glens where the snow lies throughout the year: in winter, however, it descends to the lower ridges, and it is then only that the hunters can pursue it with any hope of success. Its senses of sight and smell are remarkably acute; it scents a man at a very great distance, and displays the greatest restlessness and alarm till it obtains a sight of the object of its terror, leaping upon the highest rocks at hand in order to command a more extensive prospect, and uttering a suppressed whistle or hissing sound, being all the time in a state of the greatest agitation; but no sooner does he appear in sight than it flies with the utmost speed, scaling rocks which few other animals could attempt, and, if not intercepted by stratagem, soon leaves its pursuers far behind. The usual and most successful mode of hunting the Chamois is therefore for a party of hunters to unite, and surround some mountain-glen which they are previously known to frequent for the purpose of lying on the fresh snow during the day-time; towards this point the hunters advance simultaneously, when the animals, of course scenting those which come down the wind, retire in an opposite direction and are intercepted by another party. The food of the Chamois consists of mountain herbs, flowers, and the tender shoots of trees and shrubs; it seldom drinks. Nothing can be more admirable than the agility with which it ascends and descends rocks apparently perpendicular. It does not descend at a single bound nor in a vertical direction, but by projecting itself obliquely or diagonally forwards, striking the face of the rock three or four times with its feet for the purpose of renewing its force, or directing it more steadily to the point it aims at; and in this manner it will descend a rock almost perpendicular of twenty or thirty feet in height, without the smallest projection upon which to rest its feet. This animal is extremely partial to salt, and many stones are met with in the Alps hollowed by the continual licking of the Chamois on account of the saltpetre with which they abound. The species is found in all the high mountain-chains of Europe and western Asia, in the Pyrenees, the Alps, the Carpathian and Grecian mountains, the chains of Caucasus and Taurus, and perhaps in other situations.

Antilocapra

Has erect horns arising directly over the orbit, and ending in a conical recurved tip; the nose ovine, hairy; the fur very close; the hairs stiff, coarse, flattened, wavy; the tail very short.

65. *A. Americana* (*Antilope furcifer*, H. Smith), the Cabrit, or Prong-Horn, called Cabree by the Canadian Voyageurs, and The Goat by the Fur-Traders. This animal measures 4 feet 4 inches from the nose to the root of the tail; its height is 3 feet at the shoulder, and the same

at the croup; the ears are upwards of 6 inches long, and the tail about 4½ inches. The horns rise perpendicularly from the skull, immediately above the orbits; they spread outwards, and are perfectly straight till within 2 or 3 inches of the points, where they curve suddenly backwards and inwards, forming a small hook, like those of the Chamois. The prong is situated upon their anterior face, and in adult animals about half-way up from the root; below it the horns are strongly compressed, rough and scabrous or pearly, like the antlers of deer; above it they are round, black, and polished. The prong itself is also very much compressed; it is little more than an inch in length, and points forwards, upwards, and a little outwards. The ears are long, narrow, and pointed; the tail short and bushy; the eye large and lively; the limbs long and slender; and the whole form and appearance of the animal peculiarly graceful and elegant. The head, ears, and legs are covered with short close hair of the common description, but that of the body is long and padded, and of a texture altogether different from that of other animals. It is tubular or hollow within like the feather of a bird, but so brittle and devoid of elasticity that it snaps with the smallest effort, and, when pressed between the finger and thumb, crushes like a reed and never regains its original form. It stands directly out at right angles to the hide, is about 2 inches long on the back, sides, and buttocks, but from the ears half-way down the neck it exceeds 6 inches in length, and forms an erect mane, equally conspicuous in both sexes. On the nape of the neck, shoulders, back, and hips, it is of a uniform fawn-colour for half an inch at the point, and light-blue with a tinge of rose-colour at the root; on the sides, chest, and belly, the latter colour prevails at the root, and the point is of a pure and shining white. The extremities are uniform light fawn-colour throughout, except on the interior of the fore arms and thighs, which are white. A broad disk of pure white also surrounds the tail, and passes over the croup, and the throat is likewise marked with two transverse bands of the same colour. This is the winter dress of the animal; but Dr. Richardson, who has well described it in his 'Fauna Boreali-Americana,' informs us that in summer when the new coat appears, it has at first the ordinary texture and appearance of common hair, and that it only assumes the appearances here described on the approach of the cold season.



The Prong-Horn (*A. Americana.*)

The Prong-Horn inhabits all the western parts of North America from the 53° of north latitude to the plains of Mexico and California, that is, presuming this species to be the Mazama of Hernandez: it is particularly numerous on the banks of the southern branch of the Saskatchewan, and on the upper plains of the Columbia River, and a small herd annually visits the neighbourhood of the station called Carlton House, where some even linger throughout the winter. They are gregarious, frequent the open plains and hills of moderate height, never inhabit closely-wooded districts, and migrate from north to south according to the season. When the ground is clear, their speed surpasses that of most other animals, but a good horse easily outstrips them after a slight fall of snow. They are extremely curious, and the Indians, and even the wolves, as we are informed by Dr. Godman, know how to take advantage of their curiosity to get within reach of them, by crouching down, and moving forwards or stopping alternately. The antelopes wheel round and round the object of their attention, decreasing their distance at every turn, till at last they approach sufficiently near to be shot or captured. This habit renders them an easy prey, but as their flesh is not much esteemed by the Indians, they are only hunted in times of scarcity. The females produce one kid, and occasionally two kids, early in the month of June.

II. ANTELOPES OF THE DESERT.

In this section the animals have a broad nose with the nostrils subvalvular, and lined with bristles within. Dr. J. E. Gray divides these into two groups, the *Equine Antelopes*, and the *Bovine Antelopes*.

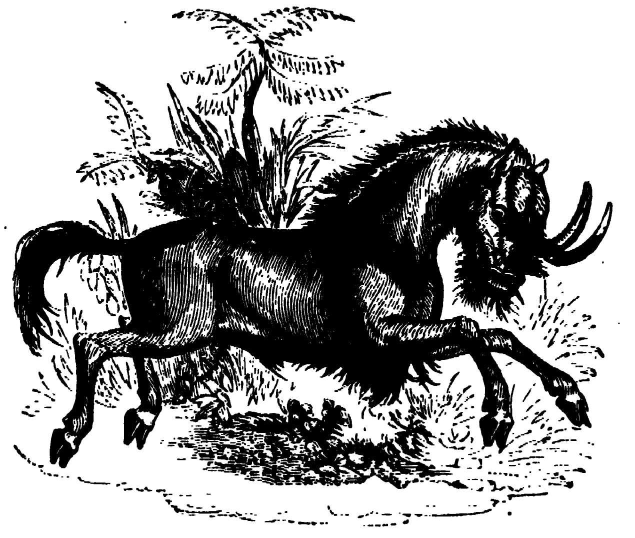
1. *Equine Antelopes.*

These Antelopes have a broad, depressed, spongy, bristly muzzle, with large nostrils, covered with a large spongy valve.

Connochetes

Has the horns bent down, and outwards on the sides, broad at the base, bent up at the tip; the nose broad, dilated, spongy, bristly; the nostrils large, operculated; the tail elongate, bushy, hairy from the base; the hoofs compressed in front; the intermaxillary bones elongated; the nose-hole rather large; the frontal bone much produced behind. The female has four teats.

66. *C. Gnu* (*Antilope Gnu*, Gmelin), the Gnu or Kokoon, is about the size of a well-grown ass. The neck, body, and tail precisely resemble those of a small horse, and the pace also, which is a species of light gallop, is so perfectly similar, that a herd of Gnus, when seen at a distance flying over the plains of South Africa, might be readily mistaken for a troop of the wild zebras or quaggas which inhabit the same localities, if their dark and uniform colour did not distinguish them.



The Gnu (*C. gnu*).

The Gnus live in extensive herds on the karroos of South Africa; they are naturally wild and difficult to approach, and when wounded will turn upon the hunter and pursue him in turn, dropping on their knees before making an attack, and then darting forwards with amazing force and velocity. When first alarmed they commence by flinging up their heels and capering like a restive horse, tossing their heads and tails, and butting at the mole-hills or other objects, but immediately after taking to flight, and traversing the desert with a speed which soon carries them beyond the reach of danger. They do not run in a confused crowd like sheep or oxen, but in single file following a leader, and have a pleasing appearance as they skim over the level plains. They are said to be subject to a cutaneous eruption at particular seasons of the year, which they sometimes communicate to domestic cattle, and which invariably ends in death.

The Kokoon (*A. taurina*, Burchell), is identical with the common Gnu, as may be seen by the specimen named Kokoon by Col. H. Smith, in the collection of the London Missionary Society.

67. *C. Gorgon* (*Catoblepas Gorgon*, H. Smith), the Gorgon, or Brindled Gnu, has a convex smooth face, covered with hair lying towards the nose; the chest not maned. It is of a black colour, varied, and striped with gray. It is the Bastard Wilde *Beest* of the Dutch at the Cape. It lives to the north of the Nu Garcep, or Black River, and though herds feed on its banks, yet it is not known to cross it. It occurs on the large plains north of the Orange River, and when alarmed each herd decamps in long regular files. The flesh is good to eat, and is much sought after. The Betchuanas use the skins for their cloaks and mantles.

2. *Bovine Antelopes.*

These Antelopes have the nose moderately broad, with a moderate or small bald moist muffle; the horns high on the frontal ridge; the grinders rather small, without supplemental lobes; the central cutting-teeth enlarged at the end.

Alcephalus

Has the horns lyrate on the upper edge of the rather produced frontal bones, thick at the base, and suddenly curved at a nearly right angle; nose moderately broad, cervine; muffle moderate, bald, moist; tear-bag covered with a tuft of hair. The female has two teats.

68. *A. Bubalis* (*Antilope Bubalis*, Pallas), the Bubale, or Bekker-el-Wash, is about the size of the largest stag, and is particularly remarkable for the great length of its head, and its narrow, flat, and straight forehead and face.

The Bekker-el-Wash (*Alcephalus Bubalis*).

This animal, called Bekker-el-Wash, or Wild Ox, by the Arabs, is common in every part of northern Africa, living in numerous herds on the confines of the Tell or cultivated parts, and the Sahara or Desert, and also, according to Captain Lyon, upon the mountains south of Tripoli. Barbary seems to be the chief habitat of the species, but it sometimes happens that a few individuals find their way across the Desert to the banks of the Nile, where, however, they are seldom seen, and, as it is said, only when they stray from their native habitat. At the same time it is to be observed, that its representation occurs among the hieroglyphics of the temples of Upper Egypt. Dr. Shaw informs us that the Bubale is naturally of a familiar disposition, that the young calves frequently mix with domestic cattle, and soon learn to attach themselves to the herd without attempting to escape afterwards. They fight like the common bull, by lowering the head, and striking suddenly upwards with the horns, which are formidable weapons either for attack or defence.

69. *A. Caama* (*Antilope Caama*, Cuvier), the Lecama, or Harte-Beest. It is of a gray-brown colour; the dorsal line, streak on face, outer side of limbs, black; a large triangular spot on the haunches whitish. It inhabits the plains of South Africa, and is the most common of all the large antelopes in that country. It resides in large herds, and is a favourite object of pursuit with the natives and colonists. Its pace, when at full speed, resembles a heavy gallop, but is tolerably quick notwithstanding; and the animal has a habit of frequently stopping to gaze at its pursuers when it has got to any distance a-head of them. Its manners are sufficiently mild and tractable, but when put upon its defence it makes good use of its powerful horns, dropping on its knees before charging, and after advancing some distance in this position, darting suddenly forwards with great force against its adversary. The flesh is rather dry, but of a fine grain, more nearly resembling the beef of the ox than that of any other antelope, except perhaps the Eland, and it has a high game flavour which makes it universally esteemed. The female produces but a single calf, which she brings forth in September or April, and which, if taken young, is easily domesticated.

Damalis

Has diverging, sub-cylindrical, lyrate horns; the nose moderately broad, cervine, with a small bald moist muffle between and below the nostrils; an exposed tear-bag. The female has two teats.

70. *D. lunatus* (*Antilope lunata*, Burchell), the Sassaby, or Bastard Harte-Beest, is of a rufous glaucous colour, with the outer sides of the limbs dark. It inhabits the south of Africa, between Latikoo and the tropic of Capricorn. It lives in herds of six or ten, in the flat or wooded districts. The flesh is esteemed. When not disturbed it is confiding and curious, but when hunted it becomes vigilant and shy.

71. *D. Senegalensis*, the Korrigum, is of a reddish-gray colour; the front of the face, from nose to occiput, a small spot behind the eyes, a small streak above the angle of the mouth, streak on outside of limbs above the knees, and tuft of the tail, black. This animal is a native of West Africa, on the Gambia River and Macarthy's Island. It is called Yonga or Yongah by the Joliffs, and Tan-Rong by the Mandingoes. This species was formerly regarded by Dr. J. E. Gray as the *Koba* of Buffon, but he believes now that this animal is referable to the next species.

72. *D. Pygarga*, the Nunni, or Bonte-Boc, is of a simple red colour; the outer side of the limbs darker; the streak between the horns, face, and rump above the tail, white; the temple and upper part of throat whitish; the legs whitish, upper and lower part brown, varied. The female has the throat and under part of the body white. The terms *Kob* and *Koba* are applied to various kinds of antelopes by the negroes, and this is the species to which Dr. Gray believes the horns of the animal belong which accompany his description of the *Koba*.

73. *D. albifrons*, the Bless-Boc, is described by Burchell. "A half-grown specimen," says Dr. Gray, "of this species, when compared

Bless-Boc (*D. albifrons*).

with a similar specimen of *D. Pygarga* in the same paddock, was darker, with a pale spot between the horns, separated by a dark spot from the white on the face; the temple was white, with a white spot; the legs had a brown stripe down the outer side of the front, and the throat and rump brown, the latter without any white spot."

74. *D. Zebra*, the Doria. The skins, without head and feet, are alone known of this animal. The specific name is commemorative of Mrs. Ogilby, whose Christian name was Doria. In the 'Catalogue of the Zoological Society,' it is called the Gilded Antelope. It is a native of West Africa. The skins are of a bright golden-brown colour, with several black cross-bands, narrowing at the end.

We might here close our notice of the family of Antelopes, as we have come to the end of the species in a scientific point of view. But popularly there is another group of Ruminants, which are known under the name of Antelopes, and which were referred to the article 'Antelope,' in the 'Penny Cyclopædia.' This group is not large, but comprises some very interesting forms of the family of Ruminating Animals. It is called *Strepsiceræ*, from the peculiar form of the horns.

Strepsiceræ.

Horns subspiral, inclined backwards; the tear-bag distinct; the nostrils nearly together in front; the forehead flat; the males not bearded on the chin; the fur white, banded or spotted; the females have four teats and a small udder. These animals are distinguished among the Hollow-Horned Bovine Ruminants, by being marked with white stripes and spots. M. Agassiz has observed that the horns of the *Strepsiceræ* and the Sheep are twisted in contrary directions. Mr. Ogilby has observed that the right horn of the *Strepsiceræ* is twisted in the same direction as the left horn of the Sheep, and *vice versâ*. There are four genera of this family which may be thus divided:—

I. Limbs equal. (Natives of Africa.)
  a. Nose cervine. Neck, with a linear mane.
    1. *Strepsiceros.* Horns spiral, keeled.
    2. *Oreas.* Horns straight, with a spiral keel.
  b. Nose bovine. Neck, with long hair.
    3. *Tragelaphus.* Horns subtriangular, subspiral.
II. Hinder legs short. (Natives of Asia.)
    4. *Portax.* Horns short, subtriangular.

75. *Strepsiceros Kudu* (*Antilope Strepsiceros*, Pallas), the Eechlongole or Koodoo, is a magnificent animal of South Africa, and one of the largest of Antelopes, measuring upwards of 8 feet in length, and being 4 feet high at the shoulder. The horns of the male are particularly magnificent; they are nearly 4 feet long, and beautifully twisted into a wide-sweeping spiral of 2½ turns, surrounded by a prominent wreath which follows all their windings, and is gradually obliterated towards the points, which are rather blunt and directed

The Koodoo (*Strepsiceros Kudu*).

outwards. They are thick at the base, and marked for some distance up with irregular wrinkles, but not annulated, dark-brown at the bottom, black in the middle, and the extreme points white. They spread boldly and widely outwards, and are usually carried couched on each side of the back, on account of their great weight. The whole make of this animal is heavy; the head large and terminated by a broad muzzle; the ears broad and slouching; the limbs thick and robust; and the whole external appearance more nearly resembling that of an ox than of an antelope. The ground-colour of the back and sides is a light fallow-brown, with a narrow white ribbon along the spine, and 8 or 10 similar bands descending from the back, and passing obliquely down the sides and hips; the belly and under parts are pale silvery brown. On the neck and withers is a thin spare mane of a brown colour, and the chin, throat, and breast are furnished with similar long hairs, forming a species of beard. The cheeks are marked with two or three round white spots, and a narrow gray line passes from the anterior angle of the eye down towards the muzzle. The tail is moderately long, and equally covered with short hair.

This magnificent animal inhabits the woody parts of Kaffraria, principally along the banks of rivers, to which it readily takes when pursued, and swims well. It lives in small families of four or five individuals. When taken young they are readily domesticated, and show no inclination to regain their original freedom. The females produce one young at a time. The large antelope called *Aggergeen* by Pearce, in his account of his 'Residence in Abyssinia,' has been supposed, but with little probability, to be the same as the Koodoo of South Africa.

The Eland (*O. Canna*).

76. *Oreas Canna*, (*Antilope Oreas*, Pallas,) the Impoofoo, Eland, Cape Elk, Canna, or Bastard Eland, is considerably the largest of all the Antelopes, being the size of a good horse, and measuring 8 feet 2 inches in length, and full 5 feet in height at the shoulder. The horns of the male are 1½ foot in length, very thick and heavy, almost staight till within 3 inches of the tips, where they bend outwards, attenuated at the points, and surrounded throughout the greater part of their length with a thick spiral wreath, which passes twice completely round them, and finishes by becoming indistinct near the points. Those of the females are longer and smaller, and the spiral wreath is, in some specimens at least, scarcely to be seen. The head is long and pointed, the ears are large, the neck thick, compressed on the sides, as in the ox, and furnished underneath with a loose hanging skin or dewlap, fringed along the margin with a border of long hair. There is likewise a large protuberance of the size of a man's fist on the larynx; and it was probably from this organ, which is likewise found in the Elk of Europe, that the animal derived the name of Eland, by which it is universally known at the Cape. From the centre of the forehead to the root of the tail runs a short erect mane of dark brown hair, which is reversed on the neck, but directed backwards in the usual manner along the spine of the back. The length of the spinous processes of the interscapular vertebræ produces a considerable and sufficiently remarkable elevation of the shoulders; but there is no actual hump, as in the Camel or Indian Ox, though at first sight such a formation might be supposed to exist. The tail is upwards of 2 feet long, and terminated by a tuft of long black hair. The colour of the body is uniform reddish-fawn on the upper parts, and white on the under; the head and neck ashy-gray, but in some individuals the latter colour extends over all the upper parts of the body.

The Eland is a large heavy animal, which, when full grown, weighs from 7 to 9 cwts. and, contrary to the usual rule observed among Antelopes, is commonly extremely fat. Its flesh is consequently more prized than that of any other wild animal of South Africa, and the large muscles of the thighs, in particular, are held in the highest estimation when dried and cured, under which form they are denominated thigh-tongues. The character of this animal is very mild, and as it were predisposed to domestication; it is gregarious, and lives in large herds upon the open plains and low hills, the old males generally residing apart. Elands were formerly very common in the immediate neighbourhood of Cape Town, but were so much hunted, that they have long since ceased to frequent the inhabited districts, and are now rarely met with except in the more distant and retired parts of the colony. Being generally very fat and pursy, they do not run well, and are soon fatigued; it is even said that when hard run a red oily perspiration has been known to ooze out from the pores of their skin, and that they occasionally drop down from plethora. Like most other animals when hunted, they always run against the wind. As the carcass is weighty and consequently difficult to transport, the great object of the hunters, in the chase of the Eland, is to turn their game in such a direction as to drive it close to their own residence before killing it; and in fact the Cape farmers, from long practice and intimate knowledge of the animal's habits, very frequently succeed in accomplishing this masterpiece of South African field-sports. They are so gentle that a man on horseback may penetrate into the very middle of a herd, without alarming them, and pick out the fattest and best-conditioned, and as the old bulls are commonly chosen on account of their greater size and weight, it not unfrequently happens that the herd is left altogether without a male. There are several very fine specimens of this animal in the Zoological Gardens, Regent's Park, presented by the late Earl of Derby.

Mr. Livingstone says of this animal—"Our party was well supplied with Eland flesh during our passage through the desert; and it being superior to beef, and the animal as large as an ox, it seems strange it has not yet been introduced into England."

77. *O. Derbianus*, the Gingi Jonga, is a species found in Western Africa on the river Cassaman. It is of a pale reddish-brown colour, with the front of the face, the neck, the front part of the under-side, a spot on the front and upper part of the fore leg, and the dorsal streak, dark black.

Tragelaphus

Has horns conical, tapering, with only one spiral turn; tear-bag distinct; neck and throat with longer hair; nape and back with a more or less distinct mane; legs slender; hoofs and false hoofs small; females hornless.

78. *Tragelaphus Eurycerus* (*Antilope Eurycerus*, Ogilby), the Broad-Horned Antelope, has the head pale-brown; a broad band before the eyes, and two large spots on cheeks, chin, and front of upper-lip, white. The horns are elongated, thick, scarcely bent forward at the tip; the throat covered with long black hairs; the specimens of this species have come from the Bight of Biafra.

79. *T. Angasii*, the Ingala, a native of Natal, is distinguished from the last species by the slenderness of its horns, the smaller size of its head, and the dark colour and small size of the bands and spots on the head.

80. *T. scripta* (*Antilope scripta*, Pallas), the Guib, measures 4½ feet from the muzzle to the root of the tail; its height at the shoulder is 2 feet 6 inches, and at the croup 2 feet 8 inches; the horns are 8 inches long, the ears 5, and the tail 6 inches. The horns are straight, a little compressed and twisted spirally upon their axis, with two wreaths passing round them strongly marked at bottom, but obliterated within an inch or two of the points. The general colour is a reddish-fawn marked with white lines and spots. The head is unmixed fawn-colour with a dark mark on the forehead and face, white spots in front and beneath each eye, and another on the cheek, at some distance beneath the opening

of the ear; the sides of the upper lip and the whole space under the chin are likewise white. The neck is unmixed fawn, deep above and lighter beneath, with a white mark on the breast: the body likewise is deep fawn-colour, with a dorsal line of white and black hair intermixed, and rather longer than those on the rest of the body. From this dorsal line originate 8 or 10 narrow transverse ribbons of pure white, which pass obliquely down over the ribs and hips, and are crossed on the sides and flanks by one or sometimes two longitudinal bands of the same colour, running from the shoulder to the hips on each side, in a direction parallel to the dorsal line. All these markings are constant in the species, and equally common to both sexes: they are at regular distances from one another, and, as Buffon has observed, present the appearance of a set of small harness. A few small round white spots are frequently also scattered over the hips and thighs, as in the Bosch-Boc, and the interior of the fore arms, thighs, and legs are likewise of this colour, but the breast, belly, and under parts of the body in general are uniform fulvous brown.

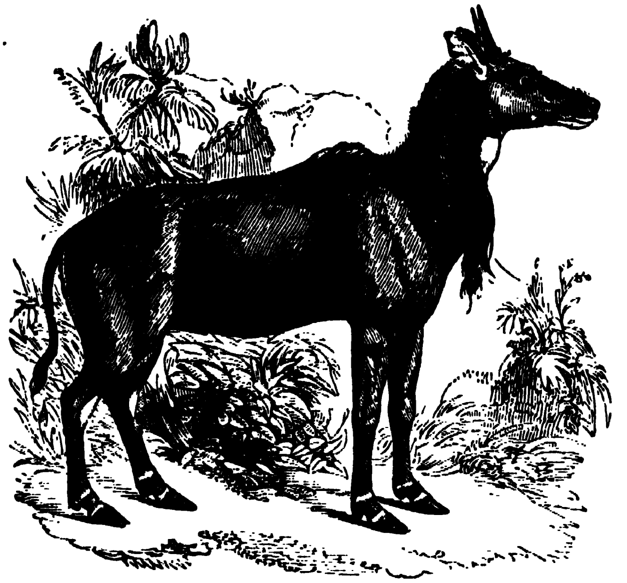
The Guib inhabits the west coast of Africa, from Sierra Leone to the banks of the Senegal, from the latter of which localities it was first brought to Europe by Adanson the naturalist. It is said to associate with its own species, and to form extensive herds, which reside equally in the forests and on the open plains, particularly in the vicinity of Podor and Goree, where these animals are very numerous. Guib is their name in the Joliff language. The colours are sometimes subject to a slight variation as far as regards the number of longitudinal and transverse bands on the sides. Colonel Smith has considered this difference specific, and has bestowed the name of *A. phalerata* upon the variety with a single longitudinal line on the flanks, retaining the original name of *A. scripta* for the variety which is marked with two of these lines. This distinction, to say the least of it, is extremely doubtful, and the difference upon which it is founded is in all probability merely accidental.

81. *T. Decula*, the Decula, is of a gray-brown colour. The back has three or four indistinct cross-bands; an arched streak on the upper part of the side, a few spots forming an arch on the haunches; dorsal line, streak on nose, and front of fore legs, blackish. It was originally described by Rüppell, and is a native of Abyssinia.

82. *T. sylvatica* (*Antilope sylvatica*, Sparrmann), the Bosch-Boc, measures about 4 feet from the nose to the root of the tail, and is 2 feet 6 inches high at the shoulder. The horns are nearly 1 foot in length, thick at the base and gradually attenuated, but ending in rather blunt points; they are twisted on their own axis, but do not form the wide-spreading spiral curves so remarkable in those of the Koodoo: from the base, however, two sharp prominent wreaths, one on the outer and the other on the inner surface, wind spirally round them for the first two-thirds of their length, and are gradually obliterated towards the points, which are smooth and polished. The ears are large and rounded at the tops; the limbs robust but clean and well-formed; the tail of moderate length, and similar to that of the common Fallow-Deer. The male and female are of different colours; the ground-colour of the male is a dark sepia-brown above, and white beneath, the head and cheeks being light and sandy-red, and the extremities fulvous; that of the female reddish-fawn above and white beneath. Two pure white bands cross the throat, one at the junction of the head and neck, and the other at the union of the neck with the chest; the lips and chin are also white; round white spots mark the cheeks, and sometimes the nose in front of the eyes; similar spots are dispersed irregularly over the hips and thighs, to the amount of a dozen or more on each side, sometimes even forming interrupted lines. The hair is of moderate length, but it is smooth and lies close to the body; the backs of the ears are covered with short brown hair; the tail is black above and white underneath, and the pastern joints are marked behind with two oblong spots of the same colour. In very old males the legs become almost uniformly gray, and at all ages there is a white line running down their inner surface even to the very hoof. All these marks are equally found in the females, but not being so prominently contrasted, on account of the lighter ground-colour of this sex, they are not so conspicuous as in the males. There is frequently also a narrow white list along the back, but this is not a constant character in either sex, and is, for the most part, wanting in the females. The young males are of the same colour as the adults, but rather lighter, and the white spots on the hips and thighs more faintly marked.

The Bosch-Boc, or Bush-Goat, as its colonial name implies, resides in the woods, which it never quits but during the bright moonlight nights, or early in the morning, when it comes out to graze on the border of the forest, or to make incursions into the neighbouring gardens and corn-fields. Its voice resembles the barking of a dog, and its deceitful tone sometimes leads the benighted traveller into the most remote and lonely depths of the forest, in the vain search after some human habitation, which he is all the time leaving behind him. It is a slow runner, and easily caught when surprised in an open situation, but it keeps close to the woods, through which it penetrates with great ease, running with the horns couched backwards along the sides of the neck, to prevent them from impeding its course by striking against the branches, and having the neck and throat frequently denuded by rubbing against the underwood, as it forces its passage through the thick covers. The species is monogamous, the male and female being always found either alone, or accompanied by one or two kids, but never by adult individuals. It is common enough in Kaffraria, and in such parts of the Cape Colony as have sufficient forest to afford it a secure asylum; its flesh makes good venison, that of the breast being particularly esteemed.

83. *Portax Tragocamelus* (*Antilope picta*, Pallas), the Nil-Ghau or Nyl-Ghau, one of the largest and most magnificent Antelopes known, being upwards of 4 feet high at the shoulder, inhabits various parts of India, whence it has often been brought to England, where it lives and breeds, and is not an uncommon animal. The face of this species is long and narrow; the muzzle large and naked; the horns about 7 inches long, small, round, and black, rather distant at the base, nearly parallel throughout their whole length, pointed and slightly curved forwards; they are perfectly smooth and without annuli, but rather triangular at the base, and gradually rounded and attenuated towards the points. The lachrymal sinuses are large; the ears 7 inches in length, broad and rounded like those of an ox; the neck deep and compressed like that of the horse, not round and cylindrical as in the Stag and most other Antelopes; and the tail broad, equally covered with hair on the sides and at the root, but terminated by a long black tuft, and descending to the houghs. The legs are small and well-formed, the anterior rather longer than the posterior; and the spinous processes of the dorsal vertebræ so much elevated between the shoulders as to give the animal the appearance of having a small hump. When at rest, the feet are gathered close under the body, and the tail turned in between the hind legs. The hair is uniformly short and close upon every part of the head, body, and limbs, excepting along the top of the neck and on the shoulders, where it is long, stiff, and upright, forming a thin erect mane which extends from between the ears half-way down the back, and on the middle of the throat, where there is a species of beard composed of stiff bristly hair. The general colour is a uniform slaty-blue on the upper parts in the male, and tawny-red in the female; on the under parts uniform white in both sexes. The limbs and face are almost brown, and the lips, chin, and under surface of the tail, white. There is a large white spot on the throat, and two smaller ones on the cheeks under the lachrymal sinuses; the pastern joints are marked in front with one spot, and in rear with two conspicuous spots of the same colour, which contrast strongly with the dark brown of the surrounding parts, and have suggested the specific name of *Antilope picta* which was given by Pallas to this animal.



The Nil-Ghau (*Portax Tragocamelus*).

The Nyl-Ghau resides in the dense forests of India, whence it occasionally makes excursions very early in the morning or during the night, to feed upon the corn-fields of the natives which happen to be situated in the vicinity of the jungle. It is a vicious animal, of very uncertain temper, and as it is both powerful and resolute, and frequently turns upon its pursuers, it is seldom made an object of chase except by the native princes, who employ elephants for this purpose, or inclose the game in nets. The usual method which the shikarrees, or professional hunters, employ for its capture is to shoot it from an elevated platform when it comes out at night or early in the morning to feed on the confines of the jungle; this being likewise their mode of destroying tigers, wild boars, and other beasts which they dare not attack openly. Even in confinement, and when domesticated from birth, the violent and changeable temper of the Nyl-Ghau cannot be trusted. Previous to making an attack, it drops upon the fore-knees, advancing in this position till within a proper distance, then darting suddenly forwards with the velocity of an arrow, and with a force which no ordinary animal can withstand. Yet, notwithstanding its vigour and resolution, it is the most common prey of the tiger, which the shikarrees often destroy in the very act of devouring the mangled remains of this animal; for, when these are discovered, the hunters always erect their platforms in a convenient situation in the neighbourhood of the carcass, knowing by experience that the tiger is sure to return on the following night to glut himself at leisure with the produce of his previous chase. The Nyl-Ghau has often bred in confinement, both in this country and in India. The period of gestation lasts eight months, and two young are most commonly produced at a birth. At first the young males are of the same reddish-brown colour as the females, and only assume the grayish-blue shade proper to their sex on arriving at maturity: their growth is, however, rapid, and they attain their adult size in the second or third year of their age.

ANTIMONOPHYLLITE. [ANTIMONY.]

ANTIMONY, a silver-white metal, slightly blue, and with a very brilliant lustre. Its hardness is as great as that of gold. It has a specific gravity of 6·7—6·8. It does not combine with oxygen at the ordinary temperature of the atmosphere, but is fused at a temperature a little below red-heat, and burns very vividly. It is a compact brittle metal, and is sometimes found pure in nature, but never abundantly. It occurs mixed with lead, silver, arsenic, and other metals, but its most important ore, and that from which it is obtained for commercial and medicinal purposes, is the sulphuret. It enters into composition with other metals of several alloys used in the arts. *Type Metal* is composed of one-fourth to one-twelfth of antimony, the rest being lead, tin, bismuth, and copper. *Hard Pewter* is made of 12 parts of tin and 1 of antimony; *Britannia Metal* of antimony, tin, bismuth, and copper. The markets are supplied with the ores of antimony from Hungary, England, France, and lately from Borneo. The following are some of the forms in which antimony occurs as a mineral:—

Native Antimony, with a little silver. *Stiblite* is an antimoniate of antimony, the oxide of antimony acting as an acid. There are two oxides or acids of antimony, both of which are found native, and are called *Antimonic Acid* and *Antimonious Acid*. *White Antimony* is a sesquioxide of antimony. *Antimonophyllite* is an impure oxide of antimony. *Gray Antimony* is a compound of three of sulphur and one of antimony. It occurs in masses or veins in Metamorphic and Igneous rocks. It fuses rapidly in the flame of a candle. It is often seen in long prismatic or acicular crystals with strong vertical striæ. *Zinkenite* is a sulphuret of antimony and lead, containing 45 per cent. of antimony. *Plagionite* is the same, but contains only 38 per cent. of antimony. *Feather Ore* is the same, with 31 per cent. *Boulangerite* the same, with 25½ per cent. *Jamesonite* is a sulphuret of antimony, with iron and bismuth, containing 35 per cent. of antimony. *Red Antimony* is also called *Kermes Mineral* and *Antimony Blende*, and is a mixture of the sulphuret and oxide of antimony, containing 75 per cent. of the latter. *Antimoniate of Lead* contains 31 per cent. of antimony. *Arsenical Antimony* contains 62 per cent. of arsenic and 37 per cent. of antimony. *Berthierite* or *Hardingerite* is a sulphuret of antimony and iron. The following are sulphurets of antimony and lead:—*Steinmannite, Killbrickenite, Kobellite, White Silver, Geokronite,* and *Boulangerite.*

(Ansted, *Elementary Course of Mineralogy*, &c.)

ANTIRRHI'NUM, a genus of plants belonging to the natural order *Scrophulariaceæ*. This genus is the type of a section of the order to which also the genera *Linaria, Anarrhinum, Maurandia, Galvesia, Lophospermum,* and *Rhodochiton* belong. It is characterised by a 5-parted oblique calyx; a personate corolla, gibbous at the base, but with no distinct spur; the lobes of the upper lip erect, those of the lower spreading, 3-fid, with the middle segment smallest, and a bearded palate which closes the mouth; the capsule 2-celled, opening by two or three pores at the top; seeds oblong, minute, with black testa. The species are annual or perennial, rarely shrubby. The leaves are feather-veined, and entire, opposite below, and usually alternate above. Two of the species are indigenous to Great Britain. All of them produce showy flowers, and are much cultivated in gardens. Their medicinal properties are not very active.

A. majus, Great or Common Snapdragon, has lanceolate, opposite or alternate glabrous leaves, racemose flowers, ovate obtuse sepals, much shorter than the corolla, and the upper lip bifid. This plant attains a height of one or two feet, and has purplish-red or white flowers. It is found in Great Britain on old walls and chalk cliffs, especially in the neighbourhood of London, but it is undoubtedly a naturalised plant, being truly indigenous in the south of Europe and the north of Africa. In gardens a variety is often seen with double flowers. The leaves are bitter and slightly stimulant.

A. Orontium, Orontium Snapdragon, or Calves' Snout, has linear-lanceolate opposite or alternate leaves; the flowers loosely spiked, distant; the sepals linear and longer than the corolla. This plant appears to be truly indigenous in England and Ireland, where it occurs in dry sandy and gravelly soils. It is also a native throughout Europe, in the islands of the Mediterranean, and the north of Africa. It has been found in Virginia, but it has been probably introduced. Its leaves as well as those of other species have been used as cataplasms in indolent tumors.

Don enumerates twelve other species, many of which have been introduced into our gardens. They are pretty border-flowers, and adapted for rock-work. They are easily cultivated; the perennial species may be increased by cuttings, and the annual raised by seeds. The species from subtropical districts will however require a frame or the greenhouse in the winter.

(Babington, *Manual of British Botany*; Don, *Gardener's Dictionary*.)

ANTRIMOLITE, in Mineralogy, a hydrous silicate of alumina, with lime and potash. According to Dr. Thomson it occurs in stalactitical-looking masses about the length and thickness of a finger, adhering to the summit of cavities in an amygdaloidal rock. In the centre of each stalactite is a crystal of calcareous spar, or a fibrous-looking round mass, pretty long, and having a foliated structure and a brown colour, consisting of calcareous spar. Colour chalk-white. Texture fine silky fibrous. The fibres diverging from the central nucleus. Opaque. Dull. Hardness 3·75. Specific gravity 2·0964.

When heated it loses water and hydrochloric acid. Before the blowpipe it softens into an enamel, and with phosphate of soda gives very slowly a transparent colourless glass. It gelatinises in hydrochloric acid.

Found on the sea-shore at Bengore, about four miles from the Giants' Causeway, on the north coast of the county of Antrim.

Analysis by Dr. Thomson:—

Silica	43·470
Alumina	30·260
Lime	7·500
Potash	4·100
Protoxide of Iron	0·190
Chlorine	0·098
Water	15·320
	100·938

AO'RTA, from a Greek word, ἀορτή. The aorta is the great vessel from which all the arteries of the body which carry red blood derive their origin. It arises from the upper and back part of the left ventricle of the heart. Its origin is directly opposite the lower margin of the cartilage of the third rib on the right side of the chest. From this point it ascends behind the pulmonary artery, still inclining a little to the right side of the chest. It continues to ascend as far as the top of the second vertebra of the back. All this part of the vessel is called the *Aorta Ascendens*. When it reaches as high as the lower margin of the first rib, it bends obliquely backwards towards the body of the third vertebra of the back. This part of the vessel is called the Curvature or the Transverse Arch of the Aorta. From the third vertebra of the back, where its arch terminates, it proceeds in a straight course downwards through the chest, immediately in front of the spinal column, and towards the left side of it. Through an opening formed for it in the diaphragm it passes from the chest into the abdomen. All this part of the vessel, namely that extending between the termination of the arch and the diaphragm is denominated the Descending or the Straight Portion of the Thoracic Aorta. Having passed through the diaphragm into the abdomen, it is called the Abdominal Aorta. It continues to descend along the front of the spine a little obliquely, until it reaches the fourth vertebra of the loins: here it divides into two branches of equal size, and may be said to terminate, for it now loses the name of aorta; the two great branches into which it divides being denominated the Common Iliac Arteries. [HEART.]

A'PATITE, a mineral substance crystallised in the regular six-sided prism, usually terminated by a truncated six-sided pyramid. It occurs variously modified by the removal of its lateral sides and angles. Its specific gravity varies from 3·25 to 3·5. It is scratched by felspar, but scratches fluor-spar. In colour it passes from white through various shades of yellow to green and blue, and some specimens possess a red tint. It is usually translucent, but rarely transparent. From the analysis of G. Rose, Apatite appears to be a compound of phosphate of lime with fluoride of calcium, in which the fluorine is more or less replaced by its isomorphous element, chlorine.

This mineral principally occurs in the Primitive rocks, and is found in the tin-veins of St. Michael's Mount, Cornwall, and also in those of Bohemia and Saxony. It has also been observed in a massive mineral called phosphorite, which appears to possess a similar chemical constitution, and has been found abundantly in beds alternating with limestone and quartz, near Logrosan, in Estremadura in Spain. Since the practice of applying phosphate of lime to the soil has come into use, it was proposed to employ this mineral; but it does not appear that any of the phosphate of lime which is now used in artificial manures is obtained from this source. The phosphate of lime thus employed seems to owe its origin to an organic cause. [COPROLITES.]

APE is sometimes employed in Zoology to express a genus of Quadrumanous Mammals, which closely approaches to the human species in anatomical structure, and is justly regarded as the connecting link between man and the lower animals. The word ape seems to be of doubtful origin: in German it is *Affe*, from which the verb *äffen* appears to have come. This is perhaps more probable than to suppose that *affe* comes from *äffen*. The name exists, with very slight variation, in all the modern languages of Teutonic origin; as *Ape* in English, *Affe* in German, *Aap* in Dutch, &c. These also are the only European languages which possess original appropriate names to distinguish these animals from monkeys in general. Our own language is even more copious than others in terms for distinguishing the different characters of this class of animals; thus we say that an *Ape* is a monkey without a tail, and a *Baboon* a monkey with a short tail, reserving the term *Monkey* more particularly for those species which have very long tails; and though our early writers use these three words indiscriminately as synonymes, and apply them indifferently to the same animal, yet the significations here given have generally prevailed since the time of Ray, and are now almost exclusively adopted. It must be confessed however that these significations are extremely vague, and certainly do not express the zoological relations which subsist between the different sections of this group of animals.

According to its modern zoological definition, the genus *Ape*, or *Pithecus*, comprises those quadrumanous mammals which have the teeth of the same number and form as in man, and which possess neither tails nor chee[illegible]. This definition, whilst, on the one hand, it excludes certain tailless baboons and monkeys, comprehends, on the other, the three sub-genera of Orangs, Chimpanzees, and Gibbons. Nor are these the only characters which the Apes share in common. They, of all other animals, approach most nearly to the human species in organisation, although their points of inferiority are more numerous than at first sight appear. The arms are so long as almost to touch the ground when the animals stand erect on their hind legs; but the legs themselves are scarcely one-third of the entire height. The legs moreover are not in the same line with the thighs; the knees are turned outwards, and the feet are articulated at the ankle in such a manner that their soles turn inwards so as to face or be opposed to one another. By these means the Apes are enabled to embrace or grasp the trunks and branches of trees with much greater force than if their members were constructed like our own. They thus become essentially sylvan or arboreal animals, and never voluntarily abandon the forests, where they find at once the most congenial food and the most perfect security.

The Chimpanzee.

Orang-Outan.

Their whole organisation peculiarly adapts the Apes to these habits. Besides the conformation of the extremities just noticed, the fingers and toes are long, flexible, and deeply separated from one another, and the thumb, or interior finger, is completely opposeable to the other four, as well on the posterior as on the anterior extremities: thus, their feet and hands are equally formed for prehension. They are not Quadrupeds, as Buffon has justly observed, but Quadrumana; not four-footed but essentially four-handed animals. One part of their organisation renders them intermediate between the bats and ordinary mammals; another makes them the connecting link between man and the inferior animals. The great length of the fingers and anterior extremities, compared with those behind, are precisely what we observe among winged mammals, only that the fingers are not connected by a flying membrane; and their economy and habitat equally correspond with this intermediate structure. They are neither confined to the surface of the earth like the generality of mammals, nor do they possess the power of elevating themselves into the air, like the bats; but they choose a middle habitat, the forests, where they habitually reside, and where they move about with an ease and velocity which can only be compared to actual flight. On the other hand, when compelled by circumstances to traverse any part of the earth's surface, their pace, properly speaking, is neither that of a biped nor of a quadruped; they do not walk upright like a man, nor yet do they walk upon all-fours like the lower animals. The great length of their arms prevents them from adopting either of these modes of progression in its simple form, but they avail themselves of this very circumstance in another manner. Their long arms serve them instead of crutches, and their pace is precisely that of a lame man who walks with the assistance of these instruments. From the oblique articulation of the posterior extremities, they rest only on the outer edge of the foot, but the wavering equilibrium thus occasioned is secured by the long fore-arms, which can easily touch the ground in all directions; and, when an advance is to be made, it is accomplished by resting the weight of the body upon the half-closed fists, and then swinging the hinder extremities forward, precisely like a man on crutches. In their na[illegible] the extreme length of their fore-arms is turned to the gr[illegible]re it acts upon the principle of the rope-danc[illegible] pole, [illegible] completely secures their equilibrium even wi[illegible] precarious footing. Thus it is that travellers have seen the A[illegible]y extremity of the slender trunks of the bamboo, [illegible] long arms from side to side with the most graceful and ea[illegible]otions.

Another circumstance in the structure of the Apes, in which they differ from most other Quadrumana, has considerable influence upon their habits; this is the entire want of a tail. Though the presence of th[illegible]n does not always indicate a corresponding function, and though its absence is not confined to this group of quadrumanous animals, yet a long tail would seriously embarrass the nearly erect motion of the real Apes; whilst its use is in other respects superseded by the length of the fore-arms, which supply its place in adjusting the proper balance of the body, the only function which the tail performs in the common monkeys. But another character of still greater importance distinguishes the real Apes from the rest of the Quadrumana, namely, the want of cheek-pouches. These are sacs or cavities in the cheeks, which open inside the mouth between the cheek and the lower jaw, and serve to hold any extra provision which the animal may not at the moment require. The *Semnopitheci* alone, of all the other monkeys of the old world, resemble the Apes in this respect, and hence arise some of the most striking resemblances which the characters and habits of these two genera present. In other respects they are sufficiently distinguished from one another by the long tails of the *Semnopitheci*, not to mention their extremities of nearly equal length, and the peculiar structure of their stomachs and teeth. Another character, which is common to all the other known Quadrumana of the old continents, is found in some species only of the real Apes, and is absent in others: this is the possession of Callosities, which are naked callous parts of the buttocks, upon which these animals sit when fatigued by the violent and rapid movements which they habitually execute. Illiger and some other zoologists have considered this circumstance of sufficient importance to warrant the separation of the Apes into two distinct genera, the one characterised by the absence of callosities, the other by the presence of them; but it is to be observed, that, even where these organs do exist in the Apes, it is always in a rudimentary form; they are never developed to such an extent as to influence the habits of the animals, and are consequently unfit to be considered as generic characters. In other respects, except in these diminutive callosities, the Gibbons do not differ from the Orangs and Chimpanzees; they have the same system of dentition, the same organs of sense, and the same singular modification of the locomotive organs; their manner of life also is precisely the same; both equally take up their habitation in the thickest and most solitary forests; they inhabit the same countries, and live upon the same food.

The teeth of the Apes, as indeed of all the other monkeys of the old world, are of the same number as in man; nor, as far as the incisors and molars are concerned, do they present any difference in form; but in the adult animals, and more especially in the old males, the canines are developed in the same relative proportion as in the Carnivora; the tusks of the full-grown Orang-Outan are at least as large as those of the lion, and are most formidable weapons. Unfortunately we know but little of the manners of these animals in their adult state; but this circumstance gives us strong reason to suppose that the extreme gentleness and placidity observed in the young individuals usually brought into Europe do not always continue to characterise them in their native climates, but that their disposition alters in proportion to the development of their muscular force, and that in their adult state they are as formidable and mischievous as the Baboons themselves.

The characters and habits of the Apes present differences which will be noticed in speaking of the several species. As far however as their general manners have been observed, they appear to be of a grave and gentle disposition, totally free from that petulance and mischievous curiosity which so strongly characterise the monkeys, properly so called, are very affectionate towards those who treat them kindly, solemn and deliberate in all their actions, extremely circumspect and intelligent, seldom moved to violent passion, but peevish and fretful when crossed or disappointed. They never walk on two legs except when they have occasion to use the fore hands in carrying something. Nearly or altogether deprived of callosities, they do not repose in the manner of ordinary monkeys, on their hams, but stretch themselves on their sides, like human beings, and support their heads upon their hands, or by some other means supply the use of a pillow.

For an account of the most remarkable Apes see CHIMPANZEE, ORANG-OUTAN, and GIBBON. For an arrangement of the species and their relation to other Monkeys see SIMIADÆ, and QUADRUMANA.

APEREA, a species of Wild Guinea-Pig. [CAVY.]

APETALÆ, Plants without Petals, constitute one of the divisions in Jussieu's arrangement of plants according to a natural system. They comprehend all genera which are Dicotyledonous or Exogenous, and which have a calyx without corolla. By some they are called Monochlamydeous. The character by which these plants are defined is as constant as any of those which botanists employ for subordinate divisions, but it must not be considered absolute; for not only are many of the genera which, in consequence of their natural affinities, are included among Apetalous Plants provided with rudimentary petals, but it occasionally happens that in orders otherwise constantly furnished with a corolla, particular genera occur in which no petals are produced; a very remarkable instance of which is to be met with in the pretty little shore-plant found on most of the sandy beaches of this country, and called *Glaux maritima*. This species is very nearly related to the Primrose, and certainly belongs to the same natural order as that plant, but it has no corolla; in place of which the border of the calyx becomes coloured, and it therefore apparently belongs to the apetalous division, although, in reality, [illegible] forms an exception to the character of monopetalous plants.

APHANESITE, a mineral consisting of arsenic acid [illegible] oxide of copper, with water.

APHERESE, a mineral consisting of phosphoric acid and oxide of copper, and water.

APHIS, the Plant-Louse, or *Puceron*, an extensive genus of insects belonging to the order *Homoptera*. They are interesting to naturalists on account of their very peculiar economy, and no less so to gardeners and farmers, on whose crops many species commit most destructive depredations. As instances of the latter we may refer to the Hop-Fly (*A. Humuli*), and the Bean-Dolphin (*A. Fabæ*), whilst all our garden flowers, such as the Rose, the China-Aster, the Chrysanthemum, and others, suffer from their attacks. During the summer of 1833, the cabbage and turnip crops in Kent were much injured and often destroyed by countless swarms of *A. Brassicæ*.

These insects are characterised by a soft oval body, a small head, entire and semi-globular eyes, antennæ of seven joints longer than the body, often setaceous, sometimes thickened towards the top, the two joints at the base very short, the next very long and cylindrical. The beak (*haustellum*) arises from the under part of the head between the fore legs, and descends almost perpendicularly. The wings, when developed, are four in number, but some naturalists represent the upper wings rather as wing-cases ([illegible]) from their difference of texture. The legs are very long and slender, in consequence of which they walk awkwardly.

At the extremity of the abdomen most species are furnished with a pair of projecting tubes, through which they eject a sweet viscid fluid, well known under the name of honey-dew, erroneously supposed to be an exudation from the leaves on which it is found. It is also said that the Aphides feed on this, which is impossible from the structure of their mouths. Ants however and bees are very fond of it.

In sketching the history of these singular insects, it will be most convenient to begin it at the close of autumn, when many of the species, such as *A. Quercus*, *A. Rosæ*, &c., are numerous, some winged and some without wings, of both sexes, so that while the first may fly to a distance, the second are confined to their native plant or its vicinity.

After pairing, the mother Aphis deposits what have been by some naturalists termed eggs, in a place suitable for their passing the winter; but different places are chosen by different species. Some choose the oak, and place the eggs on an exposed twig high on the tree, others in the sheltered crevices of bark, or even under ground. Bonnet seems to be of opinion that the Aphides are always viviparous and never lay eggs, what are commonly called eggs produced in autumn being a sort of cocoon, consisting of the young Aphis inclosed in an envelope. From our own observations on those of the oak, we are convinced that this is the fact; but we cannot affirm, upon negative evidence, that none of the species lay real eggs.

The cocoons or eggs, whichever they may be, remain torpid during the winter (the parents having died after producing them), and are called into life with the return of genial weather in the spring. The number of insects produced must of course correspond to the number of cocoons or eggs laid the preceding autumn, but being all ushered into active life at the same time, their simultaneous appearance has led to the popular but erroneous notion, that they are generated by the air. Blighting weather, as it is termed, is also accused of spreading the destructive swarms over hop-grounds or bean-fields, but their rapid increase is wholly caused by their wonderful powers of multiplying.

All the Aphides, it has been well ascertained, which appear in spring are exclusively females, no males being found till the autumn; and these females are endowed with a fecundity almost incredible. M. Latreille says that one female during the summer months will produce about 25 a day, and M. Réaumur calculated that one Aphis may be the progenitor, during its life, of the enormous number of 5,904,900,000 descendants. It is not necessary for the young female Aphides produced during summer to pair with a male, which indeed would be impossible, as no males are then to be found; yet these females go on producing each their 25 a day of living young ones, all of which become in a short time as fertile as their parent.

The following calculation of the fecundity of a species of Aphis from Professor Owen's lectures on 'Comparative Anatomy,' will afford some explanation of the extraordinary numbers in which these creatures sometimes occur. "The *Aphis lanigera* produces each year 10 viviparous broods, and one which is oviparous, and each generation averages 100 individuals:—

1st	generation	1	Aphis produces
2d	„	100	one hundred
3d	„	10,000	ten thousand
4th	„	1,000,000	one million
5th	„	100,000,000	one hundred millions
6th	„	10,000,000,000	ten billions
7th	„	1,000,000,000,000	one trillion
8th	„	100,000,000,000,000	one hundred trillions
9th	„	10,000,000,000,000,000	ten quatrillions
10th	„	1,000,000,000,000,000,000	one quintillion.

If the oviparous generation be added to this you will have a thirty times greater result."

The female Aphides thus produced must be regarded as larvæ, but they present a more developed condition than the larvæ of Coleoptera and Lepidoptera. The compound eyes are developed on the head, and the antennæ have acquired their mature form and proportions; the six thoracic legs have attained their due growth and development. The only change which these fertile larvæ afterwards undergo is increase of size, and development of the reproductive tissues. In the last generation, which, according to the species of Aphis, is the seventh, ninth, or eleventh, the power which they possess of producing individuals like themselves ceases. In the last generation wings are acquired, and male insects also with wings appear. It is these insects which produce eggs, and deposit them where, under the genial influences of the sun, they are hatched, and thus produce the multitudes which make the attacks of these creatures so remarkable.

The number of species of Aphis is very large. In the 'List of Specimens of Homopterous Insects' in the collection of the British Museum, drawn up by Mr. Francis Walker, 326 species of this genus are described. Almost every species of plant gives support to a different species of Aphis, each of which has been described with very great accuracy in the list above mentioned.

The effects of the attacks of these insects is sometimes of national importance. In the year 1802 the hop-duty fell from 100,000*l.* to 14,000*l.*, on account of the great increase of the Aphis. When the Aphis has been abse[illegible] duty has risen as high as 500,000*l.* The *Aphis Rosæ* is mo[illegible]ructive to the beautiful plant on which it is constantly found. Apple-trees and pear-trees are attacked with a species which injures greatly their produce. In most cases these insects are green, but a black species attacks the bean; whole acres of these plants will be suddenly covered by these insects. Their attacks on all plants seem regulated by the health of the plant. If atmospheric conditions occur which render plants unhealthy, then the Aphis makes its appearance. If these cease, the Aphis then disappears also, and one crop of plants will be attacked several times in the same year. The Aphides have their natural enemies. The larvæ of the Lady-Bird (*Coccinella*), the *Syrphus* or Bee-like Fly, the *Hemerobius perla*, and several species of *Ichneumonidæ*, devour with great avidity several species of Aphis.

The chief remedy for the destruction of the Aphis is tobacco. Where plants can be brought together under cover they may be easily exposed to tobacco fumes, but in the open air this is not so easily effected. In this case the best plan is to apply the tobacco in water. The affected branches or parts of plants may be syringed with the infusion, and afterwards washed with pure water.

APHRITE, in Mineralogy, a crystalline variety of carbonate of lime.

APHRODITA, a genus of Dorsibranchiate Annelides. It is easily known from the rest of the order by two longitudinal ranges of broad membranous scales covering the back, and under which the gills lie concealed in form of little fleshy crests. The body is generally flattened, and shorter and broader than in other Annelides. [ANNELIDA.]

APIOCRINI'TES (Miller), a Fossil genus of Crinoidea, found in the Oolitic formations and in the Chalk.

A'PIUM, a genus of plants belonging to the order *Umbelliferæ*. The only species of this genus of any importance is the Common Celery (*Apium graveolens*). This valuable vegetable is found naturally in the ditches of almost every part of Europe. It is even met with in the Falkland Islands, where, if it was originally carried thither, it has naturalised itself. In this country it is very common in many places, as for instance in the ditches near Sandwich.

It is a remarkable fact that this plant, which is so sweet and wholesome when cultivated, is altogether acrid and unfit for food when wild. It is by some supposed that the difference between the quality of the two states is owing to so large a part of the stem and leaves of the cultivated species being hidden from the action of light by the soil which is heaped up about it, and being in consequence unable to generate in much abundance the peculiar principle on which the acridity depends. Whatever may be the value of this explanation, it evidently does not apply to the variety called Celeriac, in which the sweetness and wholesome character of cultivated celery are maintained, although the leaves are not at all deprived of the full influence of light. [CELERY, in ARTS AND SC. DIV.]

APOCYNA'CEÆ, Dogbanes, a natural order of plants belonging to the Monopetalous subdivision of the Exogenous class. Among these they are known by their flowers being perfectly symmetrical, the segments of the corolla all twisted one way, like a Catherine-Wheel, five distinct stamens, a superior ovarium which when ripening divides into two parts that diverge from each other at right angles, and by their stems yielding, when wounded, a copious milk. The milk is generally poisonous, and that quality is general in the order, which abounds in plants the action of whose juices upon the human body is more or less violent. Among these, the Tanghin poison of Madagascar [TANGHINIA] and *Nux vomica* [STRYCHNOS] are remarkable instances. But some of the species are not unwholesome; as the Hya-Hya, or Milk-Tree of Demerara, and the Cream-Fruit of Sierra Leone. Caoutchouc is yielded in abundance by *Vahea gummifera*, *Urceola elastica*, and *Willughby edulis*. Several other species yield medicinal agents, but they are not much employed in the European practice of medicine. Considering, however, the great prevalence of poisonous qualities in the order, drugs obtained from any of its species should be administered with very great caution, until it has been ascertained that they may be employed without danger. The order *Apocynaceæ* is only distinguishable from *Asclepiadaceæ* by the stamens being distinct from the pistil, and by the pollen not being contained in little waxy bags.

A'PODES, in Zoology, an order of Fishes, including, according to the Linnæan system, all those which want the ventral fins, but restricted by Baron Cuvier to those which, besides possessing this character, are likewise Malacopterygious. In the latter sense, the Apodal Fishes compose a small natural family, almost restricted to the great genus *Muræna*, and of which the Common Eel offers a good and familiar example.

APOPHYLLITE, a crystallised mineral, whose fundamental form is the square prism, fig. 1. Its most general modification is obtained by supposing the angles of fig. 1 cut off, so as to give rise to a plane triangular surface, as is seen at *a* in fig. 2; these faces *a*, from the plane cutting deeper into the original crystal till they intersect each other, frequently lose their triangular form, and of course, at the same time, the face P again becomes a square, and the prism will be terminated by the form seen in fig. 3. On account of these modifications, Apophyllite sometimes assumes the form in fig. 4.

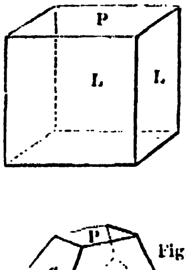


Fig. 1.

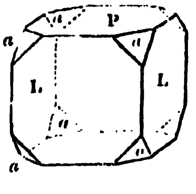

Fig. 2.

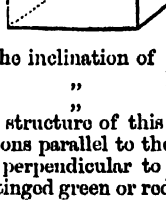

Fig. 3.

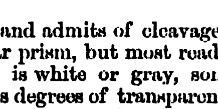

Fig. 4.

The inclination of P on *a* is 120° 5′
„ L on *a* is 128° 20′
„ *a* on *a* is 104° 18′

The structure of this mineral is lamellar, and admits of cleavage in directions parallel to the sides of the regular prism, but most readily in the perpendicular to its axis. Its colour is white or gray, sometimes tinged green or red. It possesses various degrees of transparency, and occurs even opaque. In hardness it approaches nearly to Apatite; and its density varies from 2·3 to 2·5. Before the blow-pipe it forms a white glass. Its chemical constitution is stated as follows:—

$$8\,(Ca + 3\,Si) + (K + 6\,Si) + 16\,Aq$$

and the mineral is therefore an hydrated silicate of potash and lime.

Apophyllite has been found in the mines of magnetic iron-ore of Sweden and Norway; in the lead-mines of the Harz Mountains; also in the cavities of several basaltic rocks, at Marienberg in Bohemia; at Fossa in the Tyrol; in the Isle of Skye, &c. In the basalts it is usually accompanied by *Analcime* and *Stilbite*.

This mineral is sometimes called *Tesselite*. *Albin* is a white variety.

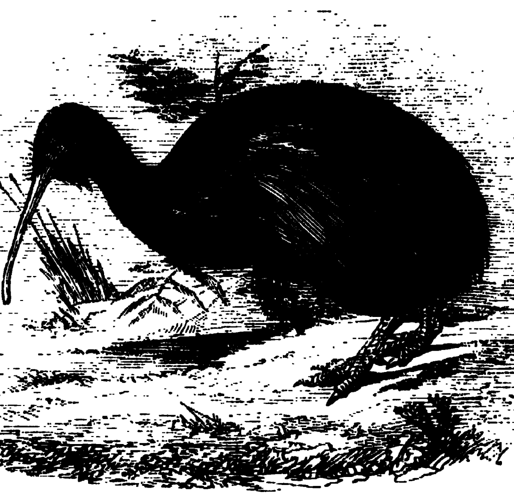
APOTHE'CIA (from the Greek ἀποθήκη, a case, a repository), in Botany, a name given to some of the organs of reproduction in *Cryptogamia*. In Lichens the reproductive matter appears on the surface of its frond or thallus in two forms. First, in the form of little coloured cups or lines with a hard disk surrounded by a rim, and containing tubes filled with sporules; and secondly, in the form of little heaps of pulverulent matter, which are scattered over the surface of the thallus. These last are called *Sordia*; the first, *Apothecia*. These organs form the principal means of distinguishing the various forms of lichens, and consequently it has been found convenient to indicate minor points in their structure by other names. Thus the Apothecium, which in English is called a Shield, has various names according to its form: *Scutellum* is a shield with an elevated rim; *Pelta*, a flat shield; *Tuberculum*, a convex shield; *Trica* or *Gyroma*, a furrowed shield; *Lirella*, a linear shield; *Globulus*, a round deciduous shield; *Pilidium*, an orbicular hemispherical shield. The parts of the Apothecium or Shield have also obtained distinct names: thus *Perithecium* is the inside of the shield, in which the sporules are immersed; *Hypothecium* is the substance that surrounds or overlies the perithecium; *Nucleus* is the disk of the shield, which contains the sporules and their cases; and *Asci* are the tubes in which the sporules are contained.

Apothecia is also the name given to the cases in which the organs of reproduction of many of the *Algæ* are contained. The reproductive granules contained in the Apothecia of both Lichens and Algæ are called by some writers *Gongyli*.

APSENDE'SIA (Lam.), a genus of Fossil *Polypiaria*, from the great Oolite near Bath.

APTERYX, a genus of Struthious Birds, inhabiting Australia and the islands of New Zealand. It was first described by Dr. Shaw, who regarded it as an extinct form of bird. It evidently belongs to a group of birds that were destined to live on the earth, only as long as they were free from the attacks of carnivorous enemies endowed with greater powers of motion than themselves. Numbers of wingless birds, not belonging to the Struthious division, as the Dodo and Solitaire, seem already to have become extinct; whilst the smaller congeners of the *Dinornis* are suffering in like manner. The Apteryx is not however extinct, as many stuffed specimens exist in the museums of England; and, at the present moment (June, 1853), there is a living specimen in the gardens of the Zoological Society, Regent's Park. Of all birds at present known the Apteryx appears to have the wings the most reduced to their simplest rudiments. Its general form is that of the Penguin, and in size it is seldom quite so big as our common goose. The beak is very long and slender, marked on each side with a longitudinal groove, and covered with a membrane at its base. It differs from other birds in the completeness of its diaphragm, and in the absence of abdominal air-cells. The bones are not hollow, as is mostly the case in birds; the sternum is very small, and the ribs are extraordinarily broad; the feathers have no accessory plume, and their shafts are prolonged beyond the back; the feet have a short and elevated hind-toe, of which the claw alone is externally visible.

The native name of this bird is *Kiwi-Kiwi*, given it on account of its peculiar cry. It is a nocturnal bird, and preys on snails, insects, and worms. Whilst at rest it has the singular habit of resting on the tip of its bill, which is its most characteristic position.



Apteryx (*A. australis*).

It runs with considerable rapidity, and when hunted by dogs it makes a hole in the earth for the purpose of concealment, or it retires into the natural cavities of the rocks. When attacked it defends itself with considerable vigour. The natives hunt it for the sake of its skin, which is used by the chiefs for their dresses, and on this account it is highly valued.

A'PTYCHUS (Von Meyer), one of the generic names of a singular Fossil, supposed to be the remains of a Conchiferous Mollusk, or the opercular shell of a Cephalopod. Its other names are *Trigonellites, Ichthyosiagonites*, and *Lepadites*. The species belong to the Ammonitiferous strata, and specimens sometimes occur (as at Solenhofen) in the last chamber of the Ammonites. The structure is fibrous.

AQUATIC ANIMALS. The element in which animals habitually reside, or to which they occasionally resort for the purpose of procuring food or seeking shelter, is so intimately connected with, and bears so obvious a relation to, not only their manners and economy, but likewise their outward forms and internal structure, that it is not surprising that those who first turned their attention to the study of zoology, and sought to introduce the principles of classification into the animal kingdom, should have been so forcibly struck with its importance as to have made it the primary basis of their system. "Animals," says Aristotle ('Hist.' b. i. c. 1), "may be distributed into different classes according to their manner of living, their actions, their character, and their parts. . . . . Considered according to their manner of living, their actions, and their character, they are divided into terrestrial and aquatic. The aquatic are divided into two classes; the one, as is the case with many fishes, pass their whole life in the water, breathe that element, and find their food in it; nor do they ever leave it: the others obtain their food in the water, and even habitually reside in it, but they do not breathe it; they breathe air, and bring forth their young on dry land. Among these latter some are provided with feet and walk upon dry land, others have wings and fly, and others, like the water-serpent, have no feet. . . . . Aquatic animals inhabit seas, lakes, marshes, and rivers." Those principles of classification, in which the habits of animals take precedence of those modifications in their organic conformation which produce these very habits, have long since ceased to be adopted by scientific naturalists; notwithstanding which there is perhaps no inquiry which can engage the attention of the zoologist more fruitful in extensive views and interesting results than the consideration of the organic structure of animals in relation to the element in which nature has ordained them to live.

Those animals which reside entirely in the water, and seek their food and nurture their young in that element, have their organisation, even to the most minute circumstance, rigidly adapted to these purposes. The extremities by which progressive motion is performed in the acts of walking and flying would be a serious impediment to the movements of animals residing in an element of the same specific gravity as their own bodies: these organs accordingly are either entirely wanting, or are reduced to mere rudiments, which serve indeed to keep the body steady and preserve its equilibrium, but are entirely useless in assisting its progression. Such are the fins of fishes, and the flippers, as they are called, of the Whale. The real organ of progression in both cases is the body itself, which is prolonged and attenuated towards the tail, compressed on the sides, and provided with extremely powerful muscles, with which, by alternately striking the water on either side, the animal propels itself forward with a force and velocity unexampled in any other class of animated beings. It is upon this principle that a boat is urged forward by means of a single oar in the stern. The great majority of these animals not only reside habitually in the water, and seek their food there, but likewise breathe that element, and are consequently furnished with an appropriate apparatus for extracting the oxygen gas from its general mass. These tribes may reside at any depth of the ocean and for any length of time; they are not under the necessity of coming frequently to the surface for the purpose of breathing, and their organisation is modified accordingly. Instead of having the tail broad horizontally, it is broad in a vertical direction, which enables them to turn with astonishing rapidity, and is no impediment, but rather an assistant to their forward movements. But the case is different in the Whales and allied animals, which, though residing entirely in the water, breathe air by means of lungs like ordinary Mammalia, and are consequently obliged to come continually to the surface. For this purpose they are provided with a powerful cartilaginous tail flattened horizontally, by moving which upwards or downwards as the occasion requires, they ascend to or descend from the greatest depths of the ocean with almost incredible speed. Fishes, though capable of proceeding straight forwards, or of turning with great rapidity, are comparatively slow in changing their depths; and if they breathed air, they would frequently be suffocated before they could arrive at the surface, from the vertical position of the tail not being adapted to propel them in a vertical direction. But by a simple change, merely by the direction of the tail being altered from the vertical to the horizontal position, the object of nature is accomplished, and the air-breathing Cetaceous Animals are adapted to all the circumstances of an aquatic life. Another beautiful adaptation is observed in the position of the mammæ, for the *Cetacea*, like warm-blooded quadrupeds, suckle their young; these are situated upon the breast, and when the young animal requires to suck, the mother stands, as it were, upright in the water, with her head and shoulders elevated above the surface, supporting herself by means of her flippers, or fore paws. In this position she is enabled to supply her cub with the food which nature has provided, and which she could not have accomplished had the mammæ been placed in any other position.

There is another extensive tribe of aquatic animals, which are provided with perfect articulated members, sometimes indeed supplied with fringes which convert them into a swimming apparatus, but always adapted to enable the animals to walk or crawl along the bottom. Such is the case with all the Crustaceous tribes — the crabs, lobsters, prawns, &c.; and these animals, as is well known, can walk on dry land with the same ease as at the bottom of the ocean. When they swim, it is by means of the tail, which is always constructed for that special purpose, and is large and powerful.

Nor is the modification of structure less striking when we examine those land-animals which breathe air, and resort only occasionally to the water. As they are intermediate in habits, so are they likewise intermediate in structure between these two extremes; and the degree in which their organisation is modified, when compared with either of the two types, is exactly proportioned to the difference of their habits and economy. All Mammals and Reptiles, for instance, which seek their food in fresh-water rivers and lakes, partake more of terrestrial than of aquatic habits. The extent of water with which they are conversant is, in this case, very small when compared to the extent of land, and their organisation differs but slightly from that of ordinary land animals; their extremities are perfectly developed, and of the ordinary form, the principal difference being that their toes are united by an expanded web or membrane, which gives the paw a broad oar-like form, and thus converts it into a convenient instrument of swimming, at the same time that it scarcely interferes with the most perfect freedom of walking and running on land. Of this nature are the extremities of all the vertebrated terrestrial animals which seek their food in fresh water, the otters, beavers, &c. among mammals; the whole order of Natatores, comprising the ducks, swans, pelicans, gulls, auks, puffins, &c. among the birds; and the crocodiles, alligators, fresh-water tortoises, and frogs, among the reptiles. All these animals are, properly speaking, web-footed, and their aquatic habits are less prominent and powerful than their terrestrial; their organs of motion in fact are but little different from those of common terrestrial animals. In those which frequent the salt-water, on the contrary, the aquatic habits greatly predominate over the terrestrial: they live less on land than in water and the structure of their extremities approximates more to that of purely aquatic than of terrestrial animals. Their legs are short, and inserted, or as it were buried, in the common integuments of the body, as far as the elbows and knees respectively, leaving apparent only a short fin-like paw, which is unadapted to terrestrial progression, exactly in proportion to its fitness as an organ of swimming. Their progress on land is consequently slow and difficult; they creep rather than walk, dragging the body along the ground, and leaving a broad mark behind them. Few species possess even this limited power of terrestrial motion; those which do however have the structure of the extremities a little less approximated to the form of fins than the purely oceanic species. The seals and walruses, for instance, have the bones of the paws and feet similar to those of ordinary land-quadrupeds, only much shorter and more flattened, and the hind legs are thrown backwards in the same direction as the tail. Still they are enabled to use the extremities in a certain degree for walking or creeping on dry land; but the numerous tribes of cetaceous animals, which can execute no kind of motion whatever out of the water, have the bones of the anterior extremities flattened and connected together like the stones of a mosaic pavement, whilst the posterior members are entirely wanting. The same is the case with the sea-tortoises, or, as they are more properly called, turtles, when compared with those which frequent fresh-water ponds and rivers; the form of their extremities approximates more nearly to that of fins than of feet, and their aquatic habits constantly predominate over their terrestrial.

Thus it is that the peculiar form of the extremities not only indicates the degree in which an animal is aquatic, but even the nature of the element which it frequents. If it inhabits fresh-water ponds and rivers, its feet are simply webbed between the toes, but in other respects perfectly developed, and its terrestrial habits predominate over its aquatic; if, on the contrary, it inhabits the salt water, its feet are flattened into the form of fins, the hind legs are thrown backwards into the plane of the body, and the aquatic habits greatly predominate over the terrestrial. The first are, properly speaking, *web-footed*, the second *fin-footed*.

AQUATIC PLANTS, or **WATER PLANTS**, are those plants which live entirely in water, or which require a preponderating quantity of water as the medium of their existence. The families of plants, like the families of animals that live in the water, are found to belong to all classes into which the whole have been divided, although those belonging to the lower classes are by far the most prevalent. Many of the families of plants having the highest organisation have members belonging to them which are inhabitants of the water: of this the *Ranunculus aquatilis* is an example in the natural order *Ranunculaceæ*. All the species of the orders *Nymphæaceæ*, *Callitrichaceæ*, *Ceratophyllaceæ*, and *Podostemaceæ*, belonging to the class Exogens, grow in water. Among Endogens, the orders *Butomaceæ*, *Naiadaceæ* or *Fluviales*, *Pistiaceæ*, *Alismaceæ*, &c. consist entirely of water-plants; whilst one of the largest of the few families into which Cryptogamic Plants are divided, the *Algæ*, consists almost entirely of plants which live in the water.

For the purpose of studying the distribution of the vegetable kingdom, water-plants are distributed into several groups. One of the first divisions that suggests itself in the study of their forms is derived from the composition of the waters in which they grow. Thus we have those which grow in the saline waters of the ocean, and those which grow in the fresh waters inland. Most of the plants which grow at the bottom of the ocean or float in its waters belong to the family of *Algæ*. [ALGÆ.] There are however many plants not belonging to this order which require the influence of salt-water on the soil on which they grow for their production. Thus species of the genera *Salsola*, *Anabasis*, *Salicornia*, and *Glaux* will not grow but where they can feel the influence of salt-water: hence they have been called *Plantæ Salinæ*. These plants are found not only where the sea washes, but wherever salt-springs find their way to the surface of the earth. There is another group of plants which have their existence determined by saline waters, but are always found near the sea or on the banks of rivers to which the sea has access. Such are species of *Chenopodium*, *Heliotropium*, *Vitex*, *Eryngium*, *Samolus*, and the Mangrove (*Rhizophora*). These are called *Plantæ Littorales*, *seu Maritimæ*.

The largest proportion of Fresh-Water Plants belong also to the natural order *Algæ*, although by far the most conspicuous specimens belong to the tribes of Exogenous and Endogenous plants. As the sea claims nearly all the species of the genus *Fucus* and its allies, so the fresh-water claims the majority of the species of the old genus *Conferva* and its allies.

Aquatic Plants, in Horticulture, are those which naturally grow in deep water, and are carefully distinguished by the cultivator from marsh-plants. The management of them, when they are hardy, is of the simplest kind, nothing being necessary beyond planting them in boxes with holes in the sides, and sinking them 3 or 4 feet below the surface of a pond, so that the boxes lie upon or among the mud at the bottom.

But for those which demand the protection of the stove or greenhouse, some additional precautions are requisite. If left to themselves in such situations, the uniformity of temperature is such as to deprive them in some measure of the repose that they naturally receive from the alternation of seasons; kept constantly in a growing state, their excitability is gradually destroyed, and death ensues as a matter of course. The plants which demand special treatment are chiefly those which belong to the natural order *Nymphæaceæ*. [WATER-LILY.] The most beautiful of these is the *Victoria regia*. Various methods have been recommended; but they all depend for their success upon keeping in view the principle of periodical rest and rapid growth under a high temperature, with but little air during the season of vegetation.

AQUAVIVARIUM, a term proposed to be applied to arrangements which contemplate the exhibition of living aquatic specimens of animals inhabiting either fresh or salt water. Although it has been known from the earliest times that animals living in water may be kept in small glass vessels for exhibition by the daily supply of fresh-water, the discoveries of modern chemistry have pointed out how animals may be kept living in only limited quantities of water which never demand renewing. The possibility of accomplishing this depends on the absolute balance in nature which exists between the animal and vegetable kingdoms. [ANIMAL KINGDOM.] The one set of these beings are for ever engaged in giving off what the other requires, and in taking up what the other rejects. It is thus that the carbonic acid which is constantly being thrown off the tissues of animals is taken up by plants, and thus prevented from contaminating the atmosphere; whilst the plant is constantly engaged in giving off oxygen gas, and supplying the atmosphere with this element of its composition which is necessary to the life of animals. The relations which are thus found to exist on the large scale of the whole surface of the earth, are found also to occur in a jar of water. If an animal is placed in pure water it quickly exhausts the oxygen it contains, and gives out into it carbonic acid gas; the consequence is, that it is quickly poisoned unless fresh water with oxygen is supplied. But if we place with the animal some plant that lives in water, it will be found that the carbonic acid given out by the animal will be taken up by the plant, and that it will give out oxygen in its place. Thus the water becomes cleared of its injurious compound, and the needed element, oxygen, is supplied. This is really what takes place in every pond and pool where the water is fresh, and all that is required to make the inhabitants of the pond visible is to put the whole pond, plant, and animals into a glass-case. Such a plan has been tried with great success, and we propose to call the apparatus in which it is effected an Aquavivarium.

The first experiments were made with fresh-water, and we believe the public is indebted for one of the earliest accounts of such an arrangement to Mr. Warington, chemist to the Apothecaries' Company. He found out, however, that it was not sufficient to have simply any kind of plants and animals; but that, in order to maintain the balance correctly, it was necessary that certain animals which lived on decomposing vegetable matter should be present. At certain seasons of the year the tendency to decomposition in the water-plants becomes so decided that the water would be rendered impure if this decomposition was not arrested. The cure for this was found in the addition of fresh-water Mollusca to the jars containing such fish as the gold-carp and stickleback and such plants as the *Vallisneria spiralis*, *Callitriche*, &c. The best kind of snails for this purpose are the various species of *Planorbis*. Not only is it necessary that this latter precaution be taken to ensure the success of the experiment, but it is of importance to guard against the preponderance of animal life. Although in most cases it appears that there cannot be too many plants for the health of the animal as long as they grow healthily and do not decompose, yet it often happens that the excess of animals over plants in a given space will destroy the balance, and lead to the destruction of life. We are not aware that any precise experiments with regard to the quantity of water and the number of plants and animals have been yet performed. We can however state as a fact, that a gold-fish has lived for nearly twelve months in about two gallons of water with several flourishing plants of *Vallisneria spiralis*. It is probable that a smaller quantity of water would have served equally well.

Amongst the fresh-water plants adapted for growing in such jars or tanks as we have mentioned, are the *Vallisneria spiralis*, various species of *Chara*, *Anacharis Alsinastrum*, *Stratiotes Aloides*, *Callitriche autumnalis*, *C. vernalis*, *Myriophyllum spicatum*, and *Ranunculus aquatilis*. Such jars afford a good opportunity for cultivating the various species of fresh-water Confervæ, which all assist in keeping the water pure. One of the most beautiful of these is the *Hydrodictyon utriculatum*, which may be easily propagated in this manner.

Although these results have been known for many years, it is only recently that any attempts have been made to carry out the same plan with regard to marine animals and plants in sea-water. The only plan adopted of keeping the Marine Invertebrate Animals was the laborious one of supplying them every day with water from the sea. For upwards of thirty years Sir John Dalyell carried on his observations on sea-animals in the city of Edinburgh upon this system. It was however known generally amongst naturalists, that by exposing sea-water to the action of the air by pouring it from one vessel into another, it became perfectly purified. In this way many persons succeeded in maintaining alive, in the heart of London, *Actiniæ*, Star-

Fishes, and other low forms of marine animal life. It was however left for Mr. Warington to demonstrate what others had often theorised on, and that was, that marine plants purified sea-water just as fresh-water plants purified fresh-water. That the same idea had occurred to others is proved by Mr. W. Thomson's communications to the 'Annals of Natural History' (May 1853), and Mr. Gosse's account of Marine Vivaria in his 'Naturalist's Rambles on the Devonshire Coast.' The difficulties, however, are greater in maintaining the balance between the plants and animals in sea-water than in fresh. This arises from the more sluggish life, both of marine plants and animals, and the greater amount of disorganised matter which they throw from their surfaces. By care in the selection of sea-weeds, avoiding those which are large and throw off much matter from their surface, and not overcrowding the water with animal life, jars or tanks containing sea-animals and sea-plants can be easily managed. Mr. Warington recommends green sea-weeds, such as the species of *Porphyra*, &c. Mr. Gosse speaks favourably of *Chondrus crispus*, *Iridæa edulis*, and the *Delesseriæ*. In jars or tanks containing these plants various forms of sea-animals have been successfully kept for many months.

The greatest experiment of this kind which has hitherto been attempted is in a large glass-building that has been erected in the gardens of the Zoological Society, Regent's Park It was opened to the public in May, 1853. This building contains an area of 60 feet by 25 feet. The sides of this parallelogram are bounded by ponds of plate-glass, each being about 6 feet in length and 2 feet 6 inches in depth. They are placed at a height of about 3 feet from the ground, so that each division presents as it were a submarine picture 'on the line,' and may be approached so closely that the minutest animals not microscopic, may be watched with the most perfect success, under circumstances which differ as little as possible from those of nature. The whole of these tanks are supplied with gravel, sand, rocks, and sea-weeds, so as to imitate the rock-pools left on the sea-shore by a receding tide, which indeed they may be said to represent; but with this great advantage to the observer, that instead of looking vertically into a cavity in which the light becomes less and less in proportion to the depth, he has here the means of examining each animal in its turn, under an effect which is not only most delightful in itself, but which, the water being seen in section through perfectly transparent walls, afford the best possible position for investigating the structure and functions of the living beings contained in it.

At present the water in the ponds or tanks in this establishment has not been left to the purifying influence of the plants which are placed in them; a certain quantity of water being supplied to the fresh-water tanks every day, whilst the salt-water is gradually drawn off and supplied again by dropping, so as to effect aëration by means of tubes above the tanks. This however is only precautionary, at the commencement of an experiment on so large a scale.

The tanks contain fresh-water animals and marine animals. The fresh-water tanks present all the more common species of British Fishes, as the Pike, Tench, Perch, Roach, Rudd, Carp, Eel, Stickleback, Minnow, Gudgeon, &c. Some of the larger forms of fresh-water Crustacea, as the Crawfish, have also been introduced. With these are placed a large variety of the fresh-water Mollusca, belonging to the genera *Limneus*, *Planorbis*, *Anodon*, *Unio*, &c. These tanks have been occupied since Christmas, 1852, with scarcely any loss.

The marine tanks are those which will undoubtedly always form the most attractive feature in an Aquavivarium, as we are less conversant with the habits of these creatures of the mighty deep, than with those of our ponds and rivers. In the establishment in Regent's Park all the classes of the Invertebrate Animals are represented as well as the fish among the Vertebrate.

Amongst the Radiate Animals none are more remarkable for their power of resisting destruction than the *Actiniadæ*, and all experimenters agree that they are amongst the animals which may be most successfully kept in the Aquavivarium. All the more common British species are now to be seen in the Regent's Park, and some of remarkable size and beauty. The Sertularian Zoophytes and the Polyzoa are also there, but their animal inhabitants are too minute to be seen with the naked eye. Specimens of the *Echinodermata*, including several forms of Star-Fishes (*Asterias*), the Sun-Star, the common Sea-Egg, and a species of *Holothuria*, which have lived for some weeks, prove that undoubtedly these beautiful forms of animal life will live in confinement, and lead to the hope that some of the rarer sorts from tropical oceans may find their way to our collections.

As was to be expected, the *Mollusca* thrive. In the sea they play the same part as in the fresh-water: they are the scavengers of the ocean. The Pinna, the Oyster, the Pecten, the Cockle, amongst bivalves; and the Whelk, the Periwinkle, with many other univalves, have demonstrated how large a field of observation is in store for those who study the Mollusca. Several species of those gems of the ocean, the Nudibranchiate Mollusca, whose forms and colours are only known to us through the great work of Alder and Hancock, have been successfully kept alive; whilst the red leaves of the species of *Rhodymenia* have been starred with their eggs. Various forms of Ascidian Mollusca have lived, and complete the evidence that this great group of animals may be watched in their living habits as easily as their shells may be examined in a cabinet.

The *Articulata* are represented in these tanks by species of Lobster, Crab, Shrimp, and Prawn. Though many of these are inhabitants of the deep ocean, and only reward the labours of the dredger, yet they live perfectly well in the shallow lodgings provided for them by the Zoological Society. These facts demonstrate that amongst the Invertebrate tribes there are none whose habits may not be studied in the Aquavivarium.

As yet the evidence is not complete with regard to marine fish. The only species at present tried in Regent's Park have been the smaller species that frequent the rocky pools of our coasts. Amongst others, the Cork-Wing (*Crenilabrus Cornubicus*), the Fifteen-Spined Stickleback, the Long-Spined Cottus, two species of Blenny, and a Goby, testify how far this portion of the collection may be extended.

As far as experiment has gone, the success of the Aquavivarium is complete; and it is not too much to suppose that the time will speedily arrive when in every exhibition of animal life glass-tanks will be fitted up for the purpose of illustrating the habits of marine and fresh-water animals. As there are scarcely any limits to the size of which vessels made with square plates of glass can be constructed, we may hope to see sporting in our zoological collections some of the monsters of the deep of whose actions and life we know absolutely nothing, and of whose forms we only judge by the shapeless masses which their skins present when stuffed, or their carcasses when bottled in spirits of wine.

Before concluding this article, we would call attention to the fact that the principles on which the Aquavivarium is constructed are also adapted to facilitate the removal from place to place of marine and fresh-water animals. These tanks may be easily fitted up on board ships, and, with a little attention from day to day, many of those creatures which are only known to the naturalist by its skeleton or its name, might be secured, and brought into our living museums.

(*Athenæum*, May 28, 1853; *Annals of Natural History*, May, 1853, Gosse, *A Naturalist's Rambles on the Devonshire Coast*; Dalyell, *Remarkable Animals of Scotland.*)

AQUIFOLIA'CEÆ (from *aqua*, water, and *folium*, leaf), *Holly-Worts*, a natural order of plants belonging to the Polycarpous group of Polypetalous Exogens. The species consist of trees or shrubs, with alternate or opposite coriaceous leaves. The flowers are small, axillary, solitary, or fascicled. The sepals 4-6, imbricated in æstivation; the corolla 4- or 5-parted, hypogynous, imbricated in æstivation; the stamens inserted into the corolla alternate with its segments, filaments erect, anthers adnate; no disk: the ovary fleshy, superior, somewhat truncate, with from 2 to 6 cells; ovules solitary, pendulous from a cup-shaped funiculus; stigma subsessile, lobed; the fruit fleshy, indehiscent, with from 2 to 6 stones; the seed suspended, nearly sessile, with large fleshy albumen, and a small 2-lobed embryo lying next the hilum, with minute cotyledons and superior radicle. (Lindley.)

This order, which is named after the *Ilex aquifolium*, the Common Holly [ILEX], was included by Jussieu in *Rhamnaceæ*. It has however been well characterised by Brongniart, in his memoir upon Rhamneous Plants, under the name *Ilicineæ*.

This order differs from *Celastraceæ*, in which it is often included as a section, in the form of its calyx and corolla, in the insertion of the stamens, and in the structure of the ovary and fruit. It agrees closely with *Ebenaceæ*, from which, according to Brongniart, it only differs in possessing hermaphrodite flowers, and stamens equal in number to the segments of the corolla.

This order has but one representative in Europe, the Common Holly (*Ilex aquifolium*). The great bulk of the species are found in North and South America; some are found at the Cape of Good Hope.

The useful plants of this order are found in the genera *Ilex*, *Myginda*, and *Prinos*. *Ilex* is remarkable for yielding in one of its species, *I. Paraguensis*, the alkaloid *Theine*, the same principle that is found in the *Thea Chinensis*. [TEA, PARAGUAY; ILEX.]

Myginda was named after Francis von Mygind, a German botanist. *M. uragoga* is a native of South America, near Carthagena. It has small dark shining red flowers, and bears a red soft fruit about the size of a pea. It is called by the Spaniards *Yerra de Maravedi*, and a decoction of the root is used as a diuretic. *M. Gongonha*, a native of Brazil, in the provinces of St. Paul and Minas Geraes, has also the reputation of being a powerful diuretic, and its roots are used in infusion or decoction by the natives.

Prinos (from the Greek for the holly, πρῖνος), Winterberry.

P. verticillatus, Whorled Winterberry, is a native of North America, from Canada to Virginia, in sandy wet woods, and on the borders of swamps. The flowers are white, and the berries are of a crimson red. The bark is bitter, and has been substituted for Cinchona Bark in the treatment of fever. It is said to act as an antiseptic, and is used in America as an application to gangrenous sores, and also in infusion or decoction, as a lotion in cutaneous disorders.

P. glaber is a low handsome shrub, with white flowers and a black fruit; hence, in Jersey, it is called Ink-Berries. It is a native of North America, from Canada to Florida. Its leaves are said to be a good substitute for those of the Paraguay-Tea Plant, and are used for making tea.

There are several other species of *Prinos*, some of which are hardy, and well adapted for shrubberies. They will thrive in most light soils, but do best in peat. They may be propagated by laying down the shoots or by seeds. The stove species should be grown in a mixture of loam and peat, and cuttings will root freely in sand, under a hand-glass. Most of the species of Aquifoliaceous Plants may be cultivated in the same manner.

(Don, *Gardener's Dictionary;* Burnett, *Outlines of Botany;* Lindley, *Natural System.*)

AQUILA, the generic name of the Eagles. (FALCONIDÆ.)

AQUILARIA. [AQUILARIACEÆ.]

AQUILARIA'CEÆ, *Aquilariads*, a small natural order of plants belonging to the Incomplete Exogens. The species are trees with smooth branches and a tough bark. The leaves are alternate, entire, seated on short stalks without stipules, and when full-grown are smooth and shiny, with very fine veins running together into a marginal vein just within the margin. The calyx is turbinate or tubular, limb 5-cleft, segments spreading, persistent, with an imbricated æstivation, the orifice furnished with 5- or 10-bearded scales (metamorphosed stamens). The stamens are 5 or 10 in number; when 5, they are opposite the segments of the calyx; the filaments are short or absent, smooth, inserted into the orifice of the calyx a little lower down than the scales, except in cases where they are united to the tube of the calyx; the anthers are narrow, oblong, attached by their back below the middle, 2-celled, opening internally and lengthwise; the ovary is superior, sessile or stipitate, downy, compressed, 1-celled, having internally, upon each flattened side, a linear prominent placenta resembling a dissepiment, hence spuriously 2-celled, with a very narrow partition; ovules two, of which one is suspended from each placenta, tapering downwards; the style is either absent or conical and thread-shaped; the stigma is simple and large; the fruit is a capsule, pear-shaped, compressed, sessile or stipitate, 1-celled, 2-valved, the valves bearing in the middle the placentæ; which almost touch each other. One seed is mostly borne on each placenta (one is sometimes abortive); the seed rises up by aid of a funiculus, originating near the apex of the placenta, and is furnished with a tail-like aril, which descends straight from the hilum to the bottom of the capsule; the radicle is straight and superior, the albumen is absent, and the cotyledons thick, fleshy, and hemispherical.

This order, which consists at present of only three genera, was constituted by Robert Brown, who regarded it as having so close an affinity with *Chailletaceæ*, as to see no objection to making it a section of that order. He also pointed out its relation to *Thymelaceæ*, in which he is followed by Lindley, who says, "*Aquilariaceæ* chiefly differ from *Thymelaceæ* in their dehiscent fruit, and probably also in the direction of their radic[illegible]. In both orders the ovary is superior and 1-celled; both have similar scale-like bodies at the orifice of the calyx, and no petals; both suspended ovules, a single style, and capitate stigma." De Candolle places the order between *Chailletaceæ* and *Terebintaceæ*.

All the species of *Aquilariaceæ* are natives of the East Indies.

The three genera of this order are *Aquilaria*, *Ophiospermum*, and *Gyrinops*. Of the last two little is known. One species of each has been described. There are three species of *Aquilaria*.

A. Malaccensis, the *Bois d'Aigle*, or Eagle-Wood, is a native of Malacca, and produces a whitish-yellow wood. This is the *A. ovata* of some botanists. *A. Agallochum* is a native of the East Indies, where it is called Ugoor, or Ugooroo, by the natives, and Lignum-Aloes, or Aloe-Wood, by the Europeans. The wood has a fine scent, and is supposed to be the Calambac, or Agallochum, of the ancients.

A. secundaria is another species which also yields a scented wood, and has been known in the Materia Medica, and used in perfumery, under the names of Agallochum, Lignum-Aloes, and Aloe-Wood. In a healthy state this wood is said to be white and inodorous; but it is subject to the attacks of disease, which causes the secretion of a resinous matter, and the wood then becomes coloured, and gives out a powerful scent. This secretion resembles camphor in many of its properties, and has a bitter flavour: hence the name Aloe-Wood. In medicine it is recommended in the same diseases as the fetid resins and volatile oils, and does not seem to possess peculiar properties; so that it is not used as a medicine in Europe. The Cochin-Chinese are said to make their paper from the bark of this or some kindred species of *Aquilaria*. These trees must not be confounded with the *Aloexylon Agallochum*, or Aloe-Wood, which is a tree belonging to the natural order *Leguminosæ*, and which also yields a scented wood used by the Chinese in medicine and perfumery.

(Don, *Gardener's Dictionary;* Lindley, *Natural System;* Royle, *Illustrations.*)

AQUILE'GIA, literally the Water-Gatherer, because the leaves collect water in their hollow, is a small genus of plants, commonly called Columbines, belonging to the order *Ranunculaceæ*, of which several species are cultivated in gardens. They are known from *Aconitum*, to which they are the most nearly related, by the leaves of the calyx being all of the same form and size, and by the petals having each a long curved horn or spur at the base. All the species are handsome perennials, easily propagated by dividing the crown of their roots: the commonest, hence named *A. vulgaris*, is found in woods and thickets in this and all other parts of Europe; it has produced many varieties, differing in the colour of the flowers, and in the multiplication of the petals, for the sake of which it is commonly cultivated. The other species are found either in the north of Asia, or in North America. They are all acrid plants, but much inferior to Aconite in their medicinal properties; hence little attention has been given to them.

A'RACHIS, a genus of plants belonging to the natural order *Leguminosæ*. One species, *A. hypogæa*, is called the Earth-Nut. The circumstance by which the *Arachis hypogæa* is particularly remarkable is the manner in which its fruit is produced. Instead of hanging down from among the leaves in the manner of other plants, this conceals itself in the earth, in which it is deeply buried at the period when it becomes ripe, a phenomenon which happens thus:—The young fruit, instead of being placed at the bottom of the calyx, as in other kinds of pulse, is found at the bottom and in the inside of a long slender tube, which looks like a flower-stalk. When the flower has withered, and the young fruit is fertilised, nothing but the bottom of this tube with its contents remains. At this period a small point projects from the summit of the young fruit, and gradually elongates, curving downwards towards the earth. At the same time the stalk of the fruit lengthens, until the small point strikes the earth, into which the now half-grown fruit is speedily forced, and where it finally ripens in what would seem a most unnatural position. When mature, it is a pale-yellow wrinkled oblong pod, often contracted in the middle, and containing two or three seeds the size of a hazel-nut. These are considered a valuable article of food in Africa and the tropical parts of Asia and America. In flavour the nuts are as sweet as an almond; and they yield, when pressed, an oil in no respect inferior to that of olives.

The plant will only grow in a light sandy soil, in which its pods can readily be buried, and it requires a climate as hot at least as that of the south of France. Its stems grow from one to two feet high; its leaves are composed of four broad and blunt leaflets; and its flowers are small and of a pale yellow colour.

ARA'CHNIDA, a class of animals including Spiders, Mites, and Scorpions, all ranked by Linnæus under Insects, but which are very properly separated from them, on account of external form, structure, and habits. The separation was first made, we believe, by Fabricius, who, looking chiefly to the structure of the mouth, characterised the greater number of the animals now ranked under *Arachnida*, by the jaws (*maxilla*) being horny and furnished with a claw (*unogata*). M. Lamarck afterwards made the *Arachnida* a distinct class; but we owe to M. Latreille and Dr. Leach the establishment of characters more precise, and extending to a greater number of genera. Much has been done in perfecting the knowledge of their structure, manners, and numerous species by Clerck, De Geer, Walckenaer, Treviranus, Leon Dufour, Herold, Straus-Dürckheim, Blackwall, and others. We shall condense into as short a compass as we can the most important points investigated by these naturalists.

The *Arachnida* (*Acera*, Virey) differ from Insects in having no antennæ; in the eyes being in most species 8, and, even when only two in number, never being placed laterally on the head; in the legs being usually 8, though in some species 6, and in others 10; and in their respiratory apparatus consisting of radiated tracheæ, communicating with a sort of gills inclosed in pouches in the lower part of the abdomen.

The skin or crust of the *Arachnida* is in general more leathery than horny; but whether it be soft, as in most species, or hard, as in a few, it performs a similar office to the bones of larger animals in giving support to the soft parts and attachment to muscles, the legs being joined upon and radiating from a common breast-plate (*sternum*) externally; while, according to Straus-Dürckheim, there is also an internal breast-plate of a gristly texture (*un sternum cartilagineux intérieur*) in form of a horse-shoe, the two ends of which are directed forwards.

The greater number of the *Arachnida* are carnivorous, and are furnished with appropriate organs for their predatory life. Some parasitic species, such as the minute Parasite Mites (*Lepti*, De Geer), which we have observed infesting numerous species of insects, from the largest butterflies to the smallest gnats, are furnished with a sucker, in some respects constructed like that of the Gadfly (*Tabanus*). In other species, there may be distinguished a pair of upper jaws (*mandibula*), a pair of under jaws (*maxilla*), carrying jointed feelers (*palpi*), and between them a sort of tongue formed by a projection from the breast. At the back part of the mouth is placed a piece of a horny texture, which Savigny, Latreille, and Audouin term the *pharynx*, forming the entrance into the gullet. The gullet, together with a bulging on the fore part of it, termed the stomach, as well as the intestines, run in a straight line from the pharynx to the vent. Near the upper portion of the gullet are found salivary vessels, whose exterior aperture is in the first joint of the upper jaws. The saliva secreted by those vessels appears to be poisonous. Lower down are the biliary vessels, which resemble those of insects.

In the greater number of *Arachnida* there is a complete and very distinct circulatory system. The heart, which differs materially from the dorsal vessel by some termed the heart in insects, occupies the abdomen, and its pulsations may be distinguished externally. It is a thick longitudinal vessel, giving origin to a certain number of arteries, and receiving veins by which the blood returns from the respiratory organs in other parts of the body.

The respiratory organs have two striking peculiarities, upon which M. Latreille founded his two great divisions of *Arachnida*.

The division furnished with air-pipes, similar to those of insects, comprises Harvest- or Shepherd-Spiders (*Phalangia*), Mites, and several other genera. "The presence of air-pipes (*trachées*)," says M. Latreille, "excludes all complete circulation, that is, the distribution of blood to different parts, and its return from the respiratory organs to the heart."

The other division of the class comprises the numerous species of Spiders, and the Scorpions, which M. Straus-Dürckheim and Leon Dufour place first. Their respiratory apparatus consists of small cavities formed by the union of a great number of triangular white laminæ of extreme thinness. The number of these is usually two, but in some species there are four, and in others eight. The external apertures of these, termed spiracles, and, as M. Latreille well remarks, objectionably *stigmata*, are transverse chinks, corresponding in number with the pulmonary pouches.

The nervous system of the *Arachnida* is ganglionic, consisting of nerve-knots (*ganglia*). In man and the larger animals, a ganglion is composed of two substances similar to the cortical and medullary substances of the brain, and differs from nerves in being firmer in texture, and covered with a membrane of closer tissue. In the *Arachnida* these nerve-knots are more concentrated, if the term may be used, than in Insects, and they are uniform in composition, rather than a chain of ganglions equally separated. Thus, in the Harvest-Spiders (*Phalangia*) there are a pair of nerve-knots in front of the gullet, and at the back of the gullet a medullary mass, apparently consisting of three ranges of nerve-knots united.

We know nothing of the organ of hearing in *Arachnida*, though it is certain enough that they do hear. Their eyes are all simple, not composite, like those of many insects. "The eyes of spiders and scorpions," says Swammerdam, "are externally formed exactly in the same manner, and are smooth, glittering, and without divisions; and are as much dispersed as those that are disposed at random over the body. The Wolf-Spider, which catches its prey by leaping on it, has its eyes placed in the same manner." In the greater number of Spiders they are 8 in number, but in some 6 (*Dysdera* and *Segestria*), and in others 2 (*Phalangium*). The arrangement of the eyes, when more than two, varies considerably in the different genera, and is taken advantage of in arranging them systematically, on the principle first pointed out by Dr. Lister, and improved upon by Latreille, Leach, and Walckenaer. Figures of various arrangements of the eyes in spiders may be seen in 'Insect Miscellanies,' pp. 125, 126, after Audouin. ('Lib. of Ent. Knowledge.')

With regard to the sexes, male spiders are always much smaller than the females, being often not more than one-fourth the size. The feelers (*palpi*), also, in the male are furnished with organs at the tip, which are of various forms, but usually bulging, whereas the feelers in the female gradually taper to a point.

Looking at the size of the female spider, and the eggs which she lays, it appears almost incomprehensible how they could be contained in so small a body. But, by observing them more closely, it may be discovered that they have not, like the eggs of birds, a hard shell, but, on the contrary, are soft and compressible. Accordingly, before they are laid, they lie in the egg-bag (*ovarium*) within the spider's body, squeezed together in a flat manner; and only come into a globular form after they are laid, partly in consequence of the equal pressure of the air on every side, in the same way as we see dew-drops and globules of quicksilver formed from the same cause.

The eggs of spiders, it is worthy of remark, are in most cases, though not always, placed in a roundish ball; and, as there is nothing in nature without some good reason, if we can discover it, we may infer that this form is designed to economise the materials of the silken web which the mother spins around them by way of protection. Whether we are right or not in this conjecture, there can be no question as to the manner in which the ball is shaped, as the writer has often observed the process. The mother spider, in such cases, uses her own body as a gauge to measure her work, in the same way as a bird uses its body to gauge the size and form of its nest. The spider first spreads a thin coating of silk as a foundation, taking care to have this circular by turning round its body during the process. It then, in the same manner, spins a raised border round this till it takes the form of a cup, and at this stage of the work it begins to lay its eggs in the cup, not only filling it with these up to the brim, but piling them up above it into a rounded heap as high as the cup is deep. Here, then, is a cup full of eggs, the under half covered and protected by the silken sides of the cup, but the upper still bare, and exposed to the air and the cold. It is now the spider's task to cover these, and the process is similar to the preceding, that is, she weaves a thick web of silk all round them, and, instead of a cup-shaped nest like some birds, the whole eggs are inclosed in a ball much larger than the body of the spider that constructed it.

There is a singular mechanism for the purpose of placing the eggs in the proper position. The eggs, different from what takes place in birds, are excluded from a cavity just behind the breast. Here there is an organ placed somewhat in the form of a hook or a bent spatula, which the spider can move in such a manner as to direct every individual egg which it lays to the exact spot in the nest-cup where it wishes it to be placed. The sense of touch in this organ must of course be very acute, as by touch it must be wholly guided; for its eyes, though eight in number, and very piercing, are situated on the upper part of the head, and cannot be brought within sight of the nest.

The hatching of the eggs of one species (*Epeira diadema*) has been traced with great minuteness, and the successive evolution of the embryo figured with great skill, by M. Herold of Marburg.

M. Latreille, whose method has been generally followed both in Britain and on the Continent, arranges the *Arachnida* into two orders, as follows:—

Class.		Orders.
ARACHNIDA	Pulmonary sacs for respiration; six to twelve ocelli	*Pulmonaria.*
	Tracheæ for respiration; not more than four ocelli	*Trachearia.*

The first order is divided into two families:—

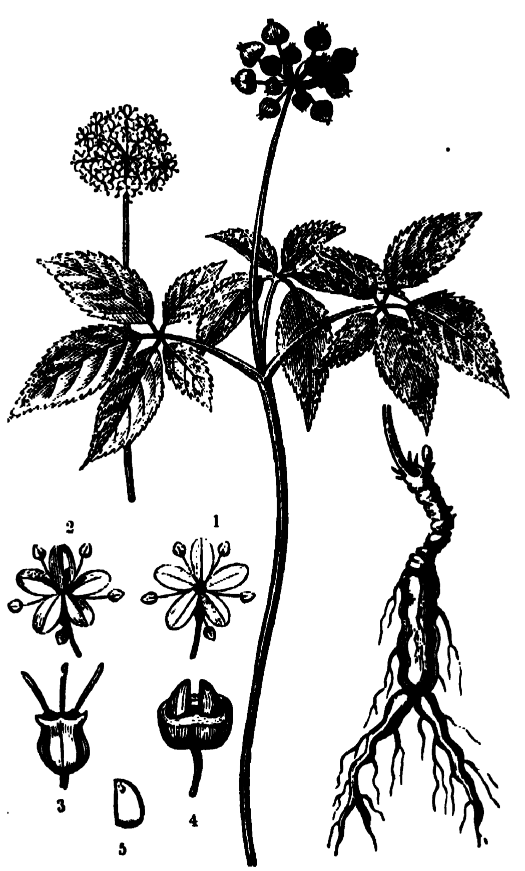
		Families.
Arachnida Pulmonaria.	Palpi simple, pediform; mandibles armed with a moveable and perforated claw, emitting a poisonous liquid; abdomen inarticulate, terminated by spinnerets . . .	*Araneidæ.*
	Palpi produced, cheliform, or shaped like pincers; mandibles with a moveable digit; abdomen articulate, without spinnerets. . . .	*Pedipalpi.*

The *Araneidæ* include our common Spiders. [ARANEIDÆ.]

The *Pedipalpi* include the Scorpions and their allies. [SCORPIONIDÆ.]

The second order, *Trachearia*, includes very various forms, as the Pycnogonums and the Mites. [TRACHEARIA; ACARIDÆ.]

ARALIA'CEÆ, *Ivyworts*, are a small natural order of plants, nearly related to the *Umbelliferæ*, from which they are solely known by their young fruit consisting of more parts than two. The species of this order, which includes the Ivy [HEDERA], are frequently shrubby, and not uncommonly furnished with powerful hard prickles; but they are often also herbaceous and unarmed, like umbelliferous plants themselves. As an illustration of the order, the American Ginseng (*Panax quinquefolium*) may be taken.



Ginseng (*Panax quinquefolium*).

1. A barren flower. 2. A fertile flower. 3. Ovarium and styles.
4. Fruit cut in half, with the seeds projecting.
5. A section of a seed, showing its minute embryo.

This plant, which is nearly related to the celebrated stimulating drug called Ginseng by the Chinese [PANAX], is found occasionally on the mountains of America, from Canada to the Carolinas. It was long since introduced into our gardens, but it is now seldom seen.

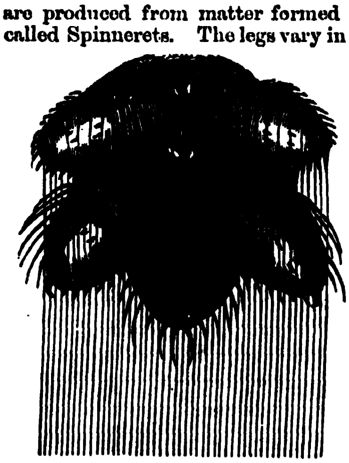
This natural order seems to possess little or no sensible properties, for the singular invigorating power ascribed to Ginseng by the Chinese is considered to be apocryphal.

Many of the species of *Aralia*, on account of their aromatic properties, are employed in medicine. An aromatic gum-resin comes from *A. racemosa*, *A. hispida*, and *A. spinosa*. *A. medicinalis* is diaphoretic, and its shoots are employed in North America as a substitute for Sarsaparilla. *A. edulis* is employed in China as a sudorific, and its young shoots are eaten. The roots of *Gunnera scabra*, or Panke, is used by tanners on account of the tannin it contains. Mr. Darwin found it on the sandstone-cliffs of Chiloe, where it resembles rhubarb on a gigantic scale. One of the leaves measured nearly eight feet in diameter.

ARANEIDÆ, the first family of the first order of the class *Arachnida*. [ARACHNIDA.] They are also called *Spinning Arachnida*, from their peculiar habit of producing long filamentous cords with which they form their nests and webs. It is to this family that the term *Spider* is more especially applied; and scientifically it embraces all those creatures which are commonly called Spiders. All these are embraced under the old Linnæan genus *Aranea*. Externally this family is distinguished by the following characters:—The palpi resemble small feet without a claw at the tip, terminated at most in the females by a small hook, but in the males supporting various appendages, more or less complicated, connected with the function of reproduction in this family. The frontal claws are terminated by a movable hook which curves downwards, and has on its under-side a little slit for the emission of a poisonous fluid which is secreted in a gland of the preceding joint. The maxillæ are never more than two in number; the tongue is of a single piece, always external, and situated between the maxillæ, and more or less square, triangular, or semicircular. The thorax has upon it a V-like impression indicating the region of the head; it consists of a single piece, to which is attached behind a movable and soft abdomen. This part of the body is furnished with four or six nipples, fleshy at the tips, round or conical, jointed, placed close together, and pierced at the extremity with an immense number of minute orifices for the discharge of silken threads, which are produced from matter formed in internal reservoirs. These are called Spinnerets. The legs vary in length, but are composed of seven joints, of which the first two form the haunch, the next the femur, the fourth and the fifth the tibiæ, and the two others the tarsus. The last is ordinarily terminated by two claws, generally toothed beneath, and by a third smaller claw which is not toothed.

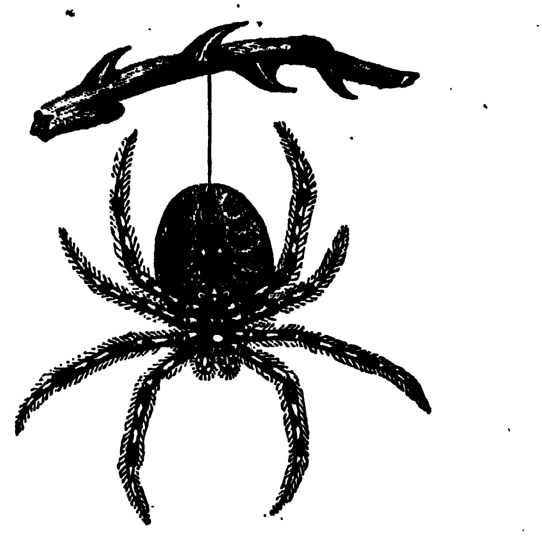
Spinnerets of a Spider, magnified.

Clawed foot of a Spider, magnified.



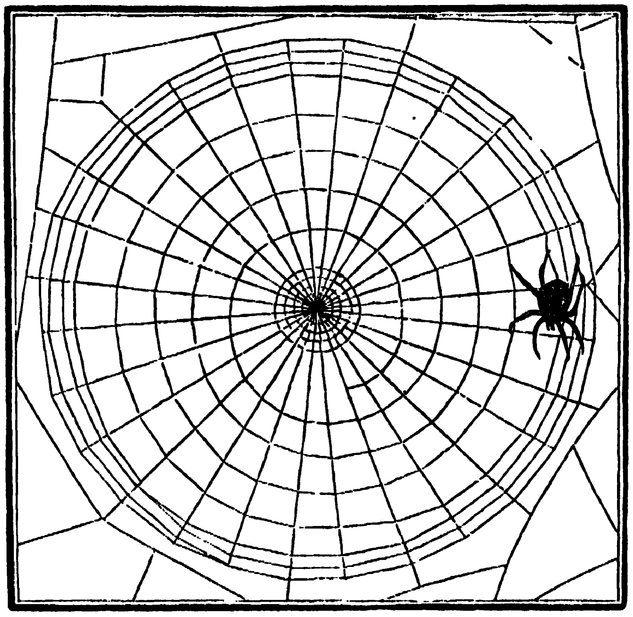
Single thread of a Spider, magnified.

The most remarkable function performed by the *Araneidæ* is that of producing silken threads by means of the spinnerets above described and figured. From each one of the minute orifices of the spinneret there exude as many little drops of a liquid, which, becoming dry the moment it comes in contact with the air, forms so many delicate threads. Immediately after the filaments have passed out of the pores of the spinneret they unite first together and then with those of the neighbouring spinnerets to form a common thread; so that the thread of the spider, when it suspends itself from any object, is composed of an immense number of minute filaments, amounting even to many thousands, each of which is of such extreme tenuity that the naked eye cannot detect them till they are formed into a common thread. The spinnerets of the same spider differ in structure, and Lyonnet has shown that one set of spinnerets is employed in producing threads which are glutinous, whilst another set produces threads which are smooth. This may be seen by throwing a little dust on a spider's web, such as that of *Epeira diadema*, when it will be found that it adheres to the threads which are spirally disposed, but not to those that radiate from the centre to the circumference. These last are also found to be stronger than the spiral ones.



Garden-Spider suspended by a thread.

The spinnerets are in connection with an internal apparatus which secretes the matter they thus elaborate. This apparatus consists of a number of intestine-like canals which are united together, and vary both in number and extent according to the species in which they occur. These canals empty themselves into tubes which open into the spinnerets from whence the thread is extruded.



Geometric Net of *Epeira Diadema*.

It is by means of these threads that spiders construct the various webs which they throw from one object to another, for the purpose of entrapping their prey. It is said that some of the larger species construct webs in which even small birds, such as the humming-bird, are caught and made subservient to the wants of the spider. No sooner is an insect or other small animal ensnared than the spider, placed in the centre of its net, or in a cell built at its side for the purpose of watching, darts forth, and uses all its efforts to inflict upon it wounds into which it pours the venom contained in its frontal claws. When the creature thus caught offers too great a resistance, so that the spider becomes endangered, he retires for a time from the contest to renew his strength, leaving his victim secure in his meshes, and gradually getting exhausted from the attempts it makes to escape. When the spider returns he frequently twists the web round and round the body of his victim, and then either at once commences to make a meal of him, or waits till his appetite suggests the proper time for feeding.

Although Spiders are not provided with wings, and are consequently incapable of flight, they have a power of ballooning with their silken threads, by means of which they can make distant journeys through the atmosphere. These aërial excursions, which appear to result from an instinctive desire to seek some more favourable spot for the gratification of their appetite or other cause, are undertaken when the weather is bright and serene, especially in the autumn, both by adult and immature individuals of many species, and are effected in the following way:—They first mount to the summit of an object, and then raise themselves still higher by straightening their limbs; the abdomen is then elevated into an almost perpendicular position, and they emit from their spinnerets a small quantity of viscid fluid, which is drawn into fine lines by the ascending current of air from the heated ground. Against these lines the current of air from below keeps impinging till the animals, finding themselves acted on with sufficient force, quit their hold of the earth and mount into the air. It has been sometimes stated that spiders can forcibly propel or dart out lines from their spinnerets; but when placed on twigs set upright in glass vessels, with perpendicular sides, all their efforts to escape are unavailing.

The webs named gossamer are composed of lines spun by spiders, which, on being brought into contact by the action of a gentle air, adhere together, till by continual additions they are accumulated into irregular white flakes and masses of considerable extent.

The poisonous effects of the wounds of spiders are produced by means of the mandibles, or frontal claws, which are each armed with a moveable and extremely sharp unguis, near to the point of which is a minute orifice, whence there is poured out a drop of poison into the wound. This orifice, which is very difficult to detect, communicates with a canal in the interior of the mandible; this canal proceeds from a gland situated in the interspace of the muscles of the thorax. The gland consists of a vesicle having internally a number of spiral filaments, which are connected together by a membrane in the form of a bag. Although dreadful stories are related of the effects of the bites of spiders on the human body, it appears from experiments made by Mr. Blackwall on British Spiders, that none of these have the power of producing any ill effects on human beings. There is still wanting good evidence on which to rest a charge of poisoning man by biting him, even against the larger forms of spiders, which inhabit tropical climates.

A curious feature in the history of spiders is the power they possess of reproducing their limbs after they have been broken off. This power, however, is not confined to spiders, as we find it in the *Crustacea* [CRUSTACEA], and even in the vertebrate animals amongst the *Amphibia*. [AMPHIBIA.] In the case of the spiders, it is never a part of a limb which is reproduced, but if a part of a leg is removed, it proceeds to throw off the remainder, and after the next moult the missing member reappears.

The species of the family *Araneidæ* are very numerous, and have been arranged by naturalists under several genera. They have been investigated with great care by M. Walcknäer, who has made them the special study of his life, and has drawn up a natural arrangement of them according to their structure and habits of life. A synopsis of this arrangement we subjoin, as by a little study it will furnish an insight into the surprisingly varied habits of this family:—

TABLE OF THE SUBDIVISION OF THE ARANEIDÆ, OR ARACHNIDA FILOSA, INTO GENERA.

				Genera.				
First Family.—ARANEIDÆ—SPIDERS.	*Mandibles* articulated horizontally; moving vertically.	8 Eyes.	*Eyes* aggregated.	Mygale.	LATEBRICOLÆ, hiding in holes and fissures.	*Venantes*, incessantly running or leaping about the vicinity of their abode to chase and catch their prey.	*Terrestres*, living on land or in holes in the ground.	ARACHNIDA.
				Oletera.				
				Fillstata.				
			Eyes segregated.	Missulena.				
				Sphodros.				
		6 Eyes.	*Eyes* anterior.	Dysdera.	TUBICOLÆ, inclosing themselves in silken tubes.			
				Segestria.				
			Eyes anterior and lateral.	Uptiotes.	CELLULICOLÆ, sheltering themselves in small cells.			
				Omosites.				
				Scytode.				
	Mandibles articulated vertically or on an inclined plane; moving laterally.	8 Eyes.	*Eyes* anterior and lateral, very unequal in size.	Lycosus.	CURSORES, running swiftly to catch their prey.			
				Dolomedes.				
				Storena.				
				Ctenus.				
				Hersilia.				
				Sphasus.				
				Dolophenes.				
				Myrmecia.	SALTATORES, leaping and springing with agility to seize their prey.			
				Fresus.				
				Platiscelum.				
				Attus.				
			Eyes anterior, almost equal in size.	Delena.	LATERIGRADÆ, walking and running sideways or backwards; occasionally throwing out threads to entrap their prey.	*Vagantes*, wandering abroad and incessantly spying out for prey; no fixed residence except at the period of oviposition.		
				Thomisus.				
				Selenops.				
				Eripus.				
				Philodromus.				
				Sparassus.				
				Clastes.				
				Clubiona.	NIDITELÆ, going abroad, but making a web for their nests, whence issue threads to entrap their prey.	*Errantes*, prowling about the neighbourhood of their nests, or near the threads which they throw out, to catch their prey.		
				Drassus.				
				Clotho.	FILITELÆ, going abroad, but spreading long threads of silk about the places where they prowl in order to entrap their prey.			
				Emyo.				
				Latrodectus.				
				Pholcus.				
				Artema.				
				Tegenaria.	TAPITELÆ, spinning great webs of a close texture like hammocks, and dwelling therein to catch their prey.	*Sedentes*, spinning large webs to entrap their prey, lying in wait in the middle or at the side.		
				Lachesis.				
				Agelena.				
				Nyssus.				
				Epeira.	ORBITELÆ, spreading abroad webs of a regular and open texture, either orbicular or spiral, and remaining in the middle or on one side to catch their prey.			
				Tetragnatta.				
				Uloborus.				
				Zosis.				
				Lynyphia.	RETITELÆ, spinning webs of an open meshwork and of an irregular form, and remaining in the middle or on one side to catch their prey.			
				Episina.				
				Theridion.				
				Argyroneta.	AQUITELÆ, spreading filaments in the water to entrap their prey.	*Natantes*, swimming in water and there spreading their filaments to entrap their prey.	*Aquaticæ*, living in water.	

(*Cyclopædia of Anatomy and Physiology*, article '*Arachnida;*' Blackwall, in *Report of British Association*, 1844; Owen's *Lectures on Comparative Anatomy;* Cuvier's *Règne Animal; Insect Architecture*, in *Library of Entertaining Knowledge.*)

ARAUCA'RIA, in Botany, is the name of a singular genus of gigantic Firs, found scattered over the southern hemisphere. It is known from all the other firs by its stiff broad leaves, by a long leafy appendage with which the scales of its cones are terminated, and by its anthers having many cells. The following species are those which are best known:—

Araucaria excelsa, commonly called the Norfolk Island Pine, is found not only in the spot after which it has been named, but also in several other places in the South Seas, as in New Caledonia, Botany Island, Isle of Pines, and in some parts of the east coast of Australia. It is described as a most majestic tree, growing to the height of from 160 to 228 feet, with a circumference sometimes of more than 30 feet. Its trunk rises erect, and is sparingly covered with long drooping naked branches, towards the extremities of which the leaves are clustered; these latter, when the plant is young, are long, narrow, curved, sharp-pointed, and spreading, but when the tree is old they have a shorter and broader figure, and are pressed close to the branches; old and young trees are consequently so different that they have the appearance of distinct species. The bark abounds in turpentine; the wood, which is destitute of that substance, is white, tough, and close-grained. It was once expected that this tree would have been valuable for its timber, and that it would have afforded spars for the navy of great size; but it has been found on trial to be too heavy, and so unsound that Captain Hunter could only find 7 trees fit for use out of 34 that he caused to be felled. Its wood is, however, useful for carpenters' indoor work. Several specimens of this tree exist in the collections of this country. Unfortunately it will not live in the open air in the winter, and its growth is so rapid as to render it very soon too large for the loftiest greenhouses. A supposed species, called the Moreton Bay Pine (*Araucaria Cunninghami*), is scarcely distinguishable from this. It is a highly interesting fact, that a plant very nearly the same as this *Araucaria excelsa* certainly once grew in Great Britain. Remains of it have been found in the Lias of Dorsetshire, and have been figured in the Fossil Flora, under the name of *Araucaria primæva.*

Norfolk Island Pine (*Araucaria excelsa*).

Araucaria Dombeyi, or, as it is more commonly called, *A. imbricata,* is a noble species, inhabiting the mountains of the Araucanian Indians in South America, whence the name of the genus derives its origin. This species has its branches closely covered with broad, lance-shaped, very rigid and pungent dark-green leaves; it produces its branches in circles around its erect stem; and when old it acquires an appearance not very unlike that of the Norfolk Island Pine, only it is much less graceful. Its wood is said to be durable, and it yields a great quantity of resin. Many specimens are now growing in England, and seem to bear our winters well.

Araucaria Brasiliensis is extremely like the last, but the leaves are longer, weaker, and less densely imbricated; and it is much more impatient of cold. It is found wild in the southern provinces of Brazil.

ARAUCARITES (Presl), a genus of Fossil Plants found in the Lias of Lyme Regis.

A'RBUTUS, a genus of evergreen shrubs, belonging to the natural order *Ericaceæ.* It is characterised by its fruit being a berry, containing many seeds. The most remarkable species is the *Arbutus* of Virgil, now called *A. Unedo,* or the Strawberry-Tree, from the resemblance borne by its berries to that well-known fruit. It is a native of the south of Europe and the Levant. In our gardens it proves a hardy evergreen-tree, sometimes as much as 18 or 20 feet high, bearing its greenish-yellow blossoms in October and November, and its bright yellow and red berries, which are studded with little projections, in November and the succeeding months. The most interesting specimens in this country are at the lake of Killarney, where they form groves of great beauty. The plant can scarcely however be considered indigenous to Ireland on this account. Its berries are hardly eatable: taken in too great quantities they are apt to produce stupefaction; nevertheless a wine, said to be pleasant enough, is prepared from them in Corsica.

A. Andrachne, the Oriental Arbutus, is superior to the last in beauty both of leaves and flowers, but it is much more tender, and does not bear fruit in Great Britain. It is readily known by its broader and less serrated leaves, and by its bark peeling off so as to leave the stem always smooth and of a clear bright cinnamon-brown. It is a native of the Levant.

A. hybrida, Mule Arbutus, is apparently a hybrid between the last two, agreeing with *A. Unedo* in the general aspect of its foliage, which is however larger and more handsome, and with *A. Andrachne* in flowers and in the deciduous bark. It is hardy, and very ornamental, but it does not bear berries in Great Britain.

A. procera, a native of California, exists in the gardens of this country. *A. mucronata,* from the Straits of Magalhaens, is a hardy evergreen bush, with small, very dark, pointed and serrated leaves, among which hang numbers of solitary white blossoms. [ARCTOSTAPHYLOS.]

ARCHER FISH (*Toxotes,* Cuvier), a genus of Acanthopterygious Fishes, belonging to the family *Squamipennæ,* or those which are distinguished by having not only the soft parts, but often the very spines of the dorsal and anal fins covered with scales like the rest of the body, and not always very easily distinguishable from it. Though the single species upon which this genus is founded had been long known to naturalists, and described under the various names of *Scarus Schlosseri, Sciæna jaculatrix, Labrus sagittarius,* and *Coïus chatareus,* by the different writers on Ichthyology, yet it was left for Baron Cuvier to point out its appropriate generic characters, and to distinguish it definitely from the different groups with which it had been previously confounded. These characters are found in the short and compressed form of the body; in the dorsal fin being situated very far back, provided with very strong spines, and like the anal, which is placed very nearly opposite to it, covered on its soft parts with large tough scales; in the short depressed shape of the muzzle; and in the length of the under jaw, which considerably surpasses the upper, and entails upon the animal the singular habit from which it has derived the name of the Archer. The gills have six branchiostegous rays; the teeth are small, sharp, and dispersed over the jaws, tongue, and palate; the stomach is short and broad, the air-bladder large, and the pylorus provided with twelve cœcal appendices. The only known species is—

The *Toxotes jaculator* of Cuvier, which is found in Java and Sumatra, and has been long celebrated for the singular instinct which it displays in catching flies and other insects which are its prey. Comparatively speaking, there are very few species, among the numerous class of fishes, distinguished by superiority of instinct or address; but the very rarity of their occurrence makes the partial instances which are occasionally met with still more remarkable, and among these the means which the Archer and a species of *Chætodon* (*C. rostratus*) employ for procuring food are entitled to especial notice. The tubular form of the mouth in these animals permits them to squirt or project small quantities of water to some distance, and with considerable force. When, therefore, the Archer perceives a fly or other insect resting on the leaves of the aquatic plants which overhang or swim on the surface of the stream, it projects, or as it were shoots a single drop, not directly towards the insect, but obliquely upwards, in such a manner as to strike it in falling, thus preventing it from perceiving its danger and escaping in time. With such accuracy is the aim taken, that though frequently projected to the height of four or five feet, the drop seldom fails to hit the mark and precipitate the insect into the water, where it is, of course, within reach of the Archer. The fish itself is of a yellowish colour, marked on the back with five brown spots.

ARCTIC FOX, in Zoology, a small species of Fox (*Canis lagopus*), celebrated for the beauty and fineness of its fur, which has long been considered a valuable article of commerce. The colour of the fur, as is the case with all animals which inhabit very high latitudes, varies according to the season, being slaty blue in summer, and pure white in winter. It is in the latter state that the fur is most esteemed, not only on account of its colour, but likewise because it is of a closer and finer quality than at any other time. The soles of the feet also are at all seasons covered with a thick coat of fur, like those of the common hare, which defends them from the severity of the snow, and is a character likewise common to most other northern animals. [Fox.]

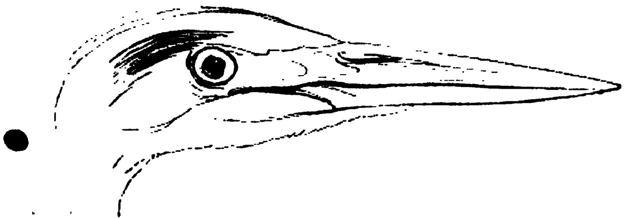
ARCTOSTA'PHYLOS, or Bear-Berry, is a genus of plants till lately considered the same as *Arbutus,* from which it is essentially distinguished by its berries containing only from one to five, instead of a great many seeds. The common Bear-Berry (*A. Uva Ursi*), is found wild in the mountainous parts of England and Scotland, and generally over the whole of the north of Europe. It is a trailing shrubby plant, with leathery dark-green entire leaves, which are broadest at their upper end. The flowers are white, tinged with pink, small, and in clusters. The berries are small and red, like those of the hawthorn. The whole plant is so astringent that it has been employed by the tanner with success, and also in dyeing a grayish black colour; it is no doubt the same property which has made it celebrated for its efficacy in gravel complaints, and in diseases of the urinary organs. When cultivated it requires to be grown in peat earth.

ARDEA (Vieillot), the Heron, a genus of birds under which Linnæus comprehended the Cranes and several other divisions now formed into distinct genera by modern naturalists. M. Vieillot followed Buffon in making four divisions of the Herons; but Temminck, who has paid peculiar attention to these birds, arranges them under one genus and two sections. The genus *Ardea*, as limited by Vieillot, is thus characterised:—

Bill strong, straight, or slightly curved, compressed, acuminated, sharp, in most species finely toothed; the upper mandible somewhat channeled, and usually notched towards the tip; nostrils on the side, almost at the base, slit lengthwise in the groove, and half shut by a membrane; eyes with a naked circle around them extending to the bill; legs long, slender, and either half-naked or feathered down to the shank (tarsus); the middle fore toe united to the outer one by a short membrane; the hind toe articulated interiorly, and upon the same level as the others; the second and third quill-feathers of the wings the longest.

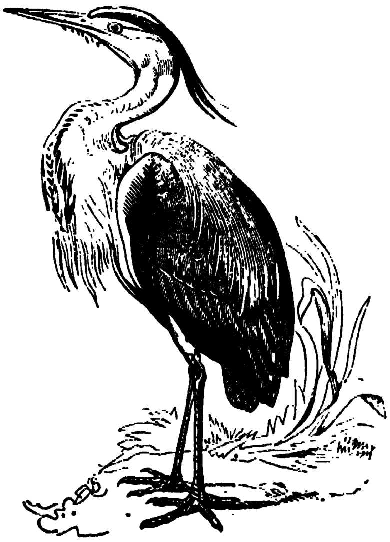
HERONS.

M. Temminck thus defines the Herons properly so called:—Bill much longer than the head, as large as it is high, or larger, at the base; upper mandible nearly straight; a great portion of the tibia naked. Food, fish principally.



Bill of Common Heron.

It will only be necessary to give a sketch of the leading forms of this group. We proceed therefore to illustrate M. Temminck's first section of the true Herons by the Common Heron, which most authors consider as the type.



Common Heron (*Ardea cinerea*).

The Common Heron is, in the opinion of Belon and some others, the 'Ερωδιός of Aristotle, but we do not consider this as certain: the term 'Ερωδιός is doubtless applied by Aristotle to the form ('Hist. Anim.', viii., 3), but what species is meant by him is not so clear. But the bird is, without doubt, the *Ardea* of the Romans. It is the *Beccapesce*, *Airone*, *Oca-Cicogna*, and *Sgarza*, of the modern Italians; the *Garza* of the Spaniards; *Reyger* and *Rheier* of the Germans; *Héron* of the French; *Cryr glâs* of the ancient British; and *Common Heron*, or *Heronshaw*, of the modern British.

Description. — Plumage bluish-ash; middle toe, the nail included, much shorter than the tarsus.

Male and Female after the Third Year.—Long loose black feathers on the back of the head; similar feathers or plumes of a lustrous white depend from the lower part of the neck; the equally elongated and subulate scapulars are of a silvery-ash. Forehead, neck, middle of the belly, border of the wings and thighs, pure white; occiput, sides of the breast, and flanks, deep black. On the front of the neck are large longitudinal black and ash spots. Back and wings very pure bluish-ash; bill deep yellow; iris yellow; naked skin of the eye bluish-purple; feet brown, but of a lively red towards the feathered part. Length 3 feet and upwards. In this state M. Temminck, whose description we have given, states the bird to be the *Ardea cinerea* (male) of Latham ('Index'); *Ardea major* of Gmelin; *Le Héron Huppé* of Buffon; *Héron commun* of Gérard; *Common Heron* (male) of Latham ('Syn.'), Pennant ('Brit. Zool.'), and Albin; *Ashgrauer Rheier* of Meyer and others; and *Sgarza cenerino* of the 'Stor. degl. Ucc.'

Young up to the Age of Three Years.—No crest, or at most the plumes composing it very short; no long loose feathers at the lower part of the neck, nor above the wings; forehead and top of the head ash-colour; throat white; neck clear ash, with numerous spots of a deeper colour than the ground; back and wings bluish-ash, mingled with brown and whitish; breast marked with longitudinal spots; upper mandible of the bill blackish-brown, with yellowish spots; lower mandible yellow; iris yellow; skin round the eyes greenish-yellow; feet blackish-ash, but yellowish towards the feathered part. In this state M. Temminck considers the bird to be the *Ardea cinerea* (female) of Latham; *Ardea Rhenana* of Sander; *Le Héron*, of Buffon; *Common Heron* (female) of Latham; *Sgarza marina*, of the 'Stor. degl. Ucc.'; and *De Blaauwe Reiger* (being the young in the first year) of Sepp.

The edge of the bill is serrated near the point, and the nail of the middle toe pectinated, as in the Herons generally.

Variety.—Nearly perfectly white. A variety of this description is figured by Frisch (t. 204); but it is very rare.

Habits, Food, Reproduction, &c.—The solitary habits of the Common Heron, excepting at the season of reproduction, are well known. At that period they congregate at their breeding stations, or heronries, for which the loftiest trees are generally chosen. Pennant says that at Cressi Hall, near Gosberton, in Lincolnshire, he counted more than eighty nests in one tree. Montagu notices a heronry on a small island in a lake in the north of Scotland, whereon there was only one scrubby oak. This being too small to contain all the nests, the herons, rather than abandon their society and a favourite station, had many of them placed their nests on the ground. In the south and west of England the heronries in Windsor Great Park in Berkshire, at Brockley in Somersetshire, and at Powderham Castle in Devonshire, are worthy of notice. The nest is built of sticks, and is large and flat. It is lined with wool or other soft materials, and on this lining are deposited four or five bluish-green lustreless eggs. The young are less prepossessing in appearance than nestlings in general, but few of which are pleasant to look upon, and they remain in the nest for five or six weeks, during which time the old birds unceasingly supply them with fish, &c. There are sometimes deadly feuds between the herons and the rooks, originating in a dispute for the possession of the nest-trees. Dr. Heysham's account of one of these battles at Dallam Tower, in Westmorland, originating in the felling of the fine old oaks occupied by the herons, and their consequent attempt upon the grove in the tenure of the rooks, is well worth perusal. The herons had the best of the fray for two successive seasons, and at length a sort of peace was patched up between the combatants; the rooks and the herons severally setting up their nests on a particular part of the now only remaining grove, and leaving the other moiety to the opposite faction.

Buffon draws largely upon his imagination for a picture of wretchedness, and then makes the heron a personification of it, with as much foundation as characterises most of his fancies of this description. When on its fishing station, the bird stands immoveable as a stump, with the neck bent and between the shoulders, watching for the passing fish, which it unerringly spears with its sharp bill. But besides fish and reptiles, such as frogs, newts, &c., mice, young water-rats, and even young water-fowl, are occasionally devoured by it. Mr. Selby, in his excellent 'Illustrations of British Ornithology,' gives, on the authority of Mr. Neill, of Canonmills, near Edinburgh, two interesting anecdotes in illustration of the habits of this bird in a state of half-domestication. "The Common Heron (a male)," says Mr. Neill, "which was winged on Coldingham Muir in autumn, 1821, when a young bird, and given to me in 1822 by Mr. John Wilson, of the College, has since resided in my garden at Canonmills, and is now so tame that he often follows me, expecting a piece of cheese, which he relishes. Four years ago Mr. Allan, of Lauriston, sent me a young female which had been taken during a severe storm. She soon associated with the older bird. In summer, 1828, she laid three or four eggs (I am not sure which) on the top of a wall next to the mill-pond. She then laid one or two on the flower-border below the wall, and close by the box-edging: here some eggs were broken by the birds suddenly starting off when alarmed by strangers walking in the garden. We supplied their place by some bantam eggs, and only one heron egg at last remained. Alas! the poor hen, having strayed to the margin of the mill-pond, was shot by some thoughtless young man with a fowling-piece. The cock continued to sit for several entire days after the death of the hen, but at last tired. He used to sit when she went off for food. During the whole time of pairing the cock was very bold, raising his feathers and snapping his bill whenever any one approached."

Mr. Neill further adds a fact, showing that the bird can swim upon occasion. "A large old willow-tree," writes Mr. Neill in continuation, "had fallen down into the pond, and at the extremity, which is partly sunk in the sludge, and continues to vegetate, water-hens breed. The old cock heron swims out to the nest, and takes the young, if he can. He has to swim 10 or 12 feet, where the water is between 2 and 3 feet deep. His motion through the water is slow, but his carriage stately. I have seen him fell a rat by one blow on the back of the head, when the rat was munching at his dish of fish."

Geographical Distribution.—Very extensive, and embracing the greater part of the Old World. (Selby.) It is permanent in England. Dr. Latham says, "In England and the milder climates this species of heron is stationary, migratory in the colder, according to the season; is rarely seen far north. Inhabits Africa and Asia in general, the Cape of Good Hope, Calcutta, and other parts of India, and is found in America from Carolina to New York." With regard to the American locality, Dr. Latham appears to have taken the Great Heron (*Ardea Herodias*, Linnæus), for the Common Heron, which last is not mentioned by any of the ornithologists who have made the birds of America their study, as an inhabitant of the New World. Dr. Von Siebold mentions this our European species among the birds which he observed in Japan.

Utility to Man.—In days of old, when the Heron was a principal feature in the noble sport of hawking, and when the destruction of its eggs was visited with a penalty of twenty shillings, it seems to have held as high a place at the tables of the great as it did in the field. Thus, at the 'intronazation' of George Nevill, archbishop of York, in the reign of Edward IV., we find in the bill of fare 400 Heronshawes and 200 Feasauntes (pheasants); and it seems, at one period, to have been valued as a dish at the same price as the latter bird, for from the prices in the household-book of the fifth earl of Northumberland, we find Hearonsewys (herons) marked at twelve pence, and pheasants at the same rate to a penny. At a marriage-feast in Henry VIII.'s time, we find Heronsews noted at the same price, and at another marriage-feast in the same year two dozen Heronsues marked at twenty-four shillings. In the first of these records no mention is made of pheasants, but in the second they appear at that earlier time to have been rather more highly valued than herons, for eighteen pheasants are priced at twenty-four shillings, the amount placed against the two dozen herons. And in the charges of Sir John Nevile of Chete (the knight in whose family the marriages above alluded to took place), at Lammas assizes, in the 20th year of the reign of king Henry VIII., the pheasants appear to have cost somewhat more than the Heronsews, thirty of which are priced at thirty shillings, while twelve pheasants cost twenty shillings. The heron-plume, made up of the fine large depending feathers, especially those above the wings, was highly valued.

In the present day the bird seems to have sunk into comparative insignificance. Mr. Selby however considers that "the low estimation in which the flesh of the Heron is now held would seem to be in a great degree the effect of prejudice, or the fashion of taste, as under proper treatment and good cookery the Heron, when fat and in fine condition, is but little inferior to some of our most approved wild-fowl."

The well-known adage expressive of ignorance, "He does not know a hawk from a hand-saw," is a corruption of "He does not know a hawk from a heronshaw."

Temminck's second section of Herons consists of the Bitterns, including the Night Herons. [BITTERN; NYCTICORAX.]

ARDWICK LIMESTONE, a Calcareous Bed, or series of beds, containing shells and fish-remains, in the upper part of the Coal Formations of Manchester and Lebetwood. There is a coal-bed above it at Manchester.

ARE'CA, a genus of Palms containing two species, both remarkable for the purposes to which they are applied. *Areca* is distinguished by a double membranous sheath in which its bunches of flowers are contained, by its female corollas containing the rudiments of stamens, its calyx being divided into three parts or leaves, and its fruit being a berry or drupe, with a fibrous rind inclosing one seed only. The leaves of all the species are pinnated, with their stalks rolled up cylindrically at the base.

Betel-Nut Palm (*Areca Catechu*).

Areca Catechu, Betel-Nut Palm, is described by Dr. Roxburgh as being the most beautiful palm in India, with a remarkably straight trunk, often from 40 to 50 feet high, and in general about 20 inches in circumference, equally thick in every part, and smooth. The leaflets are from 3 to 3½ feet long, and widest at the point, where they also are ragged. It is cultivated all over India for the sake of its nuts, which are about the size of a hen's egg, of a reddish-yellow when ripe, and with a firm fibrous rind about half an inch thick. It is this nut which, under the name of Pinang or Betel-Nut, is so universally chewed in the East Indies. It has an austere and astringent flavour, dependent upon the tannin it contains, and is not eatable alone; but mixed with lime, which no doubt destroys its acidity, and with the leaf of the Betel-Pepper it becomes milder and pleasant. The mixture is however still so hot and acrid as to be unfit for the use of any but persons accustomed to it. It is said to be aromatic and stomachic, and also to produce intoxication in beginners; but it is doubtful whether all these qualities are not to be ascribed rather to the Betel-Pepper leaf than to the nut of the Palm. It, or rather the mixture of the three substances, stains the saliva and teeth of a deep red colour. It is to the stems of *Areca Catechu* that the common black pepper vine is usually trained on the coast of Malabar. (Roxb.)

Areca oleracea, the Cabbage Palm, is the only other species that it is necessary for us to notice. The name of this plant is familiar to most persons from the often repeated fact that a tree of the growth of half a century is sometimes cut down for the sake of the single bud which terminates it, and which is called the cabbage.

The species is found in great abundance in the mountainous parts of Jamaica and other West India islands, growing to the height of from 100 to 200 feet, with a trunk not more than 6 or 7 inches in diameter. This gives it an extremely graceful appearance, especially as the leaves grow from the top only, in a kind of tuft or plume, to the length of 15 feet; these leaves are divided in a pinnated manner, and their divisions are deep green, and several feet long. The unexpanded leaves are arranged so closely one over the other as to obstruct all access of light, which causes them to be of a very tender and delicate nature. It is this which forms the cabbage, which is considered a great delicacy, either raw or boiled. The nuts, which are about the size of a filbert and covered with a yellowish skin, are produced in great abundance upon a very long and branched spadix; the kernel is white and sweet.

ARENG, a genus of Palms, the only species of which produces Sago and Palm-Wine. *Areng saccharifera*, is described as a plant of an ugly appearance, having a trunk 20 or 30 feet high, covered almost entirely with coarse black fibres resembling horse-hair. The leaves are from 15 to 25 feet long, and pinnated; their leaflets, which are from 3 to 5 feet long, widen gradually to the point, where they are ragged and prickly, in consequence of the projection of their hard veins beyond the margin; above they are of a deep shining green, but on their under surface they are firmly coated with ash-coloured mealy matter. The stalks of those leaves have intermixed with their coarse hair stiff bristles as thick as porcupine's quills. Each bunch of flowers is from 6 to 10 feet long, and when covered with fruit is as much as a man can carry. The berries are of a yellowish-brown colour, about the size of a medlar, and extremely acrid; each contains three seeds.

This palm is found in all the islands of the Indian Archipelago, in moist and shady ravines through which rivulets find a course; it is much used for the sake of its sap, which flows in great abundance from the wounded branches of the inflorescence about the time when the fruit is forming. A bamboo bottle is tied to the extremity of an amputated branch, and removed twice a day, morning and evening. A single tree will yield a large quantity of this fluid, which when first drawn from the tree is transparent, with the taste and colour of new wine; after a short time it becomes turbid and milky, and acquires a slight degree of acidity. When fit for drinking it is of a yellowish colour, with a powerful odour and a good deal of astringency. Strangers do not for some time become accustomed to it. It is exceedingly intoxicating; but, if drunk in moderation, is said to be stomachic and wholesome.

Besides yielding wine, the coarse fibres of the stem and leaf-stalks are manufactured into powerful cables, and the trunk contains a great quantity of nutritious meal-like sago. Dr. Roxburgh mentions that 150lbs. of that substance were obtained from one tree felled in the botanic garden at Calcutta.

(Roxburgh's *Flora Indica*, vol. iii. p. 627; Rumphius' *Herbarium Amboinense*, vol. i. The former calls this Palm *Saguerus Rumphii.*)

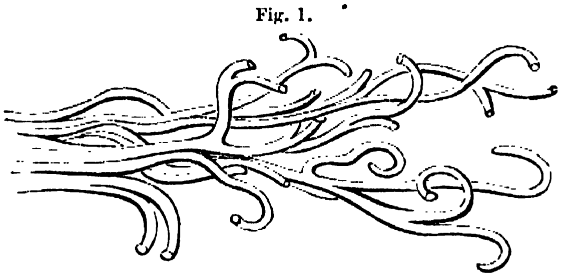
ARENICOLA, a genus of Annelidous Animals, referred by Cuvier to the Dorsibranchiate group on account of their external gills. The general structure and habits of the genus determine most naturalists in placing it with the Terricolous Annelids. [ANNELIDA.] The gills are branched, and placed upon the rings of the middle part of the body only. The mouth is fleshy, more or less dilateable, but there are no discernible teeth, tentacles, or eyes. The posterior extremity of the body has not only no gills, but is devoid of the silky bristles which are found on every other part.

A. Piscatorum, the Lob or Lug-Worm, is the most common species. It is found very abundantly in the sand of the sea-shore, where its habits afford a close resemblance to those of the earth-worm away from the shore. It is bigger than the earth-worm, sometimes being found nearly a foot in length. It is of a reddish colour, and when touched throws out a quantity of a yellow fluid which stains the hand. It is employed by fishermen as bait for various kinds of sea-fish.

AREOLAR TISSUE. The nature of this tissue will be best understood if we first describe *Fibrous Tissue*, of which it may be regarded as a modification. *Fibrous Tissue* is now usually considered under two heads, namely, as the white and the yellow tissue. *White Fibrous Tissue* occurs in ligaments, tendons, and membranes requiring great strength. On carefully dissecting away the areolar tissue with which it is associated, it seems, when examined under the microscope, to consist of extremely delicate fibrillæ running parallel to one another, and taking an undulating course. There is however reason to believe it does not in reality consist of a bundle of fibrillæ, but that it is simply a mass with longitudinal parallel streaks, and which has a tendency to split up in a longitudinal direction. (Fig. 2, *a*.)

Yellow Fibrous Tissue differs in many essential points from the preceding form. It is remarkably elastic, is of a yellow colour, and is arranged in bundles or fibres, invested by a thin sheath of areolar tissue. In man we find it extended between the laminæ of the vertebræ, in several other ligaments, and in the transversalis fascia of the abdomen. It forms the ligamentum nuchæ of animals. Examined under the microscope it is seen to consist of fibres varying in diameter from the 5000th to the 10,000th of an inch. They bifurcate, or even divide into three, and freely anastomose with each other.

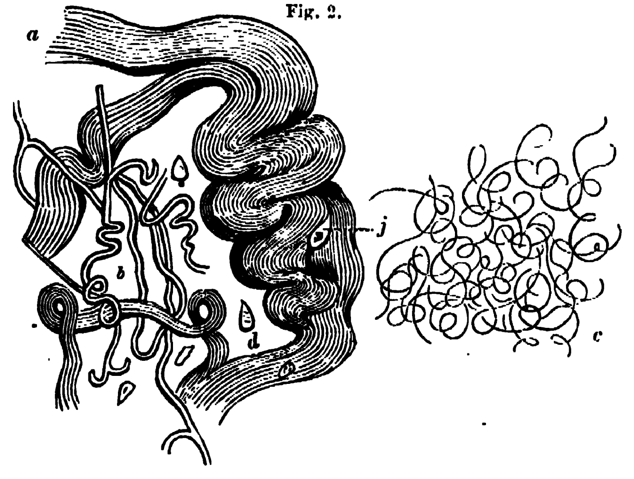
Fig. 1.



Yellow Fibrous Tissue showing the curly and branched disposition of its fibrillæ.

Areolar Tissue is dispersed over almost every portion of the body, being the substance most commonly (but incorrectly) termed *Cellular Tissue*. The following are the microscopic characters of this tissue, as described by Bowman and Todd :—"When a fragment is examined it presents an inextricable interlacement of tortuous and wavy threads, intersecting one another in every possible direction. They are of two kinds. The first are chiefly in the form of bands of very unequal thickness, and inelastic. Numerous streaks are visible in them, not usually parallel with the border, though taking a general longitudinal direction. These streaks, like the bands themselves, have a wavy appearance, but can be rendered straight by being stretched. The streaks seen have more the marks of longitudinal creasing than a true separation into threads; for it is impossible to tear up the band into filaments of determinate size, although it manifests a decided tendency to tear lengthways. The larger of these bands are often as wide as the 500th of an inch; the smaller can only be detected with high powers. These are the white fibrous element. The others are long, single, elastic, branched filaments, with a dark decided border, and disposed to curl when not put on the stretch. They interlace with the others, but appear to have no continuity of substance with them. They are most commonly about the 8000th of an inch in diameter. These form the yellow fibrous element.

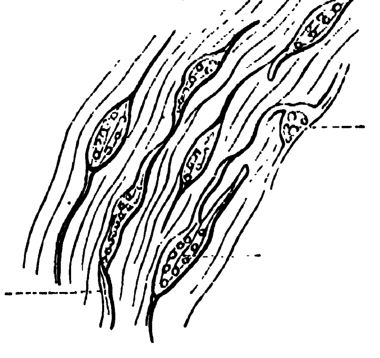
Fig. 2.



The two elements of Areolar Tissue in their natural relations to one another. *a*, the white fibrous element, with cell-nuclei, *j*, sparingly visible in it; *b*, the yellow fibrous element, showing the branching or anastomosing character of its fibrillæ; *c*, fibrillæ of the yellow element, far finer than the rest, but having a similar curly character; *d*, nucleated cell-nuclei, often seen apparently loose.

These two tissues may be most easily discriminated by the addition of a drop of dilute acetic acid, which at once swells up the former and renders it transparent, whilst it produces no change in the latter. It thus brings into view corpuscles of an oval shape, which are probably the nuclei of the cells from which the bands have been originally produced. Oval corpuscles (*fig.* 2, *d*), either altogether isolated or having very delicate prolongations with the adjacent threads, are sometimes noticed. They seem to be either advancing or receding stages of the tissue.

Fig. 3.



In *fig.* 3, which represents the Areolar Tissue from beneath the skin of a five-months fœtus, we can perceive the cells elongating into fibres.

In a chemical point of view the leading difference between the white and yellow tissues is, that the former is acted on by acetic acid in the manner described, and yields a considerable amount of gelatine in boiling; while the latter resists the action of acetic acid, and yields little or no gelatine.

ARFVEDSONITE, a mineral belonging to the Hornblende Series. The cleavage is parallel to the lateral planes and both the diagonals of a rhombic prism. The colour black; fracture uneven; hardness 6·0; lustre vitreous and opaque; and has a specific gravity of 3·4 to 3·5. It is found in Norway and Greenland. According to analysis by Dr. Thomson it contains—

Silica	50·508
Peroxide of Iron	35·144
Sesqui-oxide of Manganese	8·920
Alumina	2·488
Lime	1·560
Water	0·960

ARGALI, in Zoology, the name of a species of Wild Sheep (*Ovis Ammon*) found on the mountains of Siberia and Kamtchatka. [SHEEP.]

ARGEMO'NE, a small genus of plants belonging to the natural order *Papaveraceæ*, of which three species are cultivated in this country as ornamental plants. They are all natives of Mexico, and are characterised by having six petals and three sepals, a very unusual number of parts in the natural order to which this genus belongs. Their leaves are prickly, and generally marked with whitish or pale bluish-green veins; the flowers are white or yellow. The commonest species is *A. Mexicana*, from the seeds of which the Mexicans obtain an oil very useful to painters; the handsomest is *A. grandiflora*, the flowers of which are pure white, and as much as three inches in diameter. They are all hardy, and will thrive in almost any soil or situation. Their seeds should be sown in a hot-bed, and the young plants treated as half-tender annuals.

ARGENTINE, in Mineralogy, a white laminated variety of crystallised calcareous spar containing a little silica. [CALCAREOUS SPAR.]

ARGES (Goldfuss) is the *Paradoxides bimucronatus* of Murchison.

ARGULUS, a genus of Entomostracous *Crustacea*, belonging to the section *Pœcilopoda*. There is but one species of this genus, the *A. foliaceus*. This little creature is not unknown to fishermen, as it is frequently found parasitic upon various kinds of fish. It was first described by Baker in his 'Employment for the Microscope,' in 1753, under the name of 'The Louse of the Carp and Banstickle or Prickleback.' It is about the tenth of an inch in length, and is almost as broad as it is long. The head is in the form of a circular-shaped shield. The antennæ are short, thick, and two-jointed. Instead of a second pair of foot-jaws it has a pair of circular or disk-shaped suckers, by means of which it attaches itself to the animals on which it is parasitic. These suckers are admirably constructed for their use. Four muscles are attached to the base of each of these organs, and extend up by the sides. By this arrangement the creature can make use of these organs, by exhausting the air in the same way as in cupping-glasses, to fasten itself, and also by relaxing the muscles, to walk, when it wishes to change its position. These little creatures are nearly transparent, or of a slightly greenish hue, so that its internal organisation can be readily seen by means of the microscope by transmitted light. The body is marked on both sides by a series of ramifications of a dark colour. The female is larger than the male, and is distinguished, in addition to the ovary, by a black mark on each lobe of the abdomen.

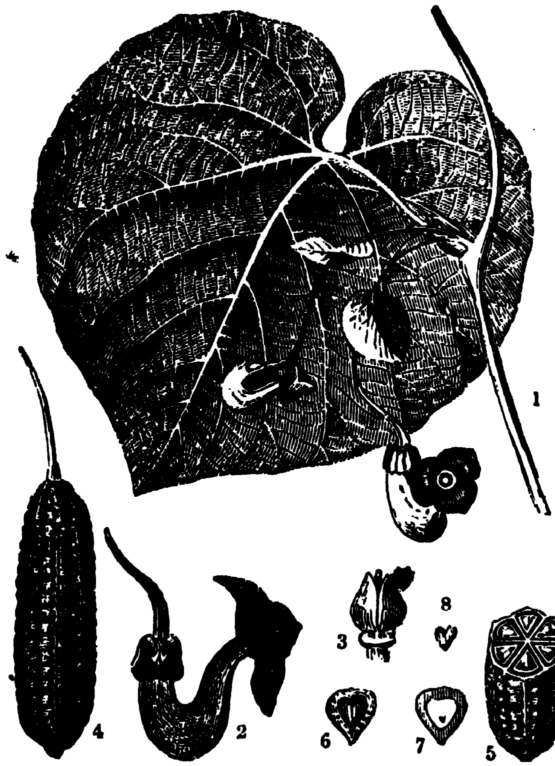
The Argulus is found upon various fresh-water fishes. It is most frequently met with near London on the Stickleback, but it has been noticed as occurring on the Carp, the Roach, the Trout, the Pike, the Rudd, and even upon the tadpole of the common Frog. It seems to abound especially when fish are in ill health.

Although mostly found upon fish it frequently leaves them, and swims freely about in the water. Fish have an instinctive knowledge of these creatures as their enemy, and it is amusing to watch in a basin of water the efforts which the stickleback will make to avoid its minute persecutor; but the efforts of the fish are in vain, for it is opposed to a creature which has the power of darting through water with such rapidity that it is almost impossible to follow it with the naked eye. The females deposit their eggs from 400 to 1500 in number on stones or other solid bodies. They are laid side by side in rows and glued together. They are hatched in about 35 days, and the young resemble their parents to a greater extent than is the case with many of the forms of *Entomostraca*. The best account, with figures and anatomy, of this parasite, is given in Dr. Baird's 'History of the British Entomostraca,' published by the Ray Society. Mr. Yarrell has given a figure of it in the second volume of his 'British Fishes.'

ARIETES. [AMMONITES.]

ARILLUS, in Botany, is a fleshy expansion either of the umbilical cord by which seeds are attached to the placenta, or of the placenta itself. It is never formed till after the fertilisation of the seed, and is only met with in a few plants; its use is entirely unknown. The most remarkable instance of the Arillus among species of common occurrence is in the Spindle-Tree (*Euonymus Europæus*), in which it is the fleshy red covering of the seed that renders that plant so ornamental in the autumn and beginning of winter. Another familiar case is the mace of the nutmeg; this substance is, when fresh, a crimson lacerated covering of the nut, which acquires its pale-brown colour in consequence of the preparation it undergoes in being dried and prepared for market. Before the term was thus accurately defined, it was applied to a variety of parts of exceedingly different natures.

ARISTOLOCHIA'CEÆ, *Birthworts*, consist of a small number of genera which principally inhabit the hotter parts of the world. They are in many cases used medicinally on account of their tonic and stimulating properties; and some of them are reputed remedies for the bite of venomous serpents. The distinguishing characters of the order reside in the flowers, which have no corolla, and are constantly divided into three segments; the number of the cells of the fruit is also three or six, and the stamens agree in the same ternary character; the fruit is always adherent to the calyx, or, as botanists say, inferior. Notwithstanding the accordance which thus exists between *Aristolochiaceæ* and Monocotyledonous Plants in the ternary number of the parts of their flowers, their structure is otherwise truly Dicotyledonous. The arrangement of the woody matter of which their stem is composed is in longitudinal plates, surrounding a central pith, and surrounded by bark; but what is very curious, these plates are not placed in concentric circles like most other exogenous plants, but continue to increase uniformly and uninterruptedly as long as the plant grows. [EXOGENS.] The leaves are veined like those of exogenous plants, and the embryo of the seed has two lobes.



Aristolochiæ.

1, A branch of *Aristolochia Sipho*; 2, one of its flowers cut lengthwise, showing the stamens lying in its bottom; 3, a cluster of stamens; 4, a seed-vessel; 5, the same cut across to show its six cells; 6, a seed; 7, a seed cut through to show the minute embryo lying in the albumen; 8, an embryo much magnified.

The most common plants of this singular order are the different species of *Asarum*, or, as the gardeners call them, Asarabacca,—little stemless plants with dingy-brown flowers hidden among the leaves. This colour, which is far from common in plants, appears characteristic of the whole order, for even in those species which have yellow flowers, a brown stain seems to be mixed with the colour so as to change it, or brown spots are scattered over the surface. The most remarkable species of the genus *Aristolochia* are those which, in many of the tropical parts of America, excite the wonder of travellers by the gigantic size or grotesque appearance of the flowers, such as *A. cymbifera*, the border of whose calyx resembles one of the lappets of a Norman woman's cap, and measures 7 or 8 inches in length, *A. cordiflora*, and *A. gigantea*, the flowers of which are from 15 to 16 inches across, and are large enough to form bonnets for the native children.

The properties of this order are generally tonic and stimulating. Many of the species, as their common name implies, have had properties attributed to them which they are now known not to possess; at the same time some of them are emetic and others purgative, and they contain undoubtedly plants which might be used with advantage in medicine. Only one has been much used, the *Aristolochia Serpentaria*. [ARISTOLOCHIA, in ARTS AND SC. DIV.]

ARKTIZITE, one of the names for the group of minerals included under *Scapolite*. [SCAPOLITE.]

ARMADILLO (*Dasypus*, Linnæus), a genus of the class *Mammalia*, belonging to the order *Edentata*, and forming, with the allied genera *Chlamyphorus* and *Orycteropus*, a small but very distinct family intermediate between the Sloths and Ant-Eaters, and characterised by the possession of molar teeth only. The Sloths [BRADYPUS] have not only the ordinary molar teeth of common quadrupeds, but are likewise provided with large and powerful canines; though, as far as we know anything of their economy, they appear to be a purely herbivorous family, and to be even incapacitated by other details of their organisation for the capture or destruction of a living prey; whilst the Ant-Eaters [ANT-EATER] are not only deprived of canine but likewise of molar teeth, consequently are without teeth of any description, and thus form the only family of the order *Edentata* that literally answers to the name and definition. Nor are these the only distinctions which subsist between the three families of edentulous mammals which we have here indicated. Others are pointed out in the articles just referred to, and it will be sufficient to mention, in addition, that the Ant-Eaters differ from the other two families by the want of clavicles (a most important and influential element in the anatomical structure of all vertebrated animals), and the Armadillos, the more immediate subject of our present consideration, by the peculiar nature of their external covering. Instead of hair, the armadillos are covered with a species of hard bony crust, forming three bucklers on the head, shoulders, and rump, respectively, the two latter being connected by a number of transverse moveable bands, very similar in form and appearance to the plate armour of the middle ages, from which indeed these animals have acquired the name of Armadillos—a name of Spanish origin, which has been adopted by English writers. Those bucklers likewise hang down on each side, so as to form an effectual protection to the belly, and partially to cover the legs and feet; whilst the pliancy produced by the moveable bands interposed between the bucklers of the rump and shoulders, and which are themselves connected by the soft pliant skin of the animal, permits the most varied and rapid motions. The bucklers themselves, as well as these connecting moveable bands, are composed of numerous small polygonal plates, placed contiguous to one another like the stones of a mosaic pavement, but without any actual articulation, and they are incapable of separate motion. The whole thus forms a kind of shelly buckler not unlike that of a lobster; and though incapable of actual motion, yet the thinness of the shell, and, during life, the pliancy occasioned by the animal oil which penetrates it, allow it to yield to a certain degree, and thus to accommodate itself in some measure to the motions of the body. But the great and principal motions, as already observed, are entirely due to the moveable transverse bands, interposed between the two principal bucklers of the body, and which vary in number according to the species, and even within certain limits according to the age, sex, or individual. These are situated immediately above the loins, or in the region to which all the principal motions of the animal economy have been assigned; the bucklers of the head and shoulders are entirely disunited, and have none of these moveable bands interposed between; but that of the head projects considerably backwards, and affords complete protection to the neck, which is indeed so short as to be barely distinguishable.

The throat, breast, belly, and thighs of the armadillo are naked, or covered with a thick granulated skin, thinly furnished with warts or tubercles, which give origin to a few coarse bristly hairs. The commissures of the moveable bands on the loins are likewise provided with a number of long hairs; but with this exception the body is covered only by its peculiar shell. The tail is straight, round, thick, and pointed; it is adapted at the root to a notch or cavity in the posterior edge of the buckler of the croup, and, with the exception of one species, is universally covered with bony rings, formed, like the rings of the bucklers, of numerous small pieces connected together, but capable of a certain degree of motion, and thus admitting of considerable flexibility in the tail itself. The head of the armadillos is flat and terminated by a pointed muzzle, which assists them, like the snout of the hog and mole, to turn up the earth in search of roots and worms. Their ears are erect and pointed, and their eyes very small. They have flat corpulent bodies; and their legs are so disproportionately thick and short that they barely serve to elevate the body above the surface of the ground. Their toes, also, of which there are either four or five on the anterior and invariably five on the posterior extremities, are remarkably short; but they are furnished with extremely long powerful claws, slightly curved, and in every respect well adapted for digging or burrowing. So rapid indeed are the armadillos at this operation that they easily bury themselves to any depth beyond the reach of their pursuers. They can only be forced from their subterranean retreat by directing smoke or water into their burrows. Their strength and the tenacity of their hold are so great, that they have been known to leave their tails in the hands of the hunter rather than permit themselves to be drawn forth. Yet notwithstanding the shortness of their legs and the heavy corpulent make of their bodies, the armadillos run with a velocity which could not be anticipated from their general appearance. Most of the species will easily outstrip a man. Their ordinary burrows most commonly run for three or four feet at an angle of about 45 degrees to the plane of the horizon, then make a sudden bend, and terminate at the distance of eight or ten feet from the mouth. Here for the most part they conceal themselves during the daytime, for the greater number of the species are nocturnal, and never move abroad whilst the sun is above the horizon. This rule however admits of some exceptions—a few species being found abroad at all times indifferently; and it has been remarked that these are neither so swift nor so timid as the nocturnal species.

The teeth of the armadillos are all of a simple cylindrical form, and stand apart from one another like those of the generality of Cetacea and Reptiles. They vary in number from 7 or 8 to 17 or 18 on each side of each jaw; and are so arranged that when the mouth is closed the upper teeth fit into the interstices of the under, and these into the interstices of the upper teeth alternately. The animals never attempt to bite, nor has nature given them any other means of defence than the ease and rapidity with which they avoid danger by burrowing. Their food consists principally of fallen fruits, roots, and worms; but they do not reject carrion, and have been known to penetrate into human graves when not properly protected by stones or brick-work. Azara informs us that ants are never found in the districts inhabited by the armadillos, and that these animals break into the ant-hills and devour the insects as greedily as the true Ant-Eaters. The ordinary food of the armadillos consists chiefly of the roots of the mandioc, of potatoes, maize, and other similar substances of a vegetable nature; though, as already observed, without rejecting animal substances naturally soft or so far decomposed as to be easily torn without the help of canine teeth. They are also very destructive to the eggs and young of such birds as build their nests on the ground, and greedily devour worms, frogs, small lizards, and, Azara says, even vipers. The chief animal food of the armadillos, however, is derived from the immense herds of wild cattle which cover the plains and savannahs of every part of South America. These are rarely slaughtered but for the sake of the hide and tallow; and as the carcasses are left to rot on the pampas or plains, the smell soon attracts vast crowds of carnivorous animals of various species, and among others great numbers of armadillos, which greedily devour the half-putrid flesh, and soon become extremely fat and corpulent. In this condition, notwithstanding the filthy nature of their food, their flesh is esteemed a great delicacy both by the native Indians and by the Portuguese and Spaniards of America. The animal is roasted in its shell, and considered one of the greatest dainties which the country produces.

The armadillos see but indifferently, particularly in bright sunshiny weather; but their sense of hearing is extremely acute, and amply compensates for any imperfection of sight. When alarmed by any unusual or strange sound they prick up their ears, stop for a moment to satisfy themselves of its distance and direction, then commence a precipitate retreat to their burrow, or, if that be too remote, begin to construct a new one. Smell is, however, by far the most acute of their senses. Azara tells a singular story, which strikingly illustrates the intensity of this sense in the armadillos, as well as the unerring certainty with which, by a kind of intuitive knowledge of the principles of engineering, they are enabled to direct their subterraneous course to any particular point. "My friend Noséda," says he, "having arranged a trap for the purpose of taking Chibigouzous, and having placed in it by way of bait a cock, with a small quantity of maize to support him, it so happened that a few grains of the maize fell through between the boards which formed the bottom of the trap. An armadillo arrived during the night, and wishing to get at the maize thus accidentally spilt, opened a trench or burrow at some distance from the trap, and without deviating a hair's breadth from the straight line of his direction, pushed it on to the very spot where the grain had fallen, and possessed himself of the booty."

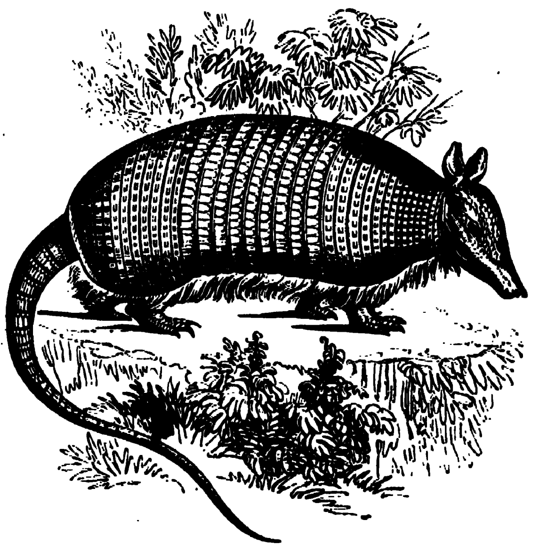
It is generally believed that the female armadillo brings forth but once during the year, but she produces at a birth frequently six, eight, or even ten young ones; yet she has never more than four teats, and, according to the report of M. Azara, the most accurate and extensive observer who has written upon the history of these animals, in some species only two—an anomaly with respect to the number of young and the number of teats which appears to contradict the general rule observable among other mammals. Azara indeed supposes that some of the young die for want of proper nourishment, and that the mother only rears those for which she has a sufficient supply of milk. This is however improbable, as we find it a general rule that only the number of young are produced at a time that can be successfully reared.

The tropical and temperate regions of South America are the original and proper habitat of all the known species of Armadillos. The armadillos are active hardy animals, and thrive and breed rapidly with a moderate portion of care in most temperate countries. Such of the species as prefer a vegetable food, and whose flesh is consequently the most palatable and wholesome, might even be domesticated with advantage, and bred in warrens, like rabbits. In their native climates, however, they still abound in such incredible numbers that the inhabitants will not be at the trouble of rearing what they can so readily procure to any required amount. When therefore the natives of Brazil or Buenos Ayres maintain the armadillo as a domestic animal, it is more for curiosity than for profit. The woods and pampas supply the wild animal in inexhaustible abundance. They are most usually taken in traps during the night; or, when found in open day at any distance from their burrows, are pursued by small dogs, which intercept their retreat till the hunter has time to secure them. One species only when thus attacked has the faculty of rolling itself up into a round ball like a hedge-hog, but they are generally timid and extremely helpless, and none ever attempt to defend themseves either by using their teeth or claws.

In arranging the Armadillos, Baron Cuvier, for the facility of definition, has divided them into five small groups.

I. The *Cachicames*, which have 4 toes on the anterior and 5 on the posterior extremities, 7 teeth only on each side both of the upper and lower jaw, a pointed muzzle, and a long tail, surrounded by a succession of osseous rings, each of which is composed of a number of polygonal plates arranged in numerous series. The two middle claws are excessively large and of equal length; the lateral, particularly the internal, which represents the thumb, are much shorter, but all are powerful, trenchant, and well fitted for burrowing. To this division belongs—

1. *Dasypus Peba* (Desmarest), the Peba, called Tatouhou, or Black Tatu, by the Guaranis, is extremely common in Paraguay, though it does not extend to the province of Buenos Ayres. This species is well figured in the original edition of Buffon's 'Histoire Naturelle,' and described by Daubenton under the name of *Cachicame*, which according to Gumilla is the generic name of the Armadillos among the Indians on the banks of the Orinoco. Azara calls it the Black Armadillo, from its Guarani name; and it has been admitted into the generality of zoological catalogues under the somewhat ambiguous appellations of *Dasypus novemcinctus*, *D. octocinctus*, and *D. septemcinctus*.—three different species being thus formed from the same animal, under the erroneous supposition that the number of moveable bands between the bucklers of the shoulders and croup was invariable in the same species.



The Peba (*Dasypus Peba*).

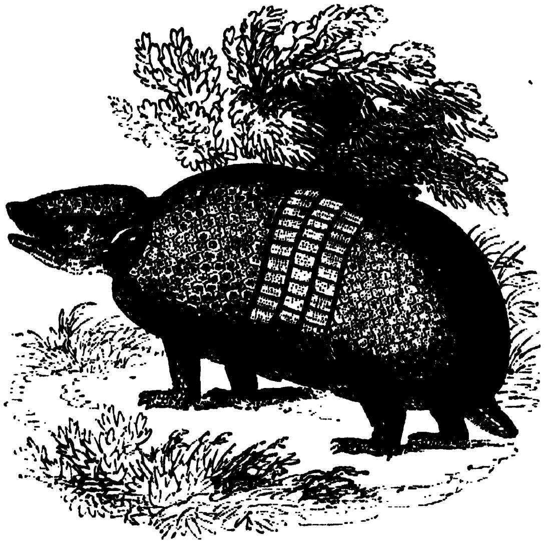
The length of the Peba, from the snout to the origin of the tail, is about 16 inches, that of the tail 14 inches, and its circumference at its base 6 inches. The head is small, long, and straight; the nose extremely elongated, taper, and terminated by a sort of small muzzle something resembling the snout of a hog; the mouth is large; the eyes small, and placed on the sides of the head; the ears long, and placed close together; the tail long and attenuated; the legs short; and the foot small. The buckler of the shoulders extends in front over the whole neck, and towards the rear as far as the back, descending on each side to the elbows. It is composed of small pieces adhering to one another, and disposed in numerous parallel concentric rings, having the concavity towards the front, the first ring embracing the neck of the animal. The buckler of the croup extends from the back to the origin of the tail, and descends on each side to the knees. It is composed, as in the former case, of small pieces arranged in a great number of parallel concentric rings, passing transversely over the hips, but having their concavity turned in the opposite direction from that of the rings on the shoulder, or in such a manner that the last embraces the root of the tail. When viewed externally, the little pieces composing these bucklers have the appearance of irregular tubercles, but when examined on the under side of the buckler they are found to be hexagons almost as regular as those of the cells of bees, and fitted as precisely to one another. Between the bucklers of the shoulders and croup are interposed a variable number of transverse moveable bands marked with zig-zag lines forming very acute angles, and in some degree gliding over one another according to the different motions of the animal. Out of 14 individuals examined by Azara, there were two with 6 of these moveable bands, one with 7, seven with 8, and four with 9; and it was observed that the full-grown ones always had the greatest number of bands, which renders it extremely probable that new bands are detached from the bucklers as they are required by the increasing growth of the animal. The buckler of the head descends from the ears to the muzzle, and covers each cheek as far down as the orbits; and there are small detached scales interspersed in various situations over the throat, the under-jaw, the legs, and feet, and even on the outer side of the ears. The tail is extremely long and taper: it is composed of a great number of osseous rings forming a long tubular case, and connected like the joints of a cane. The Peba, or, as it is commonly called in Brazil, Tatu-Peba, has 32 teeth, 8 on each side both of the upper and under jaws. It inhabits Guyana, Brazil, and Paraguay, is a timid nocturnal animal, tolerably swift-footed, and very expert in burrowing. It is never found in the woods, but delights in the open plains and cultivated fields, and is much hunted by the inhabitants on account of the delicacy of its flesh, which, when roasted in the shell, is fat and well tasted; it is said to resemble that of a sucking-pig.

2. *D. hybridus* (Desmarest), the Mule Armadillo, called M'bouriqua, or Mule Tatu, by the Guaranis, in allusion to its long upright ears, differs from the last species principally by its smaller size, and the comparative shortness and smallness of its tail. The length from the nose to the origin of the tail is stated by Azara to be only 11¼ inches; the tail itself is 6¼ inches long, and 3 inches in circumference at the root; whence it appears that the tail of the present species is only half the length of the body, whilst in the Tatu-Peba its dimensions are very nearly equal. The legs of the present species are also rather shorter than those of the Peba, the body is broader and less covered with hair on the under surface, and the moveable bands generally fewer in number, and capable of being separated to a greater distance from one another. Their number generally varies from 5 to 7, without distinction of sex, but it is to be observed that the former number is only found in very young animals; and altogether the small size and general external resemblance of the two species make it sometimes difficult to distinguish between the adult M'bouriqua and the young Peba, especially if great attention be not paid to the comparative length of the body and tail, which forms the only certain criterion. This species inhabits the open uncovered country, like the former, but extends much farther south, and is common on the pampas of Buenos Ayres.

3. *D. Verdadeiro*, the Tatu Verdadeiro, is a species very similar in size and proportions to the Mule Armadillo; but the point of its tail is terminated by a horny case of a single piece; the moveable bands are broader, and the plates of the croup-buckler are of considerably larger size. We know very little more about this species than the few characters here reported. It inhabits the woods of Brazil, resides in burrows, and is found abroad at all hours during the day-time. Koster is the only traveller who mentions this animal, but Baron Cuvier had an opportunity of establishing its specific distinctions by the examination of some specimens brought to France by M. Auguste de St. Hilaire.

II. The second subdivision which Baron Cuvier establishes among the Armadillos, and which he calls *Aparas*, is characterised by having the claws and teeth in all respects similar to those of the preceding, save that the number of the latter amounts to nine or ten on each side both of the upper and lower jaws; but the animals of the present group are immediately distinguishable from all others of the genus by the faculty which they possess of completely rolling themselves up like a hedgehog into a round ball, in which situation they may be tumbled about, or even, it is said, thrown over precipices, without receiving any material injury. There is but a single known species.

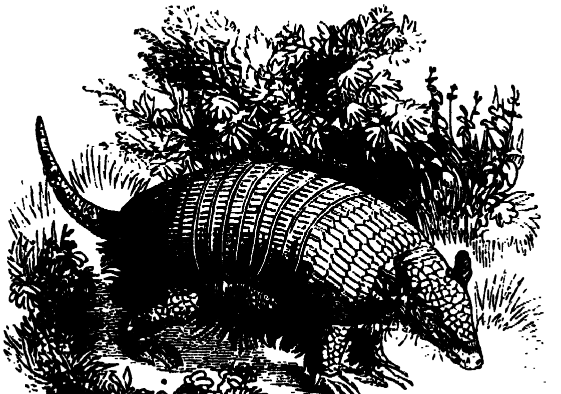
4. *D. Apar* (Desmarest), and *D. tricinctus* (Linnæus), the Mataco, called also Bolita, or the little ball, from its faculty of assuming a spherical form, is nearly 15 inches long from the nose to the origin of the tail; the head is 3 inches long, and the tail not quite 2¼ inches. The head is oblong and of a pyramidal form; the muzzle pointed; the ears short and nearly round; and the legs and claws comparatively smaller and weaker than in the other species; the tail also is much shorter, and does not taper so much; it is flattened at the root, and covered above with a rough granular crust. The small pieces which compose the bucklers and moveable bands are themselves of very irregular figures, and disposed in a more confused manner than in other species, bearing no distant resemblance to a number of small rough fragments of stones thrown at random over the surface. The buckler of the shoulders forms a prominent angle on each side which advances forwards over the cheek; it is composed of 9 or 10 parallel bands of small plates, of a polygonal figure, except those of the last row, which, like the plates of the moveable bands, form irregular parallelograms. The buckler of the croup is composed of 13 transverse rows of small plates, similar to those of the shoulders, and between the two bucklers are interposed three moveable bands only; a number by which the Mataco is readily distinguishable from all other armadillos, though it is probable that it may vary in a small degree, as it is found to do in other cases. Its usual resource, and only defence when frightened or surprised, is to roll itself up; for it does not construct burrows like the Tatu-Peba, nor does it possess sufficient speed to escape by flight. It is found in Brazil, Paraguay, and Buenos Ayres, but is nowhere very common.



The Mataco (*D. Apar*).

III. The *Encouberts*, or third division of Baron Cuvier, have 5 toes on the fore feet, and 9 or 10 teeth throughout, but they are principally distinguished by having 2 teeth in the intermaxillary bones of the upper jaw, representing, as it were, the incisor teeth of ordinary mammals, and thus forming an exception, not only to the other Armadillos, but even to the order of *Edentata*, which are principally characterised by their want of teeth of this description.

5. *D. Encoubert* (Desmarest), *D. sexcinctus* (Linnæus), the Poyou, or Yellow-Footed Armadillo (for thus Azara interprets the name), measures about 16 inches from the nose to the origin of the tail, which is itself about half the length of the body. The head is large, flat, and



The Poyou (*D. Encoubert*).

nearly triangular, the face short, the muzzle obtuse, the ears erect and of moderate size, and the eye small. The number of moveable bands varies from 7 to 8, according to the individual; the tail is surrounded at the base with three or four bony rings, but throughout the rest of its length it is merely covered with regular tuberculous scales; the interstices of the moveable bands give origin to a great number of long bristly gray hairs, and the female is provided with only two pectoral mammæ. But independently of all other considerations, the Tatu-Poyou is easily distinguished from all the other armadillos by the unusual flatness and broadness of its body, and the consequent comparative shortness of its legs. It is very common in Paraguay, and burrows in the ground with an almost incredible agility. Its strength and activity are very remarkable; and notwithstanding the shortness of its legs, it runs so swift that few men can outstrip it. It is of a restless unquiet character, bold, curious, and intrepid. When any noise is made at the entrance of its burrow, or when otherwise tormented, it grunts like a young pig, and comes forth without fear to investigate the cause; yet when actually attacked it is incapable of making any sort of defence, and can only save itself by retreating to the bottom of its hole, or burrowing to a still greater depth. The Poyou feeds much upon carrion, and for this reason its flesh, though fat, is never eaten by the inhabitants of European origin, though the Indians make no distinction in this respect between it and the other armadillos. When it stops or rests, it has a custom of squatting close to the ground like a hare in her form, and in this situation the great breadth of the body is remarkably apparent, being nearly three times its height.

6. *D. villosus* (Desmarest), the Hairy Armadillo, measures 14 inches in length from the nose to the origin of the tail; the head is nearly 4 inches in length, the ear two-thirds of an inch, and the tail 5 inches. In form and appearance this species bears a very strong resemblance to that last described, but it is of smaller size, and is comparatively better covered with hair, a circumstance from which it derives the name by which it is most usually distinguished. The head is triangular, the muzzle pointed, the ears large, elliptical, and inclined outwards, and the number of moveable bands varies from 6 to 7 according to the individual. The border of the bucklers, as well as the lower side of the moveable bands, is indented in a remarkable manner, and forms sharp angular points, which serve to approximate the present species to the following, not less than to distinguish it from all the other known armadillos. There are eight teeth on each side, both above and below. Numerous long flexible brown hairs spring from every part of the body, but more especially from the sides and belly, and even cover the first half of the tail. The female, as in the Poyou, has only two pectoral mammæ.

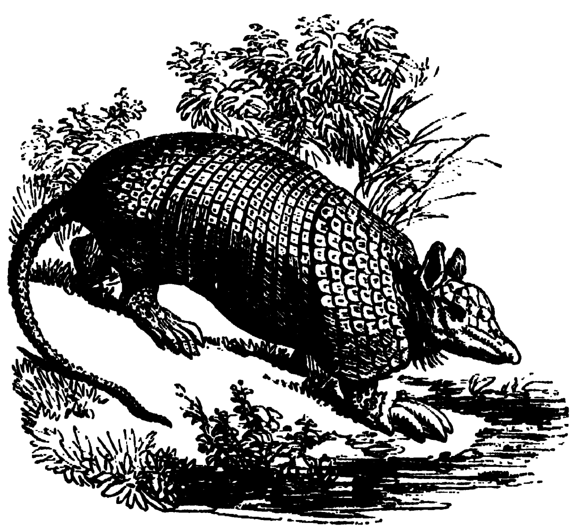
This species does not inhabit Paraguay, nor, as far as we are at present aware, any other part north of the Rio Plata, but it is found at every step on the pampas or plains of Buenos Ayres, south of that river. "In an expedition," says Azara, "which I made into the interior, between the parallels of 35° and 36° south latitude, I met with vast multitudes of this species of armadillo, so that there was scarcely an individual of the party who did not each day capture one or two at least; for, unlike the Poyou, which moves abroad only during the night, this animal is to be found at all times, and upon being alarmed promptly conceals itself, if not intercepted. In March and April, when I saw them, they were so extremely fat that their flesh surfeited and palled the appetite; notwithstanding which the pioneers and soldiers ate them roasted, and preferred them to beef and veal." "The hairy armadillo," continues M. Azara, "like others of the genus, has undoubtedly a very acute sense of smell, since it scents the carcasses of dead horses from a great distance, and runs to devour them; but as it is unable to penetrate the hide, it burrows under the body till it finds a place which the moisture of the soil has already begun to render putrid. Here it makes an entrance with its claws, and eats its way into the interior, where it continues feasting on the putrid flesh, till nothing remains but the hide and bones, and so perfectly do these preserve their position, that it is impossible, from a mere external view to anticipate the operations which the armadillos have been carrying on within." The same author observes further, that this species never constructs burrows to reside in, that it avoids low damp situations, and is only found on the dry upland plains.

7. *D. minutus* (Desmarest), the Pichiy, measures only 10 inches in length from the snout to the origin of the tail, which is itself 4¾ inches long; the head is 2 inches and 8 lines long, 2 inches broad across the orbits, and the ears are a quarter of an inch in length, and very sharp-pointed. The frontal buckler is composed of irregular plates, the eyes being small and nearly concealed under its margin; there are no plates on the temples, but their place seems to be supplied by a pencil of stiff brown hairs; the neck is extremely short, and furnished above with a row of minute scales; the shoulder-buckler presents nothing remarkable, but that of the croup is deeply indented along the edges, and the moveable bands, to the number of six or seven, according to the age of the individual, are composed of rectangular plates, bordered on each side by compressed scales, lunated and pointing backwards. Each scale is more or less distinctly marked with two longitudinal linear depressions, which divide it into three parts, of which the middle is plain and of an oblong figure, but the lateral are, as it were, divided into six or eight tubercles. The claws are but moderately developed, the tail is covered with strong scales disposed in rings, and the interstices of the scales and bands are furnished with a considerable quantity of hair, though less abundantly and not so long as in the last species.

The Pichiy inhabits the pampas to the south of Buenos Ayres, and extends from 36° of latitude southward to the confines of Patagonia. It inhabits burrows, to which however it does not confine itself during the day, like some other species. Its flesh is said to be remarkably tender and well tasted. Two individuals of this species which had been brought from Port Desire, on the east coast of Patagonia, lived for some time in the Jardin des Plantes at Paris, and would doubtless bear even the rigour of our more northern climate without injury or inconvenience.

IV. The *Kabassous* have likewise five toes, both on the anterior and posterior extremities, but those of the fore feet are disposed obliquely, in such a manner that the thumb and index are small, the middle and fourth toes armed with tremendously large tronchant claws, and the fifth very small. This construction gives them the means of burrowing with extraordinary facility, and of clinging to the ground with such determination and obstinacy that it is with the utmost difficulty they can be taken from it. They have nine or ten teeth throughout.

8. *D. Tatouay* (Desmarest), the Tatouay, or Wounded Armadillo, is so called by the Indians in allusion to its tail, which is naked, or as it were rudely deprived of the crust or bony tube which covers this organ in all the other species. The whole length of the Tatouay, as given by Azara, is 26½ inches, from which if we subtract 7½ inches for the length of the tail, it leaves 1 foot 7 inches for that of the body.



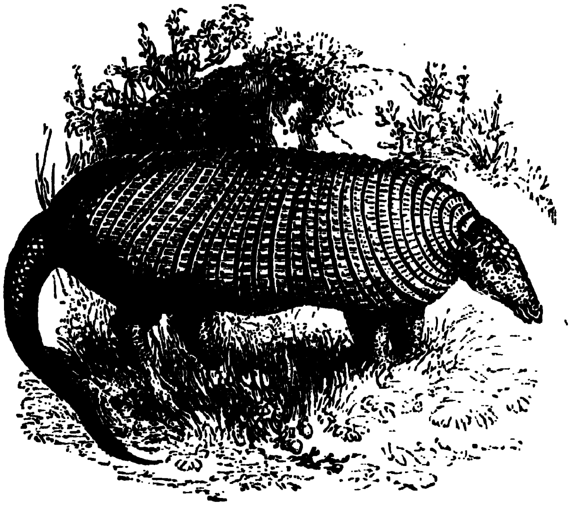
The Tatouay (*D. Tatouay*).

The tail is round, pointed and naked, with the exception of a few small round scales or crusts on the under surface of the third ring nearest to the extremity, which frequently trails along the ground when the animal walks; the rest is covered with soft brown fur, interspersed with a few stiff short hairs on the superior surface. The head is longer, narrower, and more attenuated than that of the Poyou, though considerably less so than in the Peba and Mule Armadillo; there are 8 molars on each side of the upper jaw, and 7 on each side of the lower jaw; the ears are unusually large, being nearly 2 inches long, and in figure forming a segment of a circle; the body is round; the claws of the fore feet, particularly that of the middle toe, are excessively large; and the female is provided with only two pectoral mammæ. The bucklers of the croup and shoulders are composed of 10 and 7 rows of scales respectively, each scale forming an oblong rectangle, those of the coccia being the largest of all; the moveable bands are 13 in number, composed of scales much smaller than those of the bucklers, and of a nearly square figure. The habits of this species are altogether unknown. It inhabits Guyana and Brazil, and is rarely found south as far as Paraguay.

V. The *Priodontes*, or last subdivision of the Armadillos, in addition to the unequal toes and enormous claws of the Kabassous, have from 22 to 24 small teeth throughout, on each side of the jaws, making in all from 88 to 96 teeth a greater number than is found in any other mammal. This group contains but a single species at present known, namely—

9. *D. gigas* (Cuvier), the Great Armadillo, which is nearly 3 feet 3 inches in length, from the nose to the origin of the tail; the head is 7½ inches long, the ears 1¾ inch, and the tail 1 foot 5 inches. Its superior size is alone sufficient to distinguish this species from all the other known armadillos, but it possesses numerous other characters not less remarkable. Its head is proportionably smaller than in the other species, the forehead is more protuberant, and the face from the eyes downwards assumes a tubular cylindrical form, like that of the Peba;

the ears are of a moderate size, pointed, and habitually crouched backwards; the bucklers of the shoulders and croup are composed of 9 and 18 rows of plates respectively, and separated by moveable bands to the number of 12 or 13, formed of rectangular scales, about half an inch square. The tail is remarkably thick at the root, being upwards of 10 inches in circumference: it is gradually attenuated towards the tip, covered with plates disposed in rings at the base, and forming spiral or crescent-shaped lines throughout the rest of its length. The claws are remarkably large and powerful, but in their relative form and dimensions differ little from those of the Tatouay already described.



Great Armadillo (*D. gigas*).

This species inhabits Brazil and the northern parts of Paraguay. It is never found in the open country, but keeps close to the great forests, and burrows with surprising facility. Those who are employed in collecting the Jesuit's Bark frequently meet with it in the woods, and report that when any of their companions happen to die at a distance from the settlements, they are obliged to surround the body with a double row of stout planks, to prevent it from being scratched up and devoured by the Great Armadillo.

The remains of Armadillos have been found in the Tertiary Strata, the most remarkable of which is the *Glyptodon* of Owen. [GLYPTODON.]

ARMATI. [AMMONITES.]

ARNI, the native Indian name of the Wild Buffalo. [OX.]

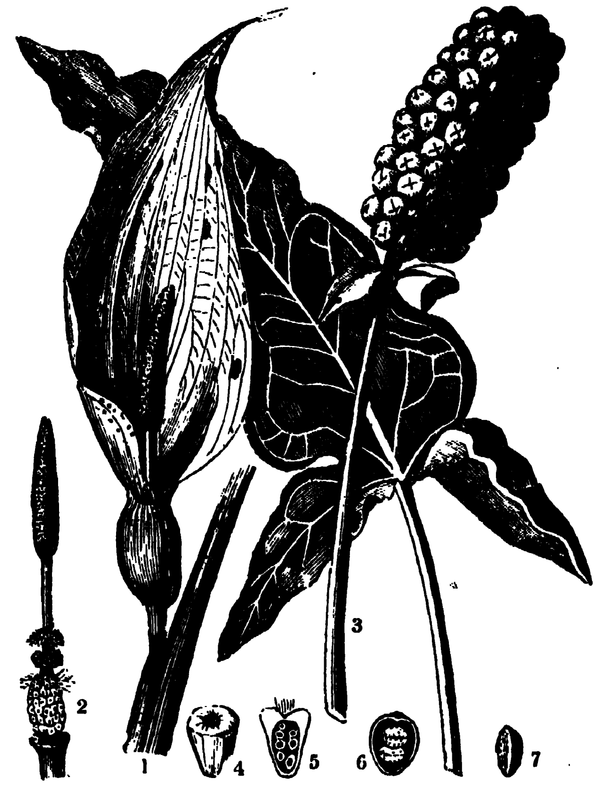
ARNI'CA, a genus of plants belonging to the natural order *Compositæ*, the tribe *Vernoniaceæ*, the sub-tribe *Senecioneæ*, and the division *Eusenecioneæ*. It has a cylindrical involucre, with equal 2-rowed scales; the flowers of the disk hermaphrodite, tubular; the limb 5-toothed; the stigmas thickened above, and terminated with a conical pubescent apex; the flowers of the ray female, bearing degenerated stamens, or with only the rudiments of an anther; the achenium winged and striated; the receptacle naked; the pappus hairy. One species of this genus grows in Europe, the *A. montana*, and is known by the common name of Leopard's-Bane. It has oblong-obovate nearly entire 5-nerved radical leaves, a few-flowered stem, with villose or glandulose pubescent peduncles and involucres. This plant is not found in the British Isles, but is abundant in the meadows and forests of mountainous districts in the middle and north of Europe, and also on the Alps. It blossoms in June and July.

This plant was at one time admitted into all the British Pharmacopœias, but at the present time is only retained in the Dublin. It does not appear ever to have been much used in this country, and perhaps never sufficiently to refute or confirm the strong recommendations of it by German writers. In Germany all parts of the plant are used, the flowers, leaves, and root. The whole plant, but especially the root, possesses a peculiar aromatic but not pleasant odour, and a nauseous taste. The plant has been examined by various chemists, and in every part there has been found an acrid resin and a volatile oil. In combination with these Chevallier and Lassaigne found in the flowers an acrid bitter principle, which they have called Arnicine, and the root contains a considerable quantity of tannin. In large doses it produces inflammation of the alimentary canal, and coma. In small doses it acts as a general stimulant, increasing the pulsations of the heart, and acting as a diaphoretic and diuretic. It is used in Germany in cases of low fever, also in nervous diseases, in amenorrhœa and adynamic diseases generally. The root by means of its tannin acts as a tonic on the system. The root is given in powder in the dose of about 10 grains, three times a day, or in infusion. The flowers are used in infusion, in the proportion of 1 drachm of the flowers to 80 of boiling water, of which 2 ounces may be given at a dose. In making this infusion care should be taken that the pappus be prevented from getting into it, by means of straining through a linen bag. The German Pharmacopœias contain several preparations of Arnica, amongst others a tincture, an extract, an essence of the flowers, and a vinegar (*Acetum Arnicæ*). Amongst homœopathic practitioners the tincture is applied to wounds and bruises, and other external uses, and infinitesimal doses of this substance are recommended, according to their practice, in many severe diseases.

(Bischoff, *Medicinisch-Pharmaceutische Botanik*, 1844; Christison's *Dispensatory*.)

AROI'DEÆ, or ARACEÆ, *Arads*, an order of Monocotyledonous Plants, which approach Dicotyledons in the form and veining of their leaves, but agree with the former in everything else of importance. They are readily known by their flowers being placed very closely upon a cylindrical or lengthened axis, called technically a spadix (*fig.* 2), which is itself inclosed in a leaf of a peculiar figure, the edges of which are curved inwards till they meet, forming a sort of hollow sheath, which botanists name spathe (*fig.* 1).

The fruit is generally a cluster of little berries, each of which contains a small number of seeds. The flowers themselves are extremely variable in structure; sometimes having neither calyx nor corolla, and sometimes possessing both those parts; sometimes furnished with anthers opening in a singular manner by little lobes, or having anthers of the commonest construction. Many of the species grow upon the trunks of trees, clinging to them in tropical countries like ivy; a very few are found in Europe, and those are always little stemless herbs; a small number are small erect shrubs. They are all acrid in a high degree, some of them so much so as to be dangerous poisons, as for example the Dumb-Cane of the West Indies, which paralyses the mouth if only chewed. Nevertheless this acrid principle is so far removed by roasting or boiling, that the underground stems may in some cases be used as food. The Colocasia of the tropics, and some other species, are common articles of food among the negroes; but they are said not to agree very well with Europeans. In this country only one kind of Aroideous plant, the *Arum maculatum*, is found wild. The root of that species which is vulgarly named the Cuckoo Pint, and its spadixes Lords and Ladies, is eatable when properly prepared, just as those which have already been mentioned. What is called Portland Sago is prepared from it. The spadixes of some species give out a fetid smell. The emanations of *Arum Dracunculus* when in flower produce dizziness, headache, and vomiting.



Arum maculatum.

1, A spathe with the point of the spadix seen within it; 2, the spadix separated; 3, the ripe fruit; 4, an ovarium; 5, the same cut perpendicularly; 6, one of the little fruit cut perpendicularly; 7, a seed.

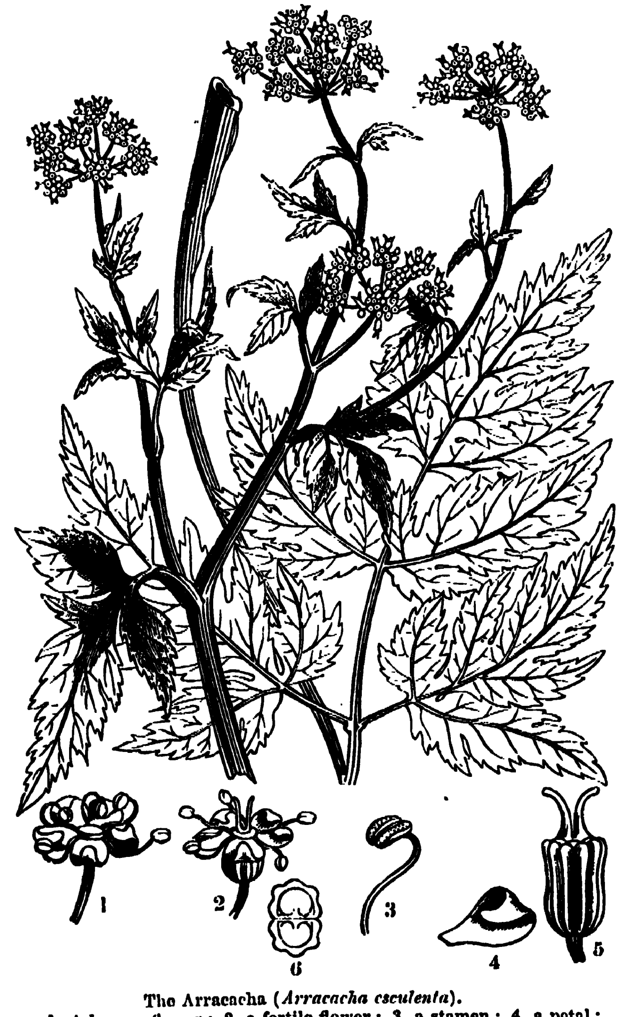
ARO'MA is the supposed principle of odour in plants, formerly called by Boerhaave *Spiritus Rector*. This quality generally resides in the essential oil; but there are some vegetables that have a strong odour which yield but little or no essential oil, as the jasmine and the violet; or when an oil in small quantity is procured from them it has not the powerful smell which, considering the smallness of its proportion compared with the fragrance of the plants, it might be expected to possess. As plants exhale their odour when exposed to the air, and communicate it to water at a lower temperature than that at which it could be distilled, it has been imagined that some principle of a more subtile nature exists in which the odour resides, and that it is this which imparts smell to the oil. In fact, however, the property of odour belongs to proximate vegetable principles of different kinds, in which there is no reason to suppose the existence of any common principle; essential oil is unquestionably the most usual cause of its production, and it is capable of being volatilised in small quantity at a low temperature, and thus diffused through the atmosphere or communicated to water.

ARONIA, the Linnæan name for a species of plants of the genus *Mespilus*, the *Mespilus Amelanchier*, or *Mespilus vulgaris*. [AMELANCHIER; MESPILUS.]

ARQUERITO, a native amalgam, consisting of six parts of silver and one of quicksilver. It has been regarded as native silver. It is malleable, and is worked with great success in the mines of Arqueros in Chile.

ARRACA'CHA, a genus of plants belonging to the natural order *Umbelliferæ*, which comprehends a species of as much importance in the tropical parts of America as the parsnip and carrot are in Europe. This plant, the *Arracacha esculenta* of botanists, is cultivated in great quantities in the neighbourhood of Santa Fé de Bogota, in the cooler districts among the mountains, and in other parts of the state of Colombia, where it is called Arracacha. It resembles the common hemlock in appearance, but the leaves are much broader, the stems are not spotted, and the flowers are of a dingy purple colour; it is also of smaller stature.

The root is of the same nature as the tuber of a potato, only it is forked, or divided into several lobes, each of which is about the size of a large carrot. These when fit for eating are boiled like the potato, and become of a firm but tender consistence, not at all mealy, and have a flavour intermediate between a chestnut and a parsnip. It appears that an immense produce of Arracacha is obtained in the South American provinces, where it has long been as much the staple nutriment of the population as the potato or the yam in other places; and as it will only thrive in the colder districts, it was once expected to form an important agricultural plant in Europe. It has however been found upon trial unable to accommodate itself to our uncertain climate, and to perish as soon as the cold nights and damp weather of autumn approach, without having been able during the summer to perfect its tubers. It is therefore only cultivated now in botanical collections. (Hooker, *Botanical Magazine*, tab. 3092.)



The Arracacha (*Arracacha esculenta*).
1, A barren flower; 2, a fertile flower; 3, a stamen; 4, a petal; 5, a ripe fruit; 6, the same cut across.

ARRAGONITE, *Prismatic Carbonate of Lime*, called by Mohs the Prismatic Lime-Haloide. It is a mineral substance consisting of carbonic acid and lime, admitting of cleavage in planes parallel to the faces of a right rhombic prism of 116° 5′ and 63° 55′, which may therefore be considered as its fundamental form (*fig.* 1). The most general modifications which occur consist either in the removal of the four acute angles at A by planes *a* intersecting each other in the short diagonal B B, and inclined to each other at an angle of 108° 18′, by which the face P being entirely removed, the form of *fig.* 2 is produced; or the change may be effected by the truncation of the acute lateral edges of the prism by planes parallel to the axis of the crystal, and therefore inclined to the faces L, at 121° 57′, giving rise to the form seen in *fig.* 3. These modified forms usually present themselves in twin crystals, in which the short diagonals of the prism B B are placed at right angles to one another, when only two crystals are present, thus producing a very simple cross. It is usual however that three of the crystals of *fig.* 3 cross each other, producing a crystal of the appearance of *fig.* 4, which at first sight may be mistaken for an hexagonal prism, but on a closer inspection it will be found that what appeared to be a single face is really composed of two planes, making a re-entrant angle.

The intersections of the individual crystals with each other are visible both in the lateral and terminal faces, and are indicated in *fig.* 4 by the dotted lines. These crystals have been found abundantly in a ferruginous clay in Aragon in Spain, where they occur accompanied by a sulphate of lime. From this circumstance the mineral has derived its name. It has also been found very beautifully crystallised in a vein of a massive variety of the same mineral traversing basalt at Bilin in Bohemia. (Mohs.) Fine specimens have been found at the following places in England: in the Dufton lead-mines; in a cavern of Grauwacke, near Merridge, Somersetshire; and also in several parts of Devonshire, &c. In an old coal-mine six miles south-west of Cockfield, Durham, it is remarkable as occurring depending from a roof of clay-slate, and accompanied by tubular calcareous stalactites. (Phillips.) Varieties of this mineral are also common in beds of iron-ore in the mines of Eisenerz in Styria, and in several other iron-mines of Hungary, of Transylvania, &c., consisting of numerous fibrous crystals, of a satin-like lustre, radiating from a centre, and to these the name of *Flos Ferri* has been applied.

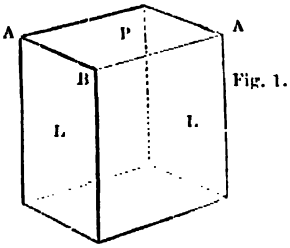


Fig. 1.

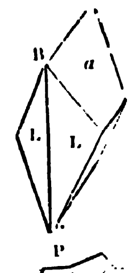

Fig. 2.

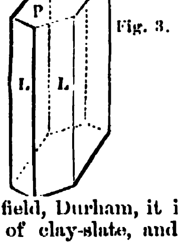

Fig. 3.

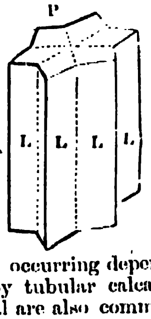

Fig. 4.

In a chemical and crystallographical point of view *Arragonite* is peculiarly interesting, as presenting to us carbonate of lime differing in its system of crystallisation from that of the common Calc-Spar, and thus affording us an instance of the influence of any difference in the aggregation of matter in changing its physical properties, as will be seen by comparing this substance with the rhombohedral Calc-Spar, with which it agrees in chemical constitution. In the scale of Mohs its hardness varies from 3·5 to 4, while that of Calc-Spar is 3. The specific gravity of

Arragonite is . . . . 2·931
Calc-Spar . . . . 2·721.

They act also differently on light, the index of ordinary refraction of

Arragonite being . . . . . . 1·693
Calc-Spar . . . . 1·519

Attempts have been made to account for these differences by considering them the effects of small quantities of carbonate of strontia, which Professor Stromeyer first discovered to be contained in many specimens of *Arragonite*; but the conclusion is unfounded, as will be seen by the results of two analyses given by Stromeyer:—

	First.	Second.
Carbonate of Lime	95·2965 . .	99·2922
Carbonate of Strontia . . .	0·5090 . .	4·1043
Water	0·1544 . .	0·5992

where the carbonate of strontia is in small and varying proportion, and must therefore be considered as an accidental impurity.

ARSENIC and ARSENICAL MINERALS. Arsenic is found pure and combined with other substances, both as an acid and a base. Those minerals in which arsenic acts the part of the electro-negative element or as an acid may be considered as forming a mineralogical family or class, according to the chemical arrangement of Berzelius. This family comprehends four genera, a tabular view of the principal species of each of which is here given :—

First genus.
Species. Metallic or native arsenic.
Second genus (metallic arseniurets).
First species. Octahedral cobalt pyrites : speiskobalt of the Germans.
Second species. Hexahedral cobalt pyrites : kobaltglanz.
Third species. Copper nickel : arsenuret of nickel : prismatic nickel pyrites.
Fourth species. Arsenical silver : octahedral antimony of Jameson : silberspeisglanz of Hausmann : antimonial silver of Phillips.
Fifth species. Arsenuret of bismuth.
Sixth species. Axotomous arsenical pyrites (Mohs).
Seventh species. Prismatic arsenical pyrites (Mohs) ; *Mispickel* (Phillips) : arsenikkies.
Third genus.
Species. White arsenic, or arsenious acid.
Fourth genus (compounds of arsenic acid).
First species. *Pharmacolite :* arseniate of lime.
Second species. Cobalt bloom.
Third species. Nickel ochre.
Fourth species. *Scorodite :* martial arseniate of copper from Cornwall.
Fifth species. *Olivenite :* of this there are two species, the one crystallised in the right, the other in the oblique, prismatic system.
Sixth species. *Euchlore Mica* (Mohs) : rhombohedral arseniate of copper (Phillips) : kupferglimmer.
Seventh species. Cube ore : hexahedral *Liriconite :* arseniate of iron.
Eighth species. Rhombohedral lead spar.

In addition to the minerals classed in the above genera, several other substances contain arsenic, acting, however, as the electro-positive element or base : of these there are but two particularly worthy of attention, namely, *Orpiment* and *Realgar*, both of which are sulphurets of arsenic in definite but different proportions. *Orpiment* (A 2, S 3) is the yellow sulphuret of arsenic. It is rarely crystalline, and contains 61 per cent. of arsenic. It is obtained from Hungary, Turkey, China, and South and North America. It is made use of as the basis of the pigment called King's Yellow. *Realgar* (As S) is the red sulphuret of arsenic. It is found in oblique prisms or massive. It comes chiefly from Transylvania and Hungary, with tellurium and gold ; it is also found in China. It contains 70 per cent. of arsenic, and is used in making fireworks.

The geological position of Arsenical Minerals is confined to primitive districts, where they occur in metalliferous veins, usually associated with metallic sulphurets, to which the arseniurets have considerable analogy. The only genus which has been found in any quantity is the second, the most abundant species of which are the arseniurets of cobalt, nickel, and iron, which are found both in veins and beds. The fourth genus appears to owe its origin to the action of the atmosphere on the arseniurets ; they occur frequently in union with the phosphates, with which they are isomorphous ; consequently the phosphoric acid is frequently more or less replaced by the arsenic, or the reverse.

The Arsenic contained in any mineral may in general be readily detected by the blow-pipe, owing to the characteristic odour of the vapour of metallic arsenic. In performing this operation it is necessary to be careful to submit the mineral to the interior or deoxidising flame, or in order to insure the reduction of the metal more completely it is advisable to add a small quantity of the powder of charcoal. This reduction to the metallic state is essential, for it is the vapour, not of the white arsenic, but only of the metallic arsenic, which possesses the peculiar smell of garlic. If the mineral be, from its colour, suspected to be orpiment or realgar, it must be mixed with a small quantity of black flux in a glass matrass, and heated in the flame of a spirit-lamp, by which the arsenic will be liberated, and a sulphuret of potassium formed.

Native Arsenic is usually found in veins, accompanied by sulphur and sulphurets ; it occurs massive, also in reticulated and stalactitic shapes, and of a curved lamellar composition, exceedingly like the layers of an onion. When fractured the new surface presents a metallic lustre and a tin white colour, which however soon tarnishes, becoming a very dark gray. It is brittle, has the specific gravity 5·766, and its hardness is 3·5.

According to Mohs it is frequently met with in the mines of Annaberg, Schneeberg, Marienberg, and Freiberg in Saxony; at Joachimsthale in Bohemia, at Andreasberg in the Harz, in the Black Forest, in Alsace, at Allemont in Dauphiny, at Kongsberg in Norway, at Kapnik in Transylvania, and in beds at Orawitza in the Bannat of Temeswar.

The second genus presents us with a very valuable series of minerals, owing to properties of the metals with which the arsenic is combined. [Cobalt Ores ; Copper Ores.] The arsenical silver, which constitutes the fourth species, has not been sufficiently investigated. Professor Hausmann considers it as a more or less intimate mixture of prismatic arsenical pyrites with antimonial silver, a compound according to Klaproth of 16 to 24 parts of antimony and 84 to 76 of silver. The same chemist states 96 parts of arsenical silver to contain of

Arsenic	35·00
Antimony	4·00
Silver	12·75
Iron	45·25

Many mineralogists, on the other hand, consider the antimonial and the arsenical silver varieties of the same species. The first of these occurs in crystals and in granular masses ; the latter possesses a curved lamellar composition of thin crystalline plates. They both readily tarnish, and assume a dark gray colour. The specific gravity has been stated by Haüy at 9·446, by Klaproth at 9·82. The antimonial siver is found in veins at Altwolfach in Fürstenberg, and at Andreasberg in the Harz ; the arsenical in various mines in the Harz, at Guadalcanal in Spain, and also in Herland mine, Cornwall, &c. It is scarcely necessary to mention that this mineral, when found in sufficient quantity, is highly valuable for metallurgic purposes.

Axotomous Arsenical Pyrites is a compound of arsenic and iron, occurring in beds of prismatic iron, and also in primitive mountains, accompanied by cobalt and nickel, at Schladming in Styria. Its specific gravity is 7·228.

Prismatic Arsenical Pyrites, described by some mineralogists under the name of *Mispickel*, is composed, according to the analysis of Stromeyer, of

Iron	36·04
Arsenic	42·88
Sulphur	21·08

This mineral possesses a tin-white colour and a metallic lustre. The specific gravity is 6·127, and its hardness 6. It occurs massive, and also crystallised in the system of the right rhombic prism ; crystals are seen in many modifications of this system ; they admit of cleavage in planes parallel to the faces of a prism whose angles are 111° 12′ and 68° 48′, which may therefore be considered as the fundamental form.

This mineral is found commonly in most of the localities of arsenical minerals, associated with ores of silver, lead, and tin, both in veins and beds. It is a product of almost every mine in Cornwall, as well as those of Saxony, &c. Some specimens contain silver, of which the principal are found at Braunsdorf near Freiberg, in veins of quartz, traversing mica-slate.

White Arsenic, which constitutes the third genus, is found crystallised in octahedrons, and also in botryoidal and stalactitic forms, frequently pulverulent. It occurs in metallic veins, and probably is the product of the decomposition of other minerals. The lustre is vitreous, and colour white, with a slight degree of transparency. Its specific gravity is 3·698. It is readily recognised by its behaviour before the blow-pipe : if alone, being volatilised ; if on charcoal, being volatilised with the production of the garlic odour.

ARTEMISIA, an extensive genus of plants belonging to the natural order *Compositæ*, and remarkable for the intense bitterness of many of its species. It is easily recognised by the multitude of fine divisions into which its leaves are usually separated, and the numerous clusters of small, round, drooping, greenish-yellow, or brownish flower-heads, with which its branches are loaded. The flowerets are all tubular, but those in the circumference of each head are very imperfect.

A. Absinthium, Wormwood, is met with frequently in waste places all over Europe and the northern parts of Asia. Its leaves have a silky or hoary aspect, in consequence of a thick covering of exceedingly delicate hairs, and they are deeply lobed. The flower-heads are very numerous, and of a light buff colour. Wormwood is celebrated for its intensely bitter, tonic, and stimulating qualities, which have caused it to be an ingredient in various medicinal preparations, and even in the preparation of liqueurs. It derives its name from its use in destroying worms in children. *A. pontica* has also the same properties.

A. Dracunculus, Tarragon, is a Siberian species, the stems of which grow 2 or 3 feet high, are perfectly smooth, and of a bright green. Its leaves are undivided, very narrow, smooth, and rather succulent ; when bruised they emit a stimulating odour, and if chewed produce a peculiarly pungent moisture in the mouth, which is so generally considered agreeable that the leaves are employed as a pickle, and as an ingredient in some kinds of vinegar. The flower-heads are small, round, and smooth, and contain seven or eight flowerets.

A. Mutellina has properties intermediate between Wormwood and Tarragon : from it and *A. spicata* the bitter aromatic liqueur called Crême d'Absinthe is prepared.

A. Abrotonum, Southernwood, an odoriferous herb found all over the south of Europe from Portugal to the Dardanelles, and thence through Palestine, Persia, and the middle of Asia into China, is frequently seen in old-fashioned gardens where it was cultivated for its peculiar aromatic scent. It is a hoary plant, becoming in warm countries a shrub, and even with us acquiring a woody stem after a few years ; its branches bear loose panicles of noddin gyellow flower-heads, which are externally gray with down; the leaves belonging to the panicles are much longer and narrower than those of the stem.

A. acetica, a Persian species, is said to have a strong odour of vinegar.

A. Chinensis yields the material from which moxas are made that are burned upon the human body as a cautery in cases of gout and rheumatism.

A. maderaspatana and *A. Indica* are used by the Indian doctors. The flower-heads of *A. Sieberi*, *Lercheana*, *Contra*, and *pauciflora* constitute the drugs called *Semen contra*, or *Semen Cinæ*, which are used as vermifuges. The same part of *A. Vahliana* yields the Persian Wormseed, or *Semen Cinæ Levanticum;* and that of *A. cærulescens*, the *Semen Seriphii*, or Barbotine. *A. camphorata* and *A. Gallica* are used in France also as anthelmintics under the name of Sanguerié or Sanguerite.

ARTERY, from the Greek ἀρτηρία, signifying an air-vessel, because the ancients, ignorant of the circulation, and finding the arteries always empty after death, supposed they were tubes containing air. Why after death the arteries are empty and the blood accumulated in the veins will be explained hereafter. By the term Artery is meant a vessel which conveys blood from the heart to the different parts of the body: a Vein, on the contrary, is a vessel which conveys blood from the different parts of the body to the heart. [CIRCULATION OF THE BLOOD.] All the arteries of the system proceed from two great trunks immediately connected with the cavities of the heart, namely, the Pulmonary Artery, which arises from the right ventricle, and the Aorta, which springs from the left ventricle. [AORTA; HEART.]

The arterial system is arborescent, that is, the branches which spring from the aorta successively increase in number and diminish in size as they proceed from the heart towards their ultimate terminations in the system. Each trunk commonly ends by dividing into two or more branches, the combined area of which is always greater than that of the trunk from which they spring. The capacity of the branches is estimated to exceed that of the trunks in the proportion of one and a half to one. The arterial trunk always dividing into branches, and the larger branches into branches more and more minute, it is obvious that the blood in the arterial system is always flowing from larger into smaller tubes.

The arteries are of a yellowish-white colour, loose and flocculent on their external surface, but their internal surface is smooth and polished. They are composed of three distinct membranes, which are superimposed one upon the other, and which are ultimately united by delicate cellular tissue. Each of these membranes is called a tunic, or coat, and each possesses a peculiar structure, and performs a separate function in the circulation of the blood.

1. The internal tunic consists of a membrane, colourless, transparent, and thin, yet so firm and strong that it is supposed to resist more than any of the others the bursting of the artery by the current of the blood; for if, in a living animal, the other coats be entirely removed, this alone is found capable of sustaining the impetus of the circulation, and of preventing rupture from the dilatation of the artery.

2. The middle tunic, called also the fibrous and the muscular, is composed of yellowish fibres [AREOLAR TISSUE], which pass in an oblique direction around the calibre of the vessel, forming segments of circles which are so joined as to produce complete rings. In the larger trunks, several layers of these fibres can be raised in succession by the forceps, so that this coat is of considerable thickness, and it is proportionally thicker in the small branches than in the large trunks. This coat is firm, solid, and highly elastic. It is the main tunic by which the artery resists dilatation in the transverse direction, which it does so effectually that when the left ventricle of the heart propels a fresh current of blood into the aorta little or no dilatation of the vessel is perceptible. The characteristic property of the fibrous coat is contractility. If it be mechanically irritated, or if a chemical stimulant, such as ardent spirit or ammonia, be applied to it, the vessel contracts forcibly upon its contents. This contractile power, which properly belongs to the muscular fibre, induced anatomists to believe that the fibrous tunic consists of muscular fibres; but careful examination has shown that its organisation possesses nothing in common with that of the muscular tissue, while chemical analysis has demonstrated that it contains no fibrin, which is the basis of muscle.

3. The external tunic, called also the cellular, consists of small whitish fibres, very dense and tough, interlaced together in every direction. It is much thicker in the large trunks than in the small branches, the reverse of the fibrous coat. Its outer surface is covered by a loose and flocculent cellular substance, which connects the artery with the surrounding parts, and particularly with the sheath of the vessel. Its firmness and resistance are so great that it is not divided however firmly a ligature may be placed around the artery; and its elasticity, especially in the longitudinal direction, is so remarkable that it has been called, by way of eminence, the elastic coat.

Arteries are themselves abundantly supplied with arteries, constituting their nutrient vessels, and called *Vasa Vasorum;* but these nutrient vessels of the artery form but few anastomoses, that is, but communications with any other arteries.

The principal nerves of arteries are derived from the ganglionic or the organic system, but with these are mingled branches derived from the sentient or the animal system. [NERVE.] Accordingly, under ordinary circumstances, arteries carry on their functions independently of any influence derived from the brain and spinal cord, but they are capable of being affected by agents applied to those organs.

Among the physical properties of arteries, the most important are their extensibility and their elasticity. Their extensibility is chiefly in the direction of their length.

After an artery has been extended, either lengthwise or transversely, it suddenly retracts on itself when the extending force is removed. If the finger be forcibly introduced into the section of a large artery, the sides of the vessel re-act on the finger, and proportionally compress it. If an artery be divided in the dead body, though emptied of its contents, it maintains its cylindrical form, and preserves its capacity unimpaired. The elastic property on which these phenomena depend is common to all the coats, but it is greatest in the external tunic, and least in the internal tunic, and it is also much greater in the large trunks than in the small branches.

The most important vital property of the artery is its contractility, that is, its power of diminishing its capacity, or approximating its parietes, and thus proportionally acting upon its contents. Even the large trunks possess this property in some degree; but it resides chiefly in the ultimate divisions of the arterial branches, that is, the capillary vessels. [CAPILLARY VESSELS.]

ARTHRO'PTERUS, a Fossil Fish from the Lias near Bristol. (Agassiz.)

ARTICULA'TA, or *Articulated Animals*, form the third great section of the animal kingdom, according to the arrangement of Cuvier. They are so called because the different portions of their body are composed of moveable pieces articulated (jointed) to each other. They differ from Molluscous Animals in generally possessing a skeleton, and from Vertebrated Animals by their skeleton being external, while that of the vertebrated is internal. Though presenting considerable diversity of character among themselves, they are generally provided with a skin, which is either soft (as in the leech), or horny and crustaceous (as in the crab and craw-fish). Certain families are destitute of feet, but the greater number are provided with these members, which, when present, are never fewer than six. The connection of the joints of the members is so close as to permit only a very limited range of motion to each; which is, however, compensated by the greater number of pieces which constitute each member or limb.

The animals of this division have the trunk of the body for the most part long and cylindrical, and divided transversely into segments. In the lowest forms of these animals the segments are perfectly simple, but as we ascend we observe that gradually the segments develop lateral organs which are of very various kinds, according to the character of the animal. In many of the *Annelida* and *Myriopoda* legs are produced on a large number of the segments, whilst in the *Crustacea* and *Arachnida* we find these reduced in number to 8 or 10, and in the Insects to 6. Where the object is lightening the body there the segments are reduced in number and size, as in the insects and the crabs, in the Annelides as the earth-worm and lug-worm, we have instances of a great extension of the number of these segments. In fact, in the same manner as we can reduce the varied bones of the vertebrate endoskeleton to the type of the vertebra, so may we reduce the varied forms of the invertebrate articulate exoskeleton to the typical form of the segment. It results from this that the parts of their skeleton or external organs are symmetrical. The animals of this class are active; hence their skeletons are light and thin. The muscles or organs of motion are attached to the interior of the skeleton; but as this is hard and unyielding, it is necessary for it to undergo a process of exuviation, which occurs in all the articulate classes. This process of exuviation goes on through all stages of life in these animals. The material out of which the skeleton is formed in the majority of cases is the phosphate of lime, the same material as enters into the bones of the vertebrate classes. In the *Mollusca*, in which the skeleton is hard, solid, and unchangeable, the carbonate of lime is the material employed.

The muscular system is more fully developed amongst the *Articulata* than in either the Radiate or Molluscous tribes of the Invertebrate classes. This corresponds to their greater activity. Perhaps in proportion to their size there are no animals that exhibit so great an amount of muscular power as the *Articulata*. Throughout the animal kingdom we find that the muscular force corresponds with the amount of respiratory action and the development of animal heat, and in various forms of articulate animals this is remarkably exemplified.

The point in which there exists the greatest degree of accordance or resemblance among Articulated Animals is the nervous system. Their brain is extremely small, and two nervous cords, surrounding the œsohpagus or gullet, and continued along the abdomen, unite here and there into knots, or ganglia: in some *Crustacea* it is still more simple, consisting merely of two knots, one placed at the head, the other in the thorax, united by slender threads. The organs of sense are very imperfectly developed, and in some cases are altogether wanting, except the organ of sight. No organ of smell has yet been discovered, unless the antennæ of insects be considered such. The eye presents considerable diversity of structure, being sometimes and single, or three united in a triangle; but in the majority of cases it is composed of a considerable number of little plates, or facettes (as in the fly), each of which receives a branch from the optic nerve. Such eyes are called Compound Eyes, whilst the Single Eyes, which exist sometimes in conjunction with the compound eyes in the same individual, are called *Ocelli*. The eye as an organ of sense is first distinctly developed in the Articulate Animals, as many of the organs which have been indicated as eyes in the Radiate Animals have probably no relation to the function of vision. Some anatomists have described organs of hearing in the insects, whilst others regard the antennæ as destined for the performance of this function.

The digestive apparatus of the *Articulata* is for the most part in accordance with their carnivorous habits. Where animal flesh is eaten there digestion is a less complicated process than where vegetable food is principally partaken of. The mouth is generally provided with masticatory organs, which move laterally and are provided with palpi. Hard parts subservient also to the function of preparing the food for digestion, are also found in the intestinal cavity. The mucous membrane which covers the alimentary passages is of the simplest kind, whilst those glands which contribute to the digestive functions in the higher animals, as the salivary and pancreatic glands and the liver, are either not present or exist only in the most elementary form.

The elongated form of the *Articulata* impresses this character on their circulating as well as digestive apparatus. In most of the articulate tribes the blood moves forwards in one or more large, dorsal, pulsating, arterial vessels. Side branches from these arteries are given off, and terminate in various trunks which convey the blood backwards to the dorsal vessel. The blood is more highly organised, has a deeper colour, containing a larger quantity of corpuscles and fibrin than in either the Radiate or Molluscous classes.

The respiration is effected either by branchiæ, as in those which habitually live in water, such as the *Crustacea*, or by tracheæ, or air-tubes formed of three parts, one membrane internal and one membrane external, both of which are cellular; and a sort of cartilaginous elastic tube, rolled spirally, and placed between the two membranes. These tracheæ receive air by certain lateral openings termed *Stigmata*. More rarely there exist cellular cavities analogous to lungs. In all instances the respiratory organs are perfectly symmetrical.

The following are the families of animals which are referred to the Articulate Type :—

1. *Entozoa*, including various forms of animals that inhabit the organs of higher animals. [ENTOZOA.]

2. *Rotifera*, or Wheel Animalcules, minute creatures scarcely visible to the naked eye, very abundant in all waters, and formerly classed with the Infusoria. [ROTIFERA.]

3. *Annelida*, or Annulose Animals, including the Leeches, Worms, and Sea-Mice, mostly inhabiting water. [ANNELIDA.]

4. *Myriapoda*, of which the Galley-Worm (*Iulus*) and the Centipede may be taken as types, and which occupy an intermediate position between the highest and lowest forms of the class. [MYRIAPODA.]

5. *Insecta*, in which the locomotive power of the class is most fully developed, nearly all possessing wings for flight. [INSECTA.]

6. *Crustacea*, the insects of the ocean, which breathe by gills instead of tracheæ, and include the well-known forms of Lobsters, Crabs, and Shrimps. [CRUSTACEA.]

7. *Cirrhipedia*, the Barnacles and Sea-Acorns. They were formerly referred to the Mollusca, but their structure, habits, and economy place them amongst the Articulata. [CIRRHIPEDIA.]

8. *Arachnida*, including Spiders, Scorpions, and Mites. They are distinguished from insects by possessing eight legs. Their instincts and intelligence place them at the head of this class as well as their structure. [ARACHNIDA.]

(Grant, *Outlines of Comparative Anatomy;* Owen, *Lectures on Comparative Anatomy;* Jones, *Animal Kingdom; Cyclopædia of Anatomy and Physiology;* Carpenter, *Principles of Physiology*.)

ARTICULATION, the term by which anatomists express the union of the different bones of the skeleton. The junction of any two bones, however firmly or loosely connected, or in whatever mode the union may be effected, is designated by the name of Articulation. Commonly two substances are employed as the media by which the connection is established, namely, a firm and strong membranous tissue termed ligament [LIGAMENT], which may be considered as the band by which the bones are tied together, and a peculiar substance termed cartilage or gristle [CARTILAGE], which is often interposed between the surfaces of the bones to be united, and which besides serving as the bond of union, accomplishes other purposes.

Of all the parts of the animal fabric, there is none in which mechanism is more clearly or beautifully shown than in the connections of the bones with each other, and more especially in the structure of joints.

The objects to be obtained in the economy by the union of the several bones of the body are various and even opposite, requiring almost every conceivable variety in the mode of their connection. And such variety actually exists; but still these varieties admit of classification, and they may all be arranged under three heads, namely, those which form Immoveable, Moveable, and Mixed Articulations.

1. One object to be accomplished by the union of bones is, to form a secure situation for tender and delicate structures. Accordingly the bones are often so disposed as to inclose cavities in which the organs that need protection are placed; such, for example, is the cavity of the head which incloses the delicate substance of the brain; the cavity of the spinal column, which incloses the no less delicate substance called the spinal marrow; and the cavities of the chest and abdomen, which inclose soft and tender organs, on the security of which life depends. Bones forming cavities of this class are generally so firmly united that they admit either of no motion whatever, or only of a very slight degree of it, the union being effected sometimes by the apposition of the surfaces of strong and flat bones; at other times by the formation of numerous prominences and depressions which mutually receive each other: examples of both these modes of union are found in the articulation of the bones of the head and face. The firmness of the union is sometimes increased by alternate indentations and projections, like the teeth of a saw, formed on the surfaces of bones, the surface of the one bone being precisely adapted to that of the other; by this mechanism the bones become firmly impacted, and deficiency in extent of contact is compensated by what may be truly called (and it is an admirable example) dovetailing. *Suture* is the term given to this mode of union, and the bones of the cranium are nicely adjusted and firmly united to each other in this manner. At other times a ridge is formed in one bone which is received into a groove fissured in another. The bony part of the septum which divides the nostrils affords a specimen of this mode of union, while the teeth are secured in their sockets (that is, a conical surface is firmly impacted in a cavity) very much as a nail is fixed in a board.

2. The Moveable Articulations are those in which the bones are in contact, but not continuous with each other; such, for example, is the union of the arm with the shoulder, the fore arm with the arm, the wrist with the hand, the lower jaw with the head, the head with the trunk, and so on. In these cases the articulating surfaces are mutually adapted to each other, in general one being convex and the other concave, and the bones are maintained in their situation by the firm and strong membranes termed ligaments. Sometimes the union is assisted by the muscles which surround the joint, as is strikingly exemplified in the shoulder-joint, in which the head of the humerus is kept in contact with the cavity which receives it, partly without doubt by ligamentous substance, but partly also by the surrounding muscles. This is proved by the effect of disease; for if by paralysis, or any other cause, the neighbouring muscles become very much weakened, dislocation of the joint readily takes place. Both the strength of the joint and the range of its motion depend mainly on the extent of its articulating surface, and on the arrangement of the ligamentous substance by which the bones are held in their situations. The extent of contact, and the strength and adjustment of the uniting band, are different in every different joint, the diversity being regulated in every case by the kind and degree of motion which it is intended that the joint should exercise.

3. The Mixed form of Articulation resembles the Immoveable, in having the bones connected by an intermediate substance (cartilage), and the Moveable in admitting some degree of motion between the surfaces. The articulations between the several bones that form the spinal column afford examples of this mode of union. There are numerous modifications of these several kinds of articulation, which are described with great minuteness in anatomical books, and most of which are distinguished by specific names.

ARTI'SIA (Presl), a Fossil Plant from the Coal Formation. At present the opinion prevails that this is an internal portion of another plant, and not a palm-stem as once conjectured.

ARTOCARPA'CEÆ, *Artocarpads*, the Bread-Fruit Tribe, a natural order of plants nearly related to *Urticaceæ* (the Nettle Tribe), from which it is so difficult to separate them by any precise character that there are many who consider them nothing more than a section of *Urticaceæ*.

Whether a distinct order or a section only of *Urticaceæ*, the *Artocarpaceæ* are known by having flowers with a very imperfectly formed calyx, no corolla, leaves with conspicuous stipules, a rough foliage, and an acrid milky juice, which often contains Caoutchouc, or Indian Rubber, in abundance; the flowers are collected into round heads, and the ovules are suspended singly from the upper part of the solitary cavity of the ovarium. They are distinguished from the *Urticaceæ* by the position of their ovules, the manner in which their flowers are arranged, and by their yielding a milky juice; the juice of *Urticaceæ* being watery.

The species are all found in the warmer parts of the world, and many of them are natives of the tropics only. Their milk, which is always acrid, renders some of them intensely poisonous, as the Upas Tree of Java [ANTIARIS], and certain Indian species of Fig [FICUS]; nevertheless, if the milk is naturally absent from any particular part of an Artocarpad that part becomes eatable and even wholesome. Thus the fruit of the cultivated fig, up to a short period before its maturity, remains milky, and at that time it would prove exceedingly unwholesome; but when ripe the milk disappears, is replaced by sugar, and the fruit becomes, as we all know, extremely wholesome. The same explanation is probably applicable to the case of the Bread-

Fruit, which forms an article of food with the South Sea Islanders. [ARTOCARPUS.]

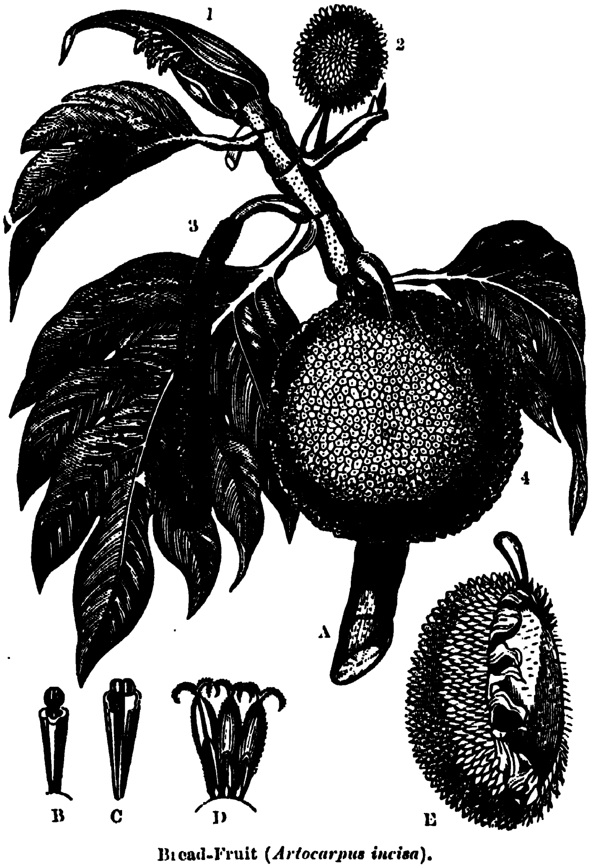
A species of *Antiaris* produces sacks, hence it is called Sack-Tree. The following is the process by which these sacks are obtained. " A branch is cut corresponding to the length and diameter of the sack wanted. It is soaked a little, and then beaten with clubs till the fibre separates from the wood. This done, the sack formed of the bark is turned inside out, and pulled down till the wood is sawed, with the exception of a small piece left to form the bottom of the sack." These sacks are in general use in the West Indies, and specimens may be seen in the Museum of the Gardens at Kew. The Water-Vine (*Phytocrene*) belongs to this order, the sap and porous wood of which when cut discharges a quantity of pure water, which is drunk by the natives of the province of Martaban, where it grows. The seeds of many of the species are eaten in the countries where they grow.

To those unacquainted with botany it may appear strange that the Nettle and the Fig are both arranged in the same order. If, however, we investigate the matter carefully, we shall find that in the structure of the stem, leaves, stipules, calyx, stamens, and fruit, these two plants are so like each other that it is impossible to discover more than one solitary essential character, namely that of the position of the young seeds, by which they can be distinguished; and that the differences which meet the unpractised eye are entirely connected with the size and manner in which the flowers are arranged.

ARTOCARPUS, the Bread-Fruit, is the genus which has given its name to the natural order *Artocarpaceæ*. It consists of trees having stems of very considerable size; large leaves, which are exceedingly rough with little points; stipules like those of the fig; and monœcious flowers, of which the stamen-bearing ones are disposed in long club-shaped spikes (*fig.* A 3), and the pistil-bearing ones in round heads (*fig.* A 2), which become the fruit, and often arrive at a very considerable size (*fig.* A 4).

A Bread-Fruit is a fig (FICUS) turned inside out, and much larger in all its parts; that is to say, the flowers which form the Bread-Fruit and Fig grow in both cases upon a fleshy receptacle; but in the former the receptacle is solid, and bears its flowers externally, while in the latter it is hollow, and bears its flowers internally.

The stamen-bearing flowers of *Artocarpus* (*figs.* B, C) consist of a tubular calyx containing a single stamen; the pistil-bearing flowers (*fig.* D) consist of two or three fleshy sepals grown closely together and meeting at the points, between which passes a long slender style with two stigmas, which are hairy and curved downwards. The ovary is simple, and contains but one ovule. At a very early period the flowers grow firmly together into a solid fleshy mass, which finally becomes the fruit. The seeds are large nut-like bodies, which lie beneath the rind of the fruit.



Bread-Fruit (*Artocarpus incisa*).

A, a shoot very much less than the natural size with stamen-bearing flowers 3; pistil-bearing flowers 2; fruit 4; and its stipules 1: B, a stamen-bearing flower; C, the same opened; D, three pistil-bearing flowers, sliced open at the bottom to show the ovaries; E, a portion of the fruit showing the nuts in the inside.

Many species are known, some of which, as *Artocarpus Chaplasha* and *hirsuta*, are large trees, and yield valuable timber in the forests of Bengal and Malabar. The species, however, best known are those which yield the Bread-Fruit and the Jack.

A. incisa (the Bread-Fruit) is a native of the South Sea Islands and of many parts of the Indian Archipelago; it inhabits only such places as are both hot and damp. Dr. Roxburgh complains that the winters of Bengal are much too cold for it. In the South Sea Islands it forms a moderate-sized tree, rarely exceeding 40 feet in height, with leaves deeply divided into sharp lobes, and sometimes as much as 3 feet long. The fruit is green and of considerable size, equalling a melon of the larger kind in dimensions, and is of many different forms: one variety produces it free from all spines on the surface or from seeds internally; this is the best sort: others are split into deep lobes, or covered all over with the sharp-pointed fleshy tops of the calyxes. The nuts, when roasted, are said to be as excellent as the best chestnuts; but it is principally for the fleshy receptacle that it is valued. When roasted it becomes soft, tender, and white, resembling the crumb of a loaf; but it must be eaten new, or it becomes hard and choky. Others compare the flavour to that of a roasted potato. What we have tasted has been in thin slices which had been thoroughly dried, and it was very like a piece of dried biscuit. In 'Anson's Voyages' it is said to be delicious when ripe, and when mixed with lime-juice or orange-juice to have a grateful tart flavour, not unlike apple-sauce.

It forms so important a part of the support of the South-Sea Islanders that it was introduced by the British Government into the West Indies, where it is still cultivated, and whence it has been carried to the continent of America. It was to obtain this plant that the unfortunate expedition of Captain Bligh was fitted out. It does not appear, however, equal to the plantain as an article of human food.

A. integrifolia, the Jack, is also a native of the islands of the Indian Archipelago, and is in its general appearance like the Bread-Fruit, but its leaves are totally destitute of all laceration, and its fruit, which is very prickly, weighs 60 or 70 lbs. This latter is yellow, and constitutes the principal part of the diet of the natives in some parts of India; but it is said to have an offensive odour, and to be little esteemed by Europeans: all, however, concur in attesting the excellence of the nuts when roasted.

Like all other Artocarpads this tree exudes a great quantity of a viscid milky juice, from which the best bird-lime of India is prepared. (*Botanical Magazine*, vol. ii.)

ARUM. [AROIDEÆ.]

ARUNDO, a genus of Grasses, possessing the following characters:— Spikelets, each containing from two to five flowerets, which are distant from each other, arranged in two ranks, hermaphrodite, the uppermost being withered; glumes two, sharp-pointed, channeled, and keeled, nearly equal, membranous, as long as the flowerets, and at some distance from each other; paleæ two, membranous; the lowermost slit at the end, with a very short beard between the sides of the slit, covered externally, especially at the lower end and rachis, with very long silky hairs. The species attain a considerable size, sometimes acquiring a woody stem, and are found in many climates.

Arundo Donax, a native of the south of Europe, the Caucasus, Egypt, and Siberia, is one of the largest grasses that we have in cultivation; it is not unusual to see it in rich soil 9 or 10 feet high, with leaves as broad and as long as the blade of a small sword. A beautifully variegated variety is usually seen in gardens.

Arundo arenaria, the Sea-Reed, or Marrum-Grass, a dwarf plant which pierces the sand-banks on the shores of the north of Europe with its tough subterranean stems, and which thus converts them into living barriers against the inroads of the ocean, differs a little from the exact character of Arundo, and is called by modern botanists *Ammophila arundinacea*. It is a very rigid plant, with bluish rolled-up leaves, and a stem 2 or 3 feet high, terminated by a dense tuft of flowers.

The Common Reed was formerly referred to the genus *Arundo*: it is now placed under *Phragmites*. [PHRAGMITES.]

A'SAPHUS (Brongniart), a very extensive genus of Fossil *Crustacea* (*Trilobites*), most abundant in the lower Palæozoic Strata. *Asaphus Buchii* marks the Cambrian or Lower Silurian, as *A. caudatus* is frequent in the Upper Silurian Beds.

ASA'RUM, a genus of plants belonging to the natural order *Aristolochiaceæ*, distinguished by having the calyx bell-shaped and 3-lobed; the stamens placed upon the ovarium, the anthers adnate to the middle of the filaments, the style short, stigma stellate, and 6-lobed; the fruit capsular and 6-celled. The *A. Europæum* is known by having two obtuse kidney-shaped leaves on each stem. It is a perennial plant, found in woods in different parts of Britain. The root, which is employed under the name of Asarabacca, contains a camphor-like principle, and a bitter principle called Asarin, which is combined with gallic acid. To these it is indebted for its action on the human system. Taken into the stomach in a state of very fine powder, it causes vomiting; in coarser powder, it generally purges. It was formerly employed as an emetic instead of ipecacuanha; but, from the violence of its effects, it is now properly laid aside in medical practice: it is still however used in veterinary medicine, to vomit and purge. The fine powder applied to the nostrils causes sneezing, and a flow of mucus from the membrane which lines those parts. It is therefore extensively employed as an errhine, and is the basis or chief ingredient of many cephalic snuffs. It is used in chronic inflammations and some other diseases of the eye, and in headaches. Where these last arise from disorders of the digestive function, such means can be of no avail: where they are connected with congestion or fullness of the vessels of the head, the increased discharge from the Schneiderian membrane may give temporary relief in the same way as a few drops of blood flowing spontaneously from the nose, or obtained by puncturing the membrane. When taken into the stomach in considerable quantity, it acts as a poison.

ASBESTUS must be considered, in Mineralogy, rather as a term implying a peculiar form sometimes assumed by several minerals, than as a name denoting a particular species; it is in fact applied to varieties of the Amphibolic Minerals, such as *Actinolite*, *Tremolite*, &c., which occur in long capillary crystals, placed side by side in parallel position, and thus giving rise to a fibrous mass. As might be expected, the above conditions are fulfilled in various degrees, and there are accordingly various kinds of Asbestus. Those varieties, the fibres of which are very delicate and regularly arranged, are called *Amianthus*, a Greek term signifying unpolluted, unstained. The individual crystals are here readily separated from each other, are very flexible and elastic, and have a white or greenish colour with a fine silky lustre. Though a single fibre is readily fused into a white enamel, in mass it is capable of resisting the ordinary flame, so that when woven it produces a fire-proof cloth, and hence the name from the Greek *ἄσβεστος*, in the sense of indestructible. The most beautiful specimens have been found in the Tarentaise in Savoy; but Corsica must be considered as its principal locality, from its great abundance. It is also found in Cornwall, at St. Neverne; likewise in several parts of Scotland. It occurs also in the United States of America, where it is sometimes used as a wick for an oil-lamp.

Those varieties in which the crystals are coarser, with scarcely any flexibility, are called Common Asbestus. It is generally of a dull green, and sometimes a pearly lustre, and readily fuses before the blow-pipe flame. It occurs more frequently than amianthus, and is usually found in veins traversing serpentine.

There are three other varieties, known by the names of Mountain Feather, Mountain Wood, and Mountain Cork, which differ from the Common Asbestus by the fibres interlacing each other. The two first have received their names from their appearance; the third from its extreme lightness, and from its swimming in water. They have been found in Scotland.

ASCARIDES. [ENTOZOA.]

ASCI'DIA, a genus of Molluscous Animals belonging to Cuvier's order of *Acephalæ* without Shells. Savigny has considered these animals sufficiently important to constitute a class under the name of *Ascedies* (*Ascidia*); while Lamarck has also formed them with others into a class under the name of *Tuniciers* (*Tunicata*). [TUNICATA.]

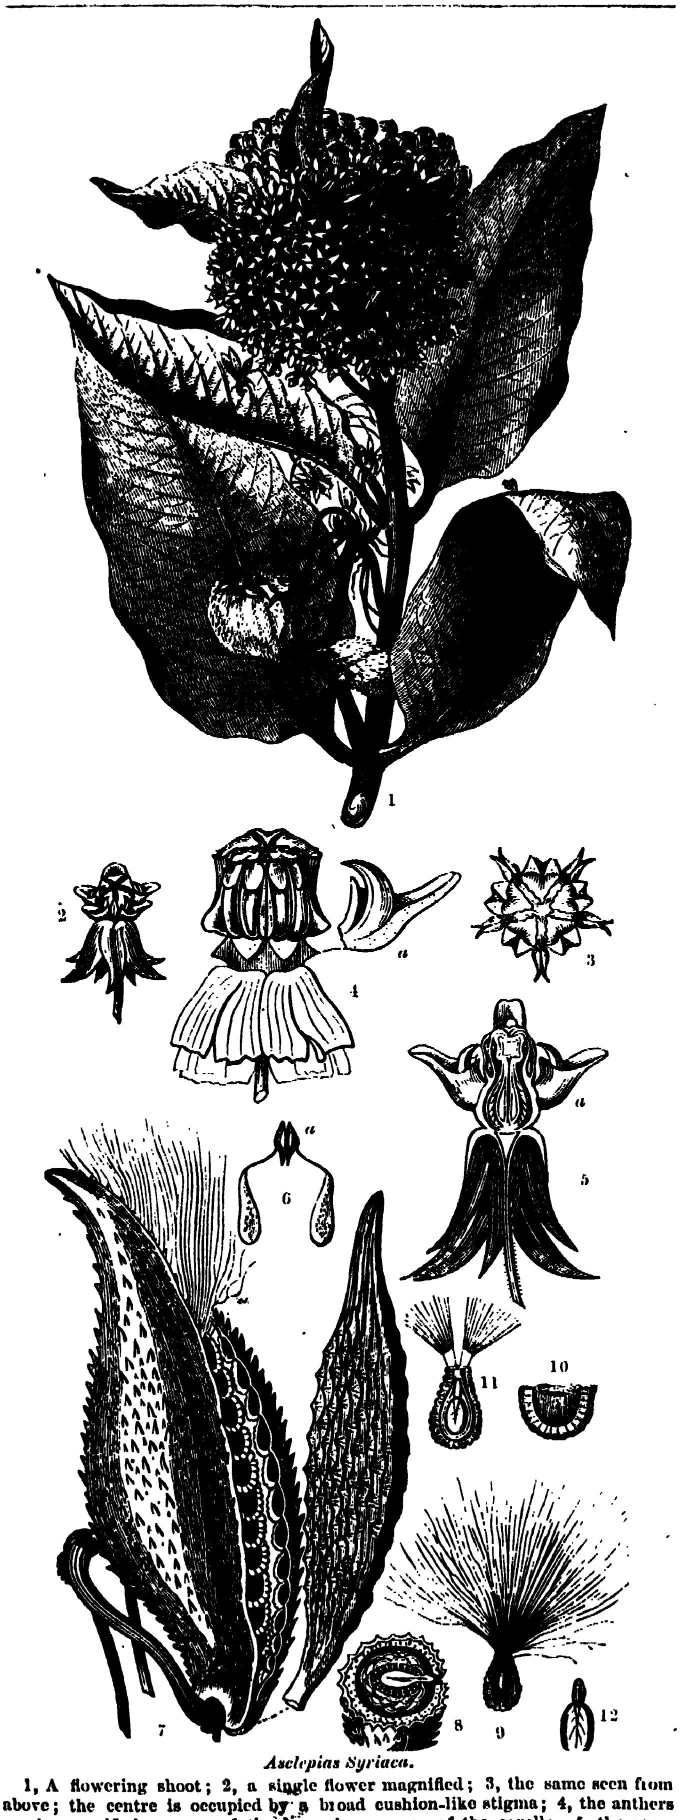
ASCLEPIADA'CEÆ, *Asclepiads*, a natural order of Exogenous Plants, known from all others by the single character of its grains of pollen adhering together within a sort of bag which occupies the whole of the inside of each cell of the anther; and when it falls out sticks to glands of a peculiar character occupying the angles of the stigma. Independently of this circumstance the anther and stigma adhere firmly together, and the fruit is a very curious body, consisting of two carpels, which, when young, are parallel to each other, and united at the point; but when ripe are both on the same plane, pointing in different directions, and shedding a large quantity of seed, the ends of which terminate in long down.

The most important and typical genus of this order is *Asclepias*. It consists of shrubs or herbaceous plants, abounding in an acrid and usually milky juice, and found in their greatest abundance in tropical countries, but rarely in cold latitudes. At the Cape of Good Hope they form a singular stunted deformed vegetation, in the form of the leafless succulent stapelias, the flowers of which are among the most fetid productions of the vegetable kingdom. A great many species of *Asclepias* inhabit North America, and for their beauty are frequently cultivated in Europe, especially the orange-coloured *Asclepias tuberosa*. Their roots are acrid and stimulating, and usually emetic. Their flowers have curious horned processes added to the corolla. [ASCLEPIAS.]

The roots of the whole order appear to be acrid and stimulating, and some of them, as *Tylophora asthmatica* and *Secamone emetica* are employed as emetics. The Cow-Plant of Ceylon, or Kiriaghuna Plant (*Gymnema lactiferum*), yields a milk which the Cingalese make use of as food. Species of *Cynanchum* act as purgatives. The leaves of *Solenostemma Argel* are used in Egypt for adulterating senna. Several species yield caoutchouc, whilst others afford indigo.

(Lindley, *Vegetable Kingdom*.)

ASCLE'PIAS, a genus of plants, the type of the natural order *Asclepiadaceæ*. Many of the species possess powerful medicinal qualities, and hence the name of the genus from Æsculapius (Asclepias), the god of medicine. The genus is characterised by possessing a reflexed 5-parted corolla; a 5-leaved corona seated on the



Asclepias Syriaca.

1, A flowering shoot; 2, a single flower magnified; 3, the same seen from above; the centre is occupied by a broad cushion-like stigma; 4, the anthers much magnified, *a*, one of the horned processes of the corolla; 5, the same cut vertically, and less magnified, *a*, one of the horned processes; 6, pollen masses, *a*, the gland; 7, one half of a ripe fruit; 8, a transverse view of its inside near the point, showing how the seeds are arranged; 9, seed; 10, the same cut across; 11, the same cut vertically, showing the embryo; 12, the embryo separate.

upper part of the tube of the filaments; the leaflets cucullate, having a horn-formed process protruding from the bottom; the anthers terminated by a membrane; pollen masses compressed, fixed by the tapering tops, pendulous; the stigma depressed; the follicles smooth; the seeds coarse. Most of the species are North American herbs, with opposite, alternate, or verticillate leaves.

A. Syriaca, Syrian Swallow-Wort, has simple stems with lanceolate oblong or oval leaves, gradually acute, and tomentose beneath; drooping umbels. Lamarck states that the native country of this plant is Syria and Egypt. The nectaries or leaflets of the corona, like some other species of *Asclepias*, act as fly-traps. The sap of this plant is white, and contains a considerable quantity of caoutchouc. It has been recommended as an expectorant. The seeds are covered with down, which it was at one time proposed to spin into textures for wearing apparel; it is, however, more adapted for stuffing mattresses and pillows.

A. Curassavica, Bastard Ipecacuanha, has a simple stem, with oblong-lanceolate glabrous leaves tapering at both ends; umbels erect, solitary, lateral. It is a native of Curaçoa, Essequibo, Cumana, and Trinidad. Its roots are frequently sent to England as ipecacuanha. The juice in the West Indies is reputed to be anthelmintic and styptic. The root dried and powdered acts as an emetic, but not so efficaciously as the root of the true Ipecacuanha (*Chepaelis Ipecacuanha*). The roots of *A. prolifera* are also emetic.

A. tuberosa, Tuberous Swallow-Wort, has suberect stems, very hairy, and branched at top; scattered oblong-lanceolate hairy leaves; umbels disposed in a terminal sub-corymb. It is a native of North America, in stony places and sandy fields. The roots are famed for diaphoretic properties, and in Virginia it is used for this purpose in inflammatory diseases, more particularly in pleuritis and dysentery. The *A. decumbens* of some authors is probably only a variety of this species, and has the same properties.

Many other species of this genus are used as medicines in the countries where they grow. The buds of *A. stipitacea* are eaten by the shepherds of Arabia after the manner of asparagus in this country. The whole plant of *A. aphylla* may be eaten. *A. gigantea*, an East Indian species, is very poisonous. It kills cattle which eat it, but it is used in Hindoo medicine in typhus fever. The milky sap of *A. lactifera* is quite innocuous, and is drunk in India as a wholesome food; whilst, on the other hand, the milk of *A. laniflora* and *A. procera* is acrid and irritating. The juice of *A. laniflora* is used with butter and lard as an ointment for itch, and that of *A. procera* is applied to hides for removing the hair before tanning. The *A. asthmatica* and *A. vincetoxicum* have both active properties, and are now included under the genus *Cynanchum*. [CYNANCHUM.]

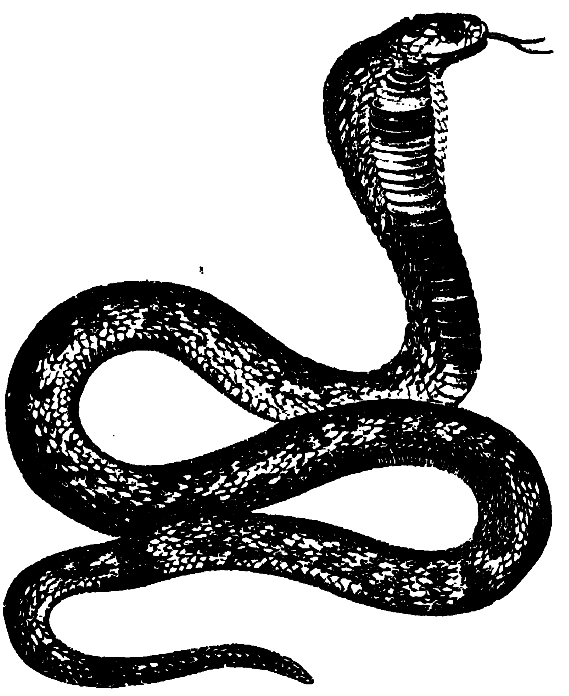
Many of the species of *Asclepias* are handsome border-flowers, and worthy of cultivation. They thrive well in peat-earth, or a light rich soil of any kind. They may be propagated by dividing the root in the spring, or by sowing the seed. Many of the species will require protection at the roots during severe winters. The tropical and subtropical species require the ordinary treatment of other stove and greenhouse plants.

ASE'LLUS, a genus of Malacopterygious Fishes, to which Willughby referred the Whiting-Pout, and Ling. They are now referred respectively to the genera *Morrhua* and *Lota*.

ASH. [FRAXINUS.]

ASP, a name commonly given to several species of venomous serpents. By naturalists the term is confined to the *Vipera aspis*, which is an inhabitant of the European Alps. The asp which is historically interesting from having been employed by Cleopatra as the instrument of her own destruction, is supposed to be the *Cerastes Hasselquistii*. The Asp (ἀσπίς) is often mentioned both by Greek and Roman writers. From various circumstances, however, and particularly from the description of Pliny ('Nat. Hist.' viii. 35.), it is evident that the most common and celebrated is the species to which the modern Arabs give the name of El Haje, or Haje Nascher. This animal measures from 3 to 5 feet in length: it is of a dark green colour, marked obliquely with bands of brown; the scales of the neck, back, and upper surface of the tail are slightly carinated, and the tail is about one-fourth part the length of the whole body. The Haje is closely allied to the Cobra Capello, or Spectacled Snake of India, the chief apparent difference being its want of the singular yellow mark on the back of the neck, from which the latter species derives its name. In other respects these two serpents are nearly of the same size; they are equally venomous, and both have the power of swelling out the neck when irritated, and raising themselves upright upon their tails to dart by a single bound upon their enemies.

The poison of the Asp is of the most deadly nature. Pliny, in the passage above referred to, gives the following account of this celebrated serpent:—"The neck of the asp is capable of distension, and the only remedy against its bite is the immediate amputation of the wounded part. This animal, otherwise so much to be dreaded, has a sentiment, or rather a kind of affection, truly wonderful. It never lives alone, the male and female being constantly found together, and if one happens to be killed, the other seeks with the utmost fury to avenge its death. It knows and selects the destroyer from among crowds; it follows him to great distances, surmounts every obstacle, and can only be deprived of its revenge by the most speedy flight, or the intervention of some rapid river. It is difficult to say whether nature has been more prodigal of evils or remedies. For instance, she has bestowed upon this reptile, so terrible from the deadly effects of its poison, so indifferent a vision, its eyes being placed on the sides of the head so as to prevent it from seeing straight before it, that it is frequently trodden under foot before it is aware of its danger." Forskål, a Swedish naturalist, who has written on the animals of Egypt, informs us that the jugglers of Grand Cairo have the art of taming the Haje, as those of India do the cobra capello, and teaching it to dance for the amusement of the populace; taking care, however, to deprive it of its poison fangs, though even then they avoid its bite when irritated. The habit which this serpent has of erecting itself when approached, made the ancient Egyptians imagine that it guarded the places which it inhabited. They made it the emblem of the divinity whom they supposed to protect the world; and accordingly they have represented it on their temples sculptured on each side of a globe.



ASPA'RAGUS, a genus of plants belonging to the natural order *Liliaceæ*. It is comprised by some botanists under the order *Asphodeleæ*. The species eaten under the name of Asparagus is the *A. officinalis*. [ASPARAGUS, in ARTS AND SC. DIV.) There are a great number of species, natives of Asia and Africa, which are cultivated in our gardens rather as matter of botanical interest than on account of their beauty or utility. The roots of *A. racemosa* and *A. adscendens* are employed medicinally in the North of India.

ASPEN. [POPULUS.]

ASPERGI'LLUM, a genus of *Tubicolous Mollusca*, furnished with a bivalve shell incrusted as it were in a tubular testaceous sheath. This tubular sheath gradually lessens in diameter to the aperture which is farthest from the incorporated bivalve. The end nearest to the bivalve is dilated into a concave disk, with a central fissure, and perforated with minute but raised holes. The disk is bordered by a tubular frill. There are but few species, and of these *Aspergillum Javanum*, known to collectors as the Watering-Pot, is the most common.

ASPE'RULA, a genus of plants belonging to the natural order *Rubiaceæ* or *Galiaceæ*. The genus is known by its funnel-shaped corolla, and by the fruit being dry and not crowned with the limb of the calyx.

A. odorata, the Woodruff, has its leaves six or eight in a whorl, with perfectly white flowers. It occurs in woods, and is found throughout Europe. It is abundant in some parts of England. The whole plant is remarkable for its fragrance when dried.

A. Cynanchica has its leaves four in a whorl, and flowers of a lilac colour. It is found on dry banks and hills in limestone districts. It is common in Great Britain, where it is called Quinsy-Wort on account of its supposed value as a remedy in sore throat. It is slightly astringent. Two other species, *A. arvensis* and *A. taurina*, are doubtful natives, but found wild now in England.

(Babington's *Manual of British Botany*.)

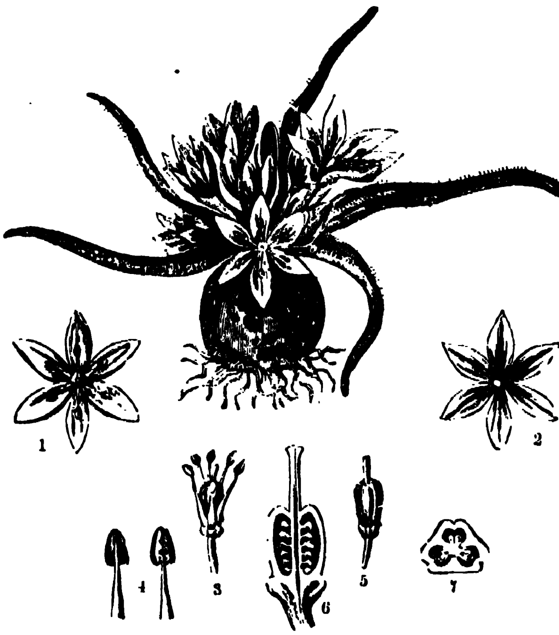
ASPHA'LTUM (a Greek word, ἄσφαλτος, of unknown etymology), frequently known by the name of Slaggy or Compact Mineral Pitch, is one of the varieties of Bitumen arising from the decomposition of vegetable matter. It occurs massive, of a dark brown or black colour, with a conchoidal fracture and a resinous lustre. It is opaque, and exceedingly brittle at a low temperature, but softens and fuses by the application of heat; in density it varies from that of water to 1·6. It may be recognised by the following characters: It is insoluble in alcohol, but soluble in about five times its weight of naphtha, with which it forms a good and useful varnish; its combustion is rapid and brilliant, with the production of the bituminous odour.

It is found in most countries, but most abundantly on the shores or floating on the surface of the Dead Sea; at Hit, above Babylon, on the Euphrates; near the Tigris: in Trinidad in the West Indies it fills a basin of three miles in circumference, and of unknown depth. There is a pitch-spring in Zante which is known to have been at work for above 2000 years. (Herod. iv. 195). It is also found in limestone at Bleiberg in Carinthia; in beds of sandstone in Albania, and in veins in the Harz in Germany; in Derbyshire, Shropshire, and several other places. It is the principal colouring matter of the dark indurated marl, or shale, which is found in coal districts.

ASPHODE'LEÆ, or the Asphodel Tribe, are Monocotyledonous Plants, which, although they form a very natural assemblage alone, are now placed by Lindley as a subdivision of the order *Liliaceæ.* They are for the most part easily recognised, although in certain species and genera they approach other orders so closely as to be distinguished only with great difficulty. They all have regular flowers with 3 sepals, and 3 petals of nearly equal size and colour, 6 (very seldom 3) stamens, and a superior 3-celled ovary, with only 1 style. Their fruit is either dry or succulent, and their seeds have a brittle coat.

Asphodeleæ are known from *Junceæ*, or the Rush Tribe, by their larger and more coloured flowers, and by the hardness of the coat of their seeds; from *Liliaceæ*, or the Lily Tribe, by the smallness of their flowers, and the hard coat of the seeds; and from *Melanthaceæ*, or the Colchicum Tribe, by their single style, and by their anthers being turned towards the ovary. They may be formed into two subdivisions.

The first, or the *Alliaceous* subdivision, in which there is no true stem, and which consists entirely of bulbous species, the roots being emitted and perishing annually. To this belong the Onion, Garlic, and their allies, together with the Hyacinth, Squill, and Star of Bethlehem (*Ornithogalum*). A great quantity of species are favourites with the horticulturists on account of their early appearance in the spring and their easy cultivation.



Star of Bethlehem (*Ornithogalum fimbriatum*).

1, A flower seen from within; 2, the same viewed from without; 3, the stamens and ovary; 4, two stamens apart; 5, an ovary; 6, the same cut perpendicularly; 7, the same cut horizontally.

The second subdivision, consisting of the true Asphodels [ASPHODELUS] and those which resemble them, have no bulbs, but in their stead clusters of fleshy roots such as we find in the Asparagus, which belongs to this subdivision; the stems of these are frequently woody, but in that case they are branched: *Dracæna*, or the Gum-Dragon Tree, is a most remarkable instance of this, it having almost the appearance of a Dicotyledon when deprived of foliage. This subdivision also contains Aloes, with their thick fleshy leaves and forked stems. [ALOE.]

ASPHO'DELUS, a genus of plants the type of the natural order *Asphodeleæ.* It comprehends some handsome hardy perennial plants, with fleshy finger-like roots, and upright undivided annual stems covered with long leaves; they are among the most highly developed of the Monocotyledonous plants of northern countries. The most remarkable species are the following:—

A. luteus, the common Yellow Asphodel, is a beautiful perennial, very often seen in cottage-gardens or on the outskirts of shrubberies. It grows wild in Barbary, Sicily, Dalmatia, the Peloponnesus, and even spreads into the Crimea. Its stems are from 2 to 3 feet high, never branched, and covered all over with long narrow bluish-green leaves, which have very broad sheathing bases. The flowers are handsome, deep yellow, with a green streak on the outside of each petal. The fruit consists of red pulpy berries.

Very nearly related to this are *A. capillaris*, which differs chiefly in its very narrow leaves, shorter bracts, and extremely narrow divisions of the flower; and *A. Sibiricus*, figured in the 'Botanical Register,' plate 1507, which is principally known by its dwarfer stature, earlier and paler flowers, more glaucous leaves, and shorter bracts.

A. albus, or the White Asphodel, found all over the southern provinces of Europe and the basin of the Mediterranean Sea, is as frequently seen as the first, and in similar situations. Its flowers are white with a reddish streak on the outside of each petal, and are disposed in branched clusters. *A. ramosus* of many gardens seems merely a branched state of this species, and several other reputed species with white flowers are also in all probability not distinct.

ASPIDIA'RIA (Presl). Several species of the *Lepidodendra* of Sternberg are thus named. They are from the Coal Formation.

ASPI'DIUM, a genus of Ferns, and one under which many species were arranged by older botanists, which are now placed under new genera. [POLYPODIACEÆ.] One of the most remarkable species of this genus is the *Aspidium Baromez*, or Tartarian Lamb, which has been referred by Mr. Smith to the genus *Cibotium.* This plant, from its peculiar colour and form, was at one time really supposed to be a kind of vegetable animal, as the following account from Struys, an old traveller, proves:—"On the western side of the Volga," he says, "there is an elevated salt plain of vast extent, but wholly uncultivated and uninhabited. On this plain, which furnishes all the neighbouring countries with salt, grows the Boranez or Bornitsch. This wonderful plant has the shape and appearance of a lamb, with feet, head, and tail distinctly formed. Boranez, in the language of Muscovy, signifies a little lamb, and a similar name is given to this plant. Its skin is covered with very white down as soft as silk. The Tartars and Muscovites esteem it highly, and preserve it with great care in their houses, where I have seen many such lambs. The sailor who gave me one of these precious plants found it in a wood, and I had its skin made into an under-waistcoat. I learned at Astracan, from those who were best acquainted with the subject, that the lamb grows upon a stalk about three feet high; that the part by which it is sustained is a kind of navel, and that it turns itself round, and bends down to the herbage which serves for its food. They also said it dries up and pines away when the grass fails." Struys adds many other wonderful things about this plant. His statement is however substantially correct. The rhizoma of the *A. Baromez* presents a rude resemblance to an animal. It is covered with a silky down, and when cut into has a soft inside with a reddish flesh-coloured appearance, sufficient to account for the origin of the fables with regard to its animal nature. Is is not improbable that this fern dries up when the grass does, but of course the one has no dependence on the other. The Baromez possesses the astringent property which is common to all ferns; hence it has been used as a styptic.

Aspidium Filix-Mas (now *Lastræa Filix-Mas*), the Male Fern, is a native of Great Britain, and is admitted into the British Pharmacopœias on account of its anthelmintic properties. It has bipinnate fronds, obtuse and serrated pinnules, the sori near the central nerve, the lateral nerves forked. It is abundant throughout Europe, and grows in stony places on the skirts of woods, in open plantations and roadsides. The part used in medicine is the root, or rather the rootstock. This part of the plant is collected for medicinal purposes between the end of May and the middle of September. It will not keep well, and should be renewed at least every two years. It has often been chemically analysed, and is found to contain—

Lignin	45
Starch	10
Uncrystallisable Sugar	10
Gum	10
Fixed Oil	7
Resin	4
Salts, Volatile Oil	14
	100

The ancients used this plant as a vermifuge, but it was nearly given up by modern practitioners of medicine when Peschier pointed out the conditions in which he had found it efficacious in expelling tapeworm. The best mode of administering it is as an etherial tincture; the ether seems to dissolve the resinous oil on which the active properties of the plant depend. The dose of the root according to Peschier is about one drachm.

A. dilatatum (*Lastræa dilatata*), a British fern, is often confounded with the last for medicinal purposes. It has sub-tripinnate fronds; oblong, blunt, inciso-pinnatifid lobes; spinose, mucronate segments; a deciduous unfringed indusium. This is a common fern, but less generally diffused than the last.

A. Filix-Fœmina (*Athyrium Filix-Fœmina*), Lady-Fern, has a lanceolate pinnate frond; pinnæ linear, acute, regularly pinnate; pinnules linear-oblong, quite distinct, deeply serrate or pinnatifid; segments with 2 or 3 teeth. This is one of the most beautiful of the British ferns. The root is sometimes gathered for that of the Male Fern. It has "a short perpendicular root-stock, black externally, with black root-fibres; and the tufts or bases of the leaf-stalks, which compose the greater part of it, form a very acute angle with its axis, while those of the Male Shield-Fern extend outwards at a more open angle." (Christison.)

(Burnett, *Outlines of Botany;* Babington, *Manual of British Botany;* Christison, *Dispensatory.*)

ASPIDOPHO'RUS, a genus of Acanthopterygious Fishes. One species, the *A. Europæus* is found on the coasts of England and Scotland. It is known by the names of the Armed Bullhead, the Pogge, the Lyrie, Sea-Poacher, Pluck, and Noble. It is a small fish seldom exceeding 6 inches in length. (Yarrell, *British Fishes.*)

ASPIDORHY'NCHUS, a genus of Fossil Ganoid Fishes, from the Lias and Oolite of England. (Agassiz.)

ASPIDU'RA. A fossil species of Ophiuroid Echinoderms is thus named by Agassiz. From the Lias of Yorkshire.

ASPLE'NIUM, a genus of plants belonging to the natural order of Ferns. [POLYPODIACEÆ.] It has elongated straight sori, with an indusium opening towards the central nerve or midrib. The species of this genus are known by the name of Spleenworts. Several of them are common in Great Britain.

A. lanceolatum, of Hudson, has lanceolate doubly pinnate fronds; the pinnules ovate and deeply and sharply toothed, or lobed; the sori short, nearly marginal. It is a native of England and Wales, on rocks and walls, but its distribution is very local. It is also a native of France, but its European habitats are few.

A. Adiantum-nigrum, Black Spleenwort, has triangular attenuated fronds, twice or thrice pinnate, the pinnæ and pinnules triangular, sharply toothed; sori elongated, central. This plant is a native of Europe, and is abundantly distributed throughout the United Kingdom, where it occurs on rocks, walls, ruins, and hedge-rows. This is one of the ferns formerly much used in medicine, and is stated by Ray to be efficacious in cough, asthma, pleuritis, jaundice, stone, gravel, and other diseases. It has not however any reputation amongst modern practitioners of medicine.

A. Ruta-muraria, Wall-Rue, has bipinnate fronds, the pinnules rhomboid wedge-shaped, notched or toothed at the end; the indusium jagged. This fern is very common on rocks and old walls in Great Britain and throughout Europe, and is also a native of North America. It was at one time used as a remedy in coughs and asthmas, obstructions of the liver, and in cutaneous diseases; but has now fallen into disuse.

A. Trichomanes, Common Spleenwort, has pinnate linear fronds; roundish ovate, crenate, stalked pinnæ; the nerves forked below the sori. It is very common throughout Great Britain on rocks, walls, churches, ruins, bridges, and hedgerows. It is a native also of Europe, Africa, and the United States. This fern has been also used in medicine, and for the same diseases as the previous species, but it has fallen now entirely into disuse.

The other British species of *Asplenium* are *A. alternifolium, A. septentrionale, A. marinum, A. viride.*

These and other ferns may be easily cultivated by placing them in situations resembling their natural habitats. They require a pure atmosphere, plenty of space, and natural shade, with a due supply of water. They may be planted on decayed wood, in holes of rocks and brick, with almost any soil. One of the most elegant modes of cultivating them is by means of inverted jars, under which they will thrive in any sandy or light soil.

(Babington, *Manual;* Newman, *History of British Ferns;* Ward, *Growth of Plants in Glazed Cases.*)

ASPRE'DO, a genus of Abdominal Malacopterygious Fishes, characterised by the horizontal flatness of the head, and the enlargement of the anterior part of the trunk, arising from an unusual development of the bones of the shoulder. They are further distinguished from the *Silures* of Linnæus (from which extensive genus, indeed, they were originally separated by that great naturalist himself) by the proportional length of the tail; by having the eyes placed in the upper surface of the head, and the intermaxillary bones concealed beneath the ethmoid, directed backwards, and furnished with teeth only along their posterior margin; and finally, they are remarkable as being the only known fish, not being cartilaginous, which have not moveable opercula, the bones of which these organs are composed being soldered on either side to the tympanum and pre-operculum. The opening of the gills is consequently formed by a single slit in the skin immediately behind the posterior side of the head; and their membrane is composed of six branchiostegous rays. The lower jaw is transverse, and the upper projects considerably beyond it, and forms a small attenuated muzzle. There is but a single dorsal fin, which is of small extent, and situated on the fore-part of the body: the anal fin on the contrary is very large, and occupies the entire length of the tail. This genus contains but very few species, the principal of which, the *Silurus Aspredo* of Linnæus, inhabits the rivers and lakes of North America.

ASS, a well-known and useful domestic animal, whose good qualities are too frequently undervalued, from being contrasted with those of the horse, without considering the different nature of the treatment which these two quadrupeds receive—the care and attention bestowed upon developing the form and cultivating the spirit of the one, and the neglect and ill usage to which the other is so generally subjected. Buffon has well observed that the ass is despised and neglected only because we possess a more noble and powerful animal in the horse; and that if the horse were unkown, the care and attention which is lavished upon him, being transferred to his now neglected and despised rival, would have increased the size and developed the mental qualities of the ass to an extent which it would be difficult to anticipate, but which eastern travellers who have observed both animals in their native climates, and among nations by whom they are equally valued and the good qualities of each justly appreciated, assure us to be the fact. Indeed, the character and habits of these two quadrupeds are directly opposed in almost every respect. The horse is proud, fiery, and impetuous, nice in his tastes, and delicate in constitution; like a pampered menial he is subject to many diseases, and acquires artificial wants and habits which are unknown in a state of nature. The ass on the contrary is humble, patient, and contented with scanty and coarse fare which other cattle reject; he bears with patience and fortitude the most cruel and oppressive treatment; yet he is more susceptible of strong attachment than the horse, has apparently more prudence and reflection, and is capable of a degree of education which would not be anticipated from the forlorn and dejected appearance which coarse food and harsh treatment have rendered habitual to him. In Persia, Arabia, and other eastern countries however the ass is a very different animal from what he is in Western Europe. There, instead of being neglected and despised, half-starved, and treated with cruelty, care is taken to cultivate the breed by crossing the finest specimens; even the Wild Ass is procured for this purpose, the pedigrees of the different races are carefully recorded, and the size, strength, and symmetry of the ass so much improved that he is rendered equal to the horse for most purposes, and in some cases even his superior. "The asses of Arabia," says Chardin, "are perhaps the handsomest animals in the world; their coat is smooth and clean; they carry the head elevated, and have fine and well-formed legs, which they throw out gracefully in walking or galloping. They are used only for the saddle, and are imported in vast numbers into Persia, where they are frequently sold for 400 livres; and being taught a kind of easy ambling pace, are richly caparisoned, and used only by the rich and luxurious nobles."

The ass is properly speaking a mountain animal; his hoofs are long, and furnished with extremely sharp rims, leaving a hollow in the centre, by which means he is enabled to tread with more security on the slippery and precipitous sides of hills and craggy places. The hoof of the horse on the contrary is round and nearly flat

Wild Ass.

underneath, and we accordingly find that he is most serviceable in level countries; and indeed experience has long since taught us that he is altogether unfitted for crossing rocky and steep mountains. As however the more diminutive size of the ass rendered him comparatively less important as a beast of burden, the ingenuity of mankind early devised a means of remedying this defect, by crossing the horse and ass, and thus procuring an intermediate animal, uniting the size and strength of the one with the patience, intelligence, and surefootedness of the other.

The Wild Ass, called Koulan by the Persians, is still common in many parts of Central Asia. It stands much higher on its limbs than the common ass, its legs are longer and more slender, and it is altogether a more graceful and symmetrical animal. The mane is composed of short erect hair of a dusky colour and rather a woolly texture; the colour of the body is a uniform silvery gray, with a broad coffee-coloured stripe extending down the back from the mane to the tail, and crossed on the shoulder by a transverse band, as in the domestic variety. The Koulan inhabits the parts of Central Asia from 48° N. lat. to the northern confines of India. They migrate from north to south according to the season. In summer they are commonly found about Lake Aral, but in autumn they collect in vast troops under the conduct of a regular leader, and proceed towards the south, arriving at Cutch and Guzerat in October or November, and returning northward again in the middle of spring. The Persians and Tartars hold the flesh of the Koulan in high esteem, and hunt it in preference to all other descriptions of game. Olearius assures us that he saw no fewer than thirty-two wild asses slain in one day by the Shah of Persia and his court, the bodies of which were sent to the royal kitchens at Ispahan; and we know from Martial that the epicures of Rome held the flesh of the Onager, or Wild Ass, in the same estimation as we do venison ('Epig.' xiii. 97).

From a passage in Pliny (lib. viii. c. 44) it would appear that the Onager inhabited Africa, and that the most delicate and best flavoured lalisiones, or fat foals, were brought from that continent to the Roman markets. Leo Africanus repeats the same story of wild asses being found in Africa, but no traveller has since met with them, and, so far as we at present know, the species is confined to Asia. It has even retired from Syria and Asia Minor, where it was formerly found. [EQUIDÆ.]

ASSAPANS, the name of a species of Flying Squirrels. [SCIURIDÆ.]

ASTACOLITES, in Zoology, one of the names given by ancient geologists to the fossil remains of the Long-Tailed or Lobster-like Crustaceans.

A'STACUS (Leach, Desmarest), a genus of Long-Tailed Crustaceous Animals, including the common Lobster. It was formed by Gronovius from the genus *Cancer* of Linnaeus and of ancient authors, which also comprised the Short-Tailed Crustaceous Decapods, with the exception of *Hippa*. Fabricius broke it down into the genera *Pagurus*, *Galathea*, and *Scyllarus*; leaving *Astacus* to represent a certain number of Crustaceans, from which he afterwards, having the advantage of Daldorff's labours, separated the genera *Palinurus*, *Palæmon*, *Alpheus*, *Peneus*, and *Crangon*. Our countryman Leach, in adopting the genus as left in its last shape by Fabricius, separates from it the genus *Nephrops*, of which there is only one species recorded, the Norway Lobster (*Nephrops Norvegicus*). Desmarest adopts the views of Leach, and the genus *Astacus* is now reduced to very few species.

Of these species the most interesting, from their commercial value as food, are the common Lobster (*Astacus marinus*) and the Craw-Fish (*Astacus fluviatilis*.)

The Lobster is found in the greatest abundance on the rocky coasts of this kingdom, in clear water of no very great depth, at the time of depositing its eggs, about the middle of summer. Pennant mentions the great quantities supplied to the London markets, in his time, from the Orkneys and the eastern coasts of Scotland; and states the number annually brought in well-boats from the neighbourhood of Montrose alone at 60,000 or 70,000. But almost incredible as the consumption of this species is, nature has provided for its security by the most profuse fecundity. Doctor Baster says that he counted 12,444 eggs under the tail of one female lobster, besides those that remained in the body unprotruded.

Lobsters are very voracious, and the fishery for them is carried on sometimes by means of traps, or 'pots' (as they are called in some places), made of twigs, baited with garbage, lowered into the sea and marked by a buoy; sometimes by nets baited with the same materials; and in some countries, by torch-light, with the aid of a wooden instrument, which acts like a forceps or a pair of tongs.

One of the best narratives of the habits of the lobster extant, is to be found in the following letter from Mr. Travis, of Scarborough, to Mr. Pennant, dated on the 25th October, 1768:—

"We have vast numbers of fine lobsters on the rocks near our coast. The large ones are in general in their best season from the middle of October till the beginning of May. Many of the small ones, and some few of the larger sort, are good all the summer. If they be 4½ inches long, or upwards, from the tip of the head to the end of the back shell, they are called sizeable lobsters. If only 4 inches, they are esteemed half size; and when sold, two of t' em are reckoned for one of size. If they be under 4 inches, they are called Pawks, and are not saleable to the carriers, though in reality they are in the summer months superior to the large ones in goodness. The pincers of one of the lobster's large claws are furnished with knobs, and those of the other claw are always serrated. With the former it keeps firm hold of the stalks of submarine plants, and with the latter it cuts and minces its food very dexterously. The knobbed, or numb claw, as the fishermen call it, is sometimes on the right side, and sometimes on the left, indifferently. It is more dangerous to be seized by them with the cutting claw than the other; but, in either case, the quickest way to get disengaged from the creature is to pluck off its claw. It seems peculiar to the lobster and crab when their claws are pulled off that they will grow again, but never so large as at first.

"The female or hen lobster does not cast her shell the same year that she deposits her ova, or in the common phrase, is 'in berry.' When the ova first appear under her tail, they are very small and extremely black; but they become, in succession, almost as large as ripe elderberries before they are deposited, and turn of a dark-brown colour, especially towards the end of the time of her depositing them. They continue full and depositing the ova in constant succession, as long as any of that black substance can be found in their body, which when boiled turns of a beautiful red colour, and is called their Coral. Hen-lobsters are found in berry at all times of the year, but chiefly in winter. It is a common mistake, that a berried hen is always in perfection for the table. When her berries appear large and brownish, she will always be found exhausted, watery, and poor. Though the ova be cast at all times of the year, they seem only to come to life during the warm summer months of July and August. Great numbers of them may then be found, under the appearance of tadpoles, swimming about the little pools left by the tides among the rocks, and many also under their proper form, from half an inch to four inches in length.

"In casting their shells, it is hard to conceive how the lobster is able to draw the fish of their large claws out, leaving the shells entire and attached to the shell of their body; in which state they are constantly found. The fishermen say the lobster pines before casting, till the fish in its large claw is no thicker than the quill of a goose, which enables it to draw its parts through the joints and narrow passage near the trunk. The new shell is quite membranous at first, but hardens by degrees. Lobsters only grow in size while their shells are in their soft state. They are chosen for the table by their being heavy in proportion to their size, and by the hardness of their shells on their sides, which when in perfection will not yield to moderate pressure. Barnacles and other small shell-fish adhering to them are esteemed certain marks of superior goodness. Cock-lobsters are in general better than the hens in winter; they are distinguished by the narrowness of their tails, and by their having a strong spine upon the centre of each of the transverse processes beneath the tail which support the four middle plates of their tails. The fish of a lobster's claw is more tender, delicate, and easy of digestion, than that of the tail. Lobsters are not taken here in pots, as is usual where the water is deeper and more still than it is upon our coast. Our fishermen use a bag-net fixed to an iron hoop, about 2 feet in diameter, and suspended by three lines like a scale. The bait is commonly fish-guts tied to the bottom and middle of the net. They can take none in the daytime, except when the water is thick and opaque: they are commonly caught in the night; but even then it is not possible to take any when the sea has that luminous appearance which is supposed to proceed from the *Nereis noctiluca*. In summer, the lobsters are found near the shore, and thence to about 6 fathoms depth of water; in winter, they are seldom taken in less than 12 or 15 fathoms. Like other insects [crustaceans] they are much more active and alert in warm weather than in cold. In the water they can run nimbly upon their legs or small claws, and if alarmed can spring tail foremost to a surprising distance, as swift as a bird can fly. The fishermen can see them pass about 30 feet, and by the swiftness of their motion, suppose they may go much farther. Athenaeus remarks this circumstance, and says that the incurvated lobsters will spring with the activity of dolphins. Their eyes are raised upon moveable bases, which enables them to see readily every way. When frightened they will spring from a considerable distance to their hold in the rock; and, what is not less surprising than true, will throw themselves into their hold in that manner through an entrance barely sufficient for their bodies to pass, as is frequently seen by the people who endeavour to take them at Filey Bridge. In frosty weather, if any happen to be found near the shore, they are quite torpid and benumbed. A sizeable lobster is commonly from one pound to two in weight. There was one taken here this summer which weighed above four pounds, and the fishermen say they have seen some which were of six pounds, but these are very rare."

There is no doubt that the lobster changes its shell annually; but the mode in which this operation is performed is not satisfactorily known. Some suppose that the old shell is thrown off, and that the animal retires to some lurking place to avoid the voracity of his crust-clad fellows, till his new covering acquires sufficient hardness; others contend that the process is one of absorption, and these ask, in proof of their views of the case, what becomes of the old shells if there is a true ecdysis or moult, for that the sea-coast at the moulting period would be strewed with them? The most probable conjecture is, that the shell sloughs off piecemeal as it does in the crawfish. Lobsters, in common with most of the Crustaceans, have the power of reproduction to a great extent. If a claw be torn off, it is renewed; and if it be injured, the animal will sometimes throw it off by an effort. It seems that any violent shock to the nervous system will cause this act. If a lobster be thrown into boiling water, it will generally throw off its large claws on the instant; and the same effect has been produced by plunging the animal, when in full life, into spirit. Pennant goes so far as to make them out to be very nervous subjects indeed. "Lobsters," says he, "fear thunder, and are apt to cast their claws on a loud clap. I am told they will do the same on firing a great gun; and that when men-of-war meet a lobster-boat, a jocular threat is used, that if the master does not sell them good lobsters they will salute him."

That the lobster was well known to the ancients appears from the reference in Mr. Travis's letter, and from many other evidences. It will be sufficient to add that, under the name of ἀστακὸς, Aristotle, in the second chapter of the fourth book of his 'History of Animals,' gives a most faithful and elaborate account of the species which is still an inhabitant of the Mediterranean.

Astacus fluviatilis, the Crawfish, is to be found in the fresh waters of Europe and the north of Asia. It thrives best in rivers, where in holes in the banks and under stones it lies in wait for the small molluscous animals, little fishes, the larvæ of insects, and decomposing animal substances, which form its prey. Desmarest says that it will live for upwards of 20 years, and that it becomes large in proportion to its age; that towards the end of spring it casts off the pieces which form its shell, and some days after becomes covered with a crust as solid as the former one, but larger, sometimes by as much as one-fifth. The eggs, which are excluded about two months after impregnation, are collected under the lower part of the body or tail, as it is popularly called, after the manner of the hen-lobster. From these proceed the young crawfishes, which are very small and soft, but which bear an exact resemblance to the parent, under whose tail they are nursed for several days.

The crawfish is taken either by nets or by bundles of thorns in which flesh in a state of decomposition is placed. It is also taken by inserting the hand into the hole which it inhabits; and at night it is caught by means of lighted torches. [CRUSTACEA.]

ASTA'RTE, a genus of *Conchiferous Mollusca*, with two muscular impressions and a simple mantle-line. The hinge has two divaricated teeth in the right-hand valve; in the other, one distinct and one obsolete tooth, and the rudiment of a lateral tooth. The ligament is external.

The species consist of some of the *Veneres* of Montagu, one of which is a *Crassina*. (Lam.) Some of them are English shells, and they are generally found on the sandy mud of coasts at a depth which ranges from near the surface to ten fathoms.

The Crag, the Green-Sand, and some of the old fossiliferous beds afford many species.

A'STER, a genus of plants belonging to the natural order *Compositæ*, and comprehending a great multitude of species scattered over all parts of the world, especially North America and Australia. Many of them are handsome herbaceous plants, others are small-leaved shrubs, and the remainder are mere weeds. (Nees von Esenbeck, 'Genera et Species Asterearum.')

Although the number of species of this genus is very great, none of them are of any use to man. A large number are cultivated, and we are indebted to their very handsome flowers for some of the greatest ornaments of our gardens at the latter end of summer. One of the species, *Aster Tripolium*, is a British plant. It is very common in muddy salt marshes. It has a stem from 1 to 2 feet high, which is erect, hollow, leafy, and many-flowered. The flowers are yellow in the disk and lilac in the circumference. Sometimes the latter are wanting.

ASTERACA'NTHUS, a genus of Fossil Placoid Fishes, including five British species, from the Oolitic and Lias Formations. (Agassiz.)

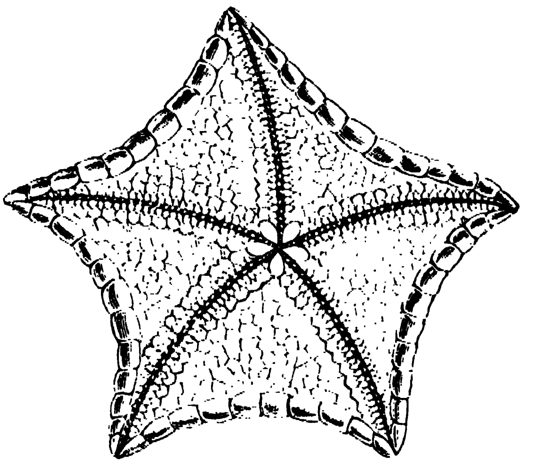
ASTERI'ADÆ, a family of the order *Echinodermata* including the true Star-Fishes. This family is distinguished from the rest of the order by the body being more or less lobed, and the lobes channeled beneath for cirrhi, which act as suckers and are the organs of motion. Professor E. Forbes in his 'History of British Star-Fishes' has arranged the British species of this family under four heads: –

1. The *Urasteriæ*, Stellate Star-Fishes with rounded arms and four ranges of suckers in each avenue. Of this family there is only one genus *Uraster*, inhabiting the British coasts. Of this there are four species—*U. glacialis*, *U. rubens*, *U. violacea* and *U. hispida*.

2. The *Solasteriæ*, also stellate (sometimes multi-radiate), with rounded arms, but only two ranges of suckers in each avenue. To this tribe belong the genera *Cribella* and *Solaster* of which *C. oculata*, *C. rosea*, *S. endeca*, and *S. papposa* inhabit the British coasts.

3. *Goniasteriæ*, which are pentagonal and have two ranges of suckers. The British genera of this tribe are *Asterina*, *Palmipes*, and *Goniaster*. The species are *A. gibbosa*, *P. membranaceus*, *G. Templetoni*, and *G. equestris*.

4. *Asteriæ*, Stellate Star-Fishes with the upper surface of the body flat. It includes the British genera *Asterias* and *Luidia*. Each of these have one species, *A. aurantiaca* and *L. fragilissima*. [ECHINODERMATA.



Asterias tessclata.

ASTE'RIAS (Lam.), a genus of Radiated Animals widely diffused over the seas. The Linnæan genus comprises every form of radiation which appears in the tribe, but the genus *Asterias* of Lamarck includes only the Star-Fishes properly so called. These are divided into two sections, 'the Scutellated Star-Fishes,' and 'the Radiated Star-Fishes.' The former have an angular body, the lobes or rays of which are short, their length not exceeding the diameter of the disk: the latter have a body furnished with elongated rays, whose length far exceeds the diameter of the disk. The following is a general description of the animals to which the name *Asterias* has been applied:

Each ray is furnished with a longitudinal furrow on its lower side, and this furrow is pierced laterally with small holes, through which pass the feet or tentacula, which are membranous, cylindrical, and each of them terminated with a little disk, which performs the office of a cupping-glass, somewhat in the same manner as the acetabula or suckers of the cuttle-fishes. By elongating or shortening these numerous little organs, and by fixing them by means of their terminal disks, the progressive motions of the Star-Fish are regulated. The rest of the lower surface is furnished with small moveable spines, which also assist progression. The whole surface is also pierced by pores, through which pass tubes much smaller than the feet, serving probably to absorb the water, and to introduce it into the general cavity, for the purposes of a kind of respiration. A large stomach lies close to the mouth; and two ramified cæca, each suspended to a kind of mesentery, are given off to each ray, which is also furnished with two ovaries, by means of which the animals are supposed to reproduce their species without the aid of a second individual. A fine cord, which surrounds the mouth and sends a branch to each arm, is considered as the development of their nervous system. [ASTERIADÆ; ECHINODERMATA.]

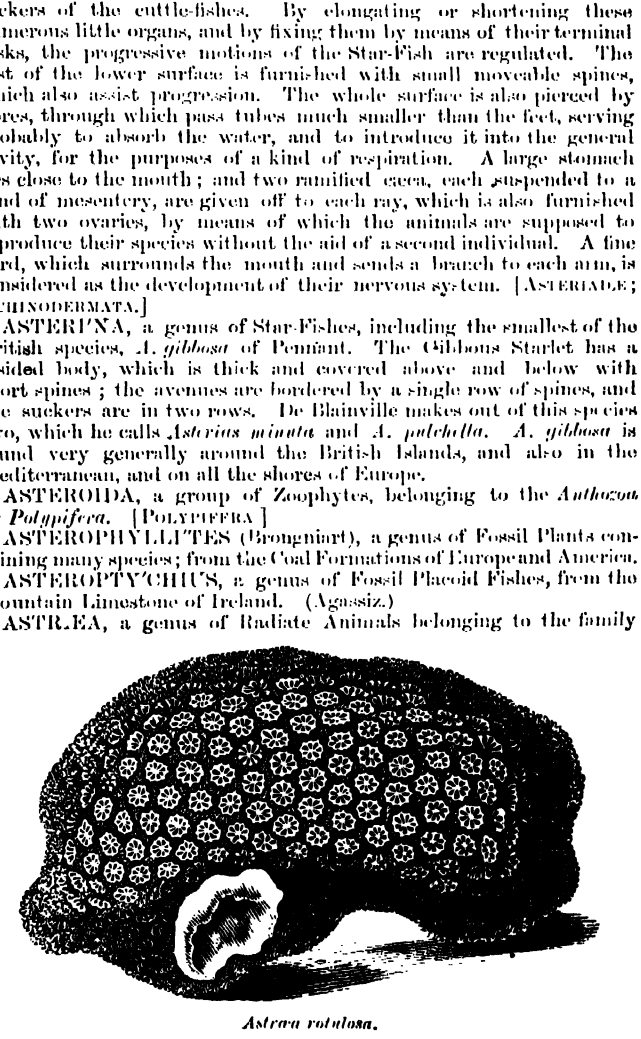
ASTERI'NA, a genus of Star-Fishes, including the smallest of the British species, *A. gibbosa* of Pennant. The Gibbous Starlet has a 5 sided body, which is thick and covered above and below with short spines; the avenues are bordered by a single row of spines, and the suckers are in two rows. De Blainville makes out of this species two, which he calls *Asterias minuta* and *A. pulchella*. *A. gibbosa* is found very generally around the British Islands, and also in the Mediterranean, and on all the shores of Europe.

ASTEROIDA, a group of Zoophytes, belonging to the *Anthozoa* or *Polypifera*. [POLYPIFERA.]

ASTEROPHYLLITES (Brongniart), a genus of Fossil Plants containing many species; from the Coal Formations of Europe and America.

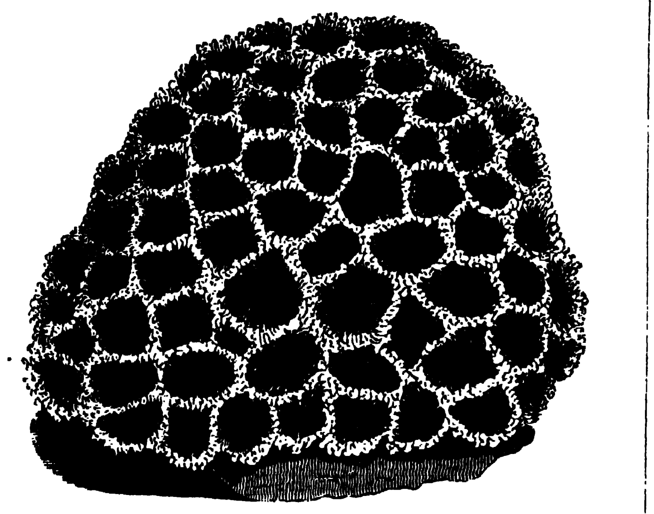
ASTEROPTY'CHUS, a genus of Fossil Placoid Fishes, from the Mountain Limestone of Ireland. (Agassiz.)

ASTRÆA, a genus of Radiate Animals belonging to the family *Polypifera*. The species are found sometimes incrusting marine



Astræa rotulosa.

bodies, sometimes collected in a hemispherical or globular mass, which is occasionally lobated. The upper surface is covered with orbicular or subangular starry disks, which are lamellar and sessile. Each disk is the seat of a polype, with a single row of numerous arms, in the centre of which is the mouth. Lamarck divides these corals into two sections: the first, consisting of species whose starry disks are separated from each other, leaving interstices between them; and the second, of species whose starry disks are contiguous. Of the first section, *A. rotulosa*, an inhabitant of the West Indian seas, is an example; of the second, *A. favosa*, common in the seas of the East Indies affords a good illustration. The species are numerous.



Astræa favosa.

ASTRA'GALUS, a genus of plants belonging to the natural order *Leguminosæ*. It has the calyx 5-toothed; the keel of the flower obtuse; the stamens diadelphous; the legume bilocular or half-bilocular, from the upper suture being bent in so much. The species are shrubs or under-shrubs.

A. hypoglottis, the Purple Milk-Vetch, is a native of Europe in gravelly and chalky places.

A. glycyphyllos, Liquorice-Vetch, is another British species. It has a sweetish taste in its leaves, but they are not pleasant, and cattle do not eat it.

A. verus, Goat's-Thorn, is the plant which is said to yield Gum Tragacanth. It is a small bush with pinnated gray leaves, terminated by a spiny midrib and half-covering clusters of axillary pale yellow flowers. It grows in the Levant. The gum is a natural exudation from the plant. Many other species of *Astragalus*, as *A. Creticus*, *A. gummifer*, *A. aristatus*, and *A. strobilifera*, are now known to yield this substance. The species of *Astragalus* are very numerous, and above 250 have been described by botanists. Many of them are cultivated, most of them being hardy plants, but they are not remarkable for their beauty.

ASTRAKANI'TE, a variety of native sulphate of magnesia (Epsom Salts), which is called *Epsomite*.

ASTROCA'RYUM, a genus of Palms found in small groups, or in single specimens, in the tropical parts of America, of middling stature, and of a very singular appearance on account of the spines with which they are armed. Their stems are covered all over, except at the places where the leaves are set on, with stiff and very numerous prickles. The leaves are pinnated. The fruit resembles cocoa-nuts.

These plants are found exclusively in South America, where several species were collected by Dr. Von Martius, the great illustrator of the Palm Tribe. Among the more remarkable are *Astrocaryum murimuri*, a common inhabitant of swampy places in the neighbourhood of Para, where it is called Murumurú. The flesh of the fruit resembles the melon in flavour and the musk in odour, and is considered a great delicacy by the Americans. We give a figure of it in the next column, but so much reduced that the armature of the stem cannot be shown. The leaves are found to form an excellent thatch.

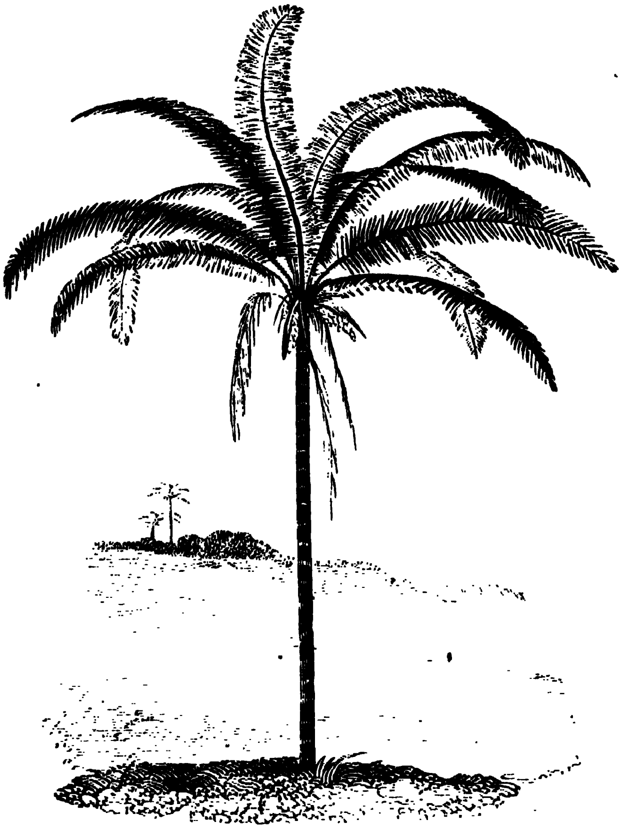
Another species, *A. airi*, has very hard wood, which is much used for bows and similar purposes, where hardness and toughness are required.

The fibres of the leaves of *A. Tucuma* are greatly valued for fishing-nets. (Martius, *Palms*, p. 69, &c.)

ASTROCRINI'TES (Austin), a genus of Fossil *Crinoidea*, from the Mountain Limestone of Yorkshire.

ASTROLO'MA, a genus of plants belonging to the natural order *Epacridaceæ*. One species, the *A. humifusa*, yields the Tasmanian Cranberry. The fruit is of a green or whitish colour, sometimes slightly red, of the size of a black currant, and consisting of a viscid apple-flavoured pulp, inclosing a large seed. It grows singly on the trailing stems of the plant. The flowers are of a beautiful scarlet. (Lindley, *Vegetable Kingdom*.)

ASTROPECTEN, a genus of Star-Fishes, including the *Asterias aurantiaca* of Müller and others, which is called *Astropecten irregularis*. [ECHINODERMATA.]



Astrocaryum murimuri.

ASTROPHY'TON, a genus of Star-Fishes, remarkable for the branched character of its rays. One species, the *A. scutatum*, is British. It is however a rare animal; and although occasionally found in other places, is most commonly caught off the Shetlands: hence it is called the Shetland Argus. (Forbes, *British Star-Fishes.*)

ASTUR, a genus of Hawks formed by Bechstein, and characterised by a short beak bent downwards from the base and convex above, with somewhat oval nostrils. The feet are rather short, and the toes (of which the exterior are united at the base by a membrane) are long.

Numerous species of this genus are diffused over all parts of the world; but Europe only contains one, *Astur palumbarius*, the Goshawk, so highly prized by the falconers of old, and famous for its flights at cranes, geese, pheasants, and partridges. [FALCONIDÆ.]

ATACAMI'TE (*Chloride of Copper, Muriate of Copper*). It occurs massive, pulverulent, and crystallised. Its primary form is a right rhombic prism. The colour is green, of various shades, but chiefly emerald green. The streak is lighter. The fracture uneven. Hardness 3·0 to 3·5. Lustre vitreous. Transparent to opaque. Specific gravity 4·4. It is found at Remolenos in Chili; the pulverulent variety at Atacama in Peru. The massive variety is reniform, with a fibrous structure. The analysis by Proust is as follows:—

Muriatic Acid	10·6
Oxide of Copper	76·6
Water	12·8
	100·0

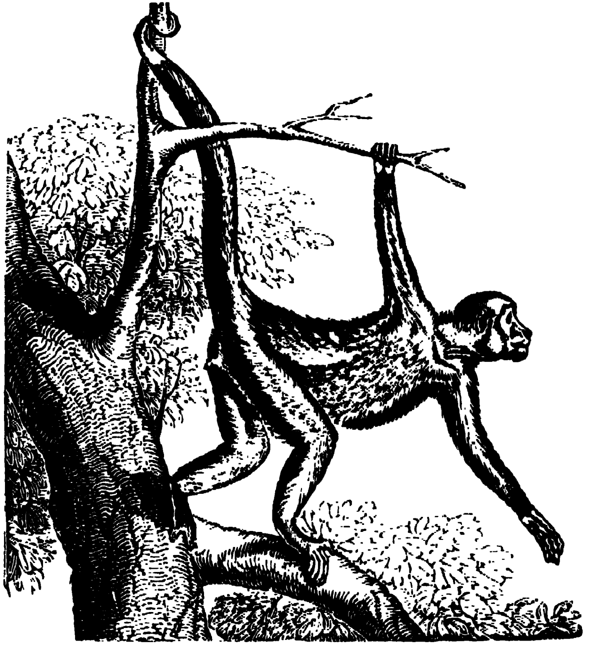
A'TELES, a genus of *Sapajous*, or American Monkeys, called also Spider Monkeys, formed by M. Geoffroy St. Hilaire, and presenting numerous and remarkable modifications of organic structure, which readily distinguish them from all other groups of *Quadrumana*. The most prominent characters of the genus consist in their long, attenuated, and powerfully prehensile tails; fore hands either entirely deprived of thumbs, or having only a very small rudiment of that organ; and their dental system, which, like that of all the American Quadrumanes, consists of two molar teeth in each jaw (one on each side) more than are found either in man or in the kindred genera of the Old World. The first and last of these modifications are common to the *Ateles* and other American genera; the second is shared with them only by the *Colobi*, a small African genus, consisting only of two species, neither of which has been observed by any zoologist since the days of Pennant, and with whose other characters we are very imperfectly acquainted. The *Ateles* are further distinguished by their small round heads, corpulent bodies, and remarkably long slender limbs, which characteristics giving these animals much of the general appearance of a spider, have procured for them the appellation of Spider-Monkeys, by which they are commonly known. Like the other *Quadrumana* of the New World, they are destitute of cheek-pouches and callosities—characters which approximate them in some measure to the real Apes. The skull of the *Ateles* is rounder and the brain larger than in the common monkeys; the forehead also is more elevated, and the muzzle less prominent. The eyes are widely separated from one another by the base of the nose; the nostrils open laterally, and are separated by a thick cartilaginous partition; the ear only differs from that of man in having no inferior lobe; the mouth is small, the lips thin and extensible, and the hair generally long, coarse, and of a glossy appearance.

But they are chiefly distinguished by the organs of locomotion. The anterior extremities, in particular, are by their length and the slenderness of their form out of all proportion with the other parts; they are in general, as above observed, destitute of thumbs; or if some species are provided with this organ, it is only in a rudimentary form, and consists merely of a flat nail, or at most of a single joint. On the posterior extremities, on the contrary, the thumb is largely developed, placed far back towards the heel, and is completely opposeable to the fingers. But these animals possess, in their long and muscular tail, an organ of prehension much more powerful than the other extremities; it executes in fact all the functions of a fifth limb, though probably, on account of its distance from the seat of sensation, it is not endowed with a very delicate sense of touch. For six or seven inches from the point it is naked and callous on the under surface; and it is by this portion that the animal hangs suspended from the branches, or swings itself from tree to tree with an ease and velocity almost incredible.

Their entire organisation is adapted exclusively to an arboreal life; on the earth nothing can be more awkward and embarrassed than their motions. They trail themselves along with a slow and vacillating gait, sometimes using their long fore-arms as crutches, and resting upon their half-closed fists whilst they project the body and hind legs forward; at other times walking in a crouching position on the hind legs only, balanced by the long arms and tail, which are elevated in front and rear respectively, and always ready to take advantage of any object by which to avail themselves of their natural powers of progression. But in proportion to their embarrassment on a plain surface is their dexterity and agility among the trees of their native forests. Here they live in numerous troops, mutually support one another in danger, beat and expel the less favourably organised Sakis from the vicinity of their cantonments, and exercise a perfect tyranny over all the other arboreal mammals of their neighbourhood. Though leaves and wild fruits compose the principal part of their food, yet they do not reject flesh, but hunt after insects and the eggs and young of birds, and are even said to adopt the stratagem of fishing for crabs with their long tails. They are exceedingly intelligent, easily domesticated, and soon become strongly attached to those who treat them kindly: they exhibit none of the petulance and insatiable curiosity of the common monkeys; their character, on the contrary, is grave, and approaches even to melancholy: but if their passions are less violent, and more difficult to excite, their affections are infinitely stronger; and if they are without the amusing tricks of the monkeys, so likewise are they without their fickleness and mischief.

Dampier relates, that when a troop of *Ateles* have occasion to pass any of the larger rivers of South America, they select a situation in which the trees are highest and project farthest over the stream; then mounting to the topmost branches, they form a long chain by grasping one another's tails successively. This chain being allowed to hang freely at the lower end, whilst it is suspended from the top, is put in motion, and successively swung backwards and forwards till it acquires an impetus sufficient to carry it over to the opposite bank. When this is accomplished, the animal at the lower end catches the first branch which comes within his reach, and mounts to the highest, where as soon as he is firmly attached, the other end of the chain is permitted to swing, and thus the whole troop are passed over. The *Ateles*, as well indeed as all the other American Quadrumanes, are esteemed as an article of food by the native Indians; and even Europeans, whom curiosity or necessity has induced to taste it, report their flesh to be white, juicy, and agreeable. The only thing disgusting about it is a strong resemblance which the whole body, and particularly the head and hands, bear to those of a young infant. Nor is it without being strongly disposed to question the nature of the act, that European sportsmen, unaccustomed to shooting monkeys, witness for the first time the dying struggles of these animals. Without uttering a complaint, they silently watch the blood as it flows from the wound, from time to time turning their eyes upon the sportsman with an expression of reproach which cannot be misinterpreted: some travellers even go so far as to assert that the companions of the wounded individual will not only assist him to climb beyond the reach of further danger, but will even chew leaves and apply them to the wound for the purpose of stopping the hemorrhage. The following species of *Ateles* have been distinguished and characterised by naturalists and travellers:

1. *A. paniscus* (Geoff.), the Quata, or as the French write it Coaita, is a large species, covered with long coarse hair of a glossy black colour; the belly is protuberant, the head small and round, the limbs long and slender, the fore hands entirely deprived of thumbs, the tail robust and powerful, the eyes and cheeks deeply sunk, and the face copper-colour. On the back and outsides of the limbs the hair is very long and thick, but the belly and groins are nearly naked, and the mammæ of the females are placed in the armpits. The hair of the head is directed forwards, and the ears, concealed beneath it, differ from those of the human species only in having no inferior lobe. This species is very common in the woods of Surinam and Brazil. It is active and intelligent, and unites considerable prudence and penetration to great gentleness of disposition. They go in large companies, and when they meet with a man or any animal which is strange to them, come down to the lower branches of the trees to examine them, and having satisfied their curiosity, begin to pelt them with sticks, and endeavour to frighten them away. They cannot leap, but exhibit the most surprising agility in swinging from tree to tree. Acosta, in his 'History of the West Indies,' relates the following anecdote of a Quata which belonged to the Governor of Carthagena:—"They sent him," says he, "to the tavern for wine, putting the pot in one hand and the money in the other; they could not possibly get the money out of his hand before his pot was full of wine. If any children met him in the street and threw stones at him, he would set his pot down and cast stones against the children, till he had assured his way, the would he return to carry home his pot. And what is more, although he was a good bibber of wine, yet he would never touch it till leave was given him."



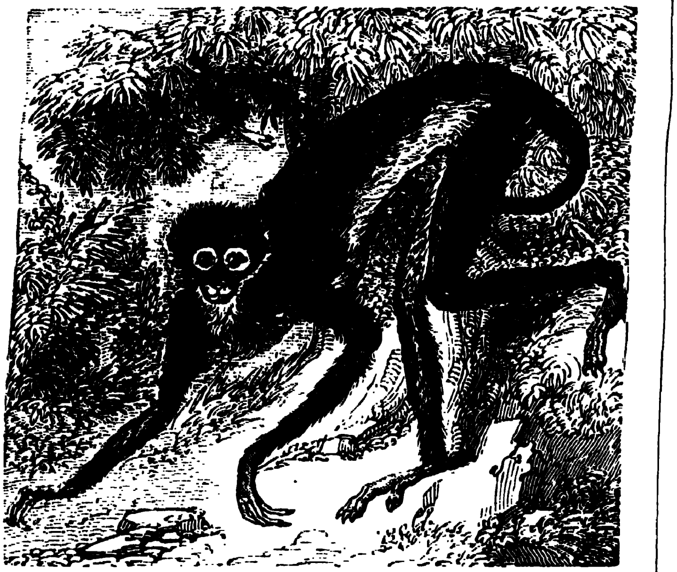
The Quata (*Ateles paniscus*).

2. *A. marginatus* (Geoff.), the Chuva, closely resembles the Quata in physiognomy, size, and proportions. The quality and colour of the hair are also the same in both, except that the face of the Chuva is surrounded with a rim of white, which on the forehead particularly is broad, and directed upwards, so as to encounter the hair of the occiput and form a low crest on the top of the head. The hair of the fore-arm is directed partially towards the elbow; like that of the body it is long and coarse, and though perfectly black, has not the glossy appearance of the Quata's covering. The face is nearly naked, and tan-coloured; the palms of the hands, soles of the feet, and callous part of the tail are violet black, and the whole skin beneath the hair appears to be of the same hue. The disposition and manners differ in no respect from those of the Quata.

3. *A. ater* (F. Cuvier), the Cayou, is considered by Messrs. Geoffroy and Desmarest as a variety of the Quata; but F. Cuvier, from observations which he made upon the living animal, has recognised and described it as a distinct species. It must however be confessed that it approaches so nearly to the Quata as to render further observations necessary to determine the question of their specific difference. The size, form, and colour are the same in both, and the only marked distinction reported by M. Cuvier consists in the colour of the face, which is black in the Cayou and copper-coloured in the Quata. "The hair," says M. Cuvier, "is long, and of a harsh silky quality. It is rather shorter on the head and tail than on the rest of the body, where it falls backwards in the ordinary way, but on the head it is directed forwards, and falls over the face."

4. *A. Belzebub* (Geoff.), the Marimonda, has the top of the head, the back, sides, and external surface of the extremities black, and all the under parts, the cheeks, throat, breast, belly, inside of the limbs, and under surface of the tail for its first half, white, with a slight shade of yellow. The naked parts are violet-black, except immediately about the eyes, which are surrounded by a flesh-coloured circle. This species, according to Humboldt, replaces the common Quata in Spanish Guyana, where it is extremely common, and is eaten by the

Indians. "It is," says this celebrated traveller, "an animal very slow in its movements, and of a gentle, melancholy, and timid character; if it occasionally bites, it does so only in its fits of terror. The Marimondas unite in great companies and form the most grotesque groups.



The Marimonda (*Ateles Belzebub*).

All their attitudes announce the extremity of sloth. I have frequently seen them, when exposed to the heat of a tropical sun, throw their heads backwards, turn their eyes upwards, bend their arms over their backs, and remain motionless in this extraordinary position for many hours together." The young of this species appear to have the upper parts of the body mixed slightly with gray, but this mixture gradually disappears as it grows towards maturity, till the adult animal presents the uniform black above and white below, as already described.

5. *A. melanocheir*, Geoff., with the native Indian name of which we are unacquainted, is also a distinct species. The head, members, and tail are black or dark brown on the superior surface; the internal face of the arms and fore-arms as far as the wrists, and of the thighs and legs, the under surface of the tail, the throat, breast, belly, and sides of the hips, are white or silvery gray; the shoulders are yellowish gray, and the remainder of the upper parts of the body, as well as the whiskers, are pure gray; the four hands and the naked part of the tail are black, as are also the face, the cheeks, and the under half of the nose; but round the mouth and eyes the fur is flesh-coloured. The hair is uniformly of a silky quality: that on the black and white parts is of the same colour throughout, but on the gray parts it is annulated with alternate rings of black and white. This species, as well as all those hitherto described, is entirely deprived of the fore thumb, and does not even exhibit a rudiment of that organ. Only a single individual has been observed alive; its manners are the same as those of the *Ateles* in general, but its habitat has not been definitely determined.

6. *A. Arachnoïdes*, or the Brown Quata, as it is called by Baron Cuvier, partakes in fact very much of the characters and appearance of the common Quata, from which it is principally distinguished by its uniform reddish-brown colour. This species when full grown measures rather more than 2 feet in length; the tail is about 2 inches longer than the body; the fore legs are 1 foot 9 inches long, the hind legs 1 foot 8 inches, and the hands 6 inches. The hair is short, fine, and soft, and that of the forehead is directed backwards, contrary to what is usually observed in the other Ateles; the back and upper parts of the body are, generally speaking, well covered with hair, but the breast, belly, and groins are nearly naked, or at least sparingly covered with scattered hairs, of a longer and coarser quality than those on other parts; the root of the tail is rather thick and bushy, but it is gradually attenuated towards the point, and for the last ten inches naked underneath. The general colour is uniform chestnut-brown, the first of these colours becoming clearer and more intense upon the head, and more especially round the eyes; the forehead is bordered by a circle of stiff coarse black hairs, beneath which a semicircle of light silvery gray passes over the eyes in the form of brows, and becomes gradually more and more obscure, till it is finally lost in the uniform reddish-brown of the temples. The face is naked and flesh-coloured, the under parts of the body of a silvery gray slightly tinged with yellow, with the exception of the abdomen, which, as well as the inner surface of the thighs, and the naked stripe underneath the tail, are of a bright red colour. The manners and habits of this species are unknown in its native forests. Those which have been observed in a state of confinement exhibited all the gentleness and listless apathy of character which distinguish the *Ateles* from the common monkeys of South America, as eminently as they do the Gibbons of the Indian isles from the other Quadrumanes of the Old World. Except in the total want of the thumb on the anterior extremities, the *A. Arachnoïdes* approaches very nearly to the following species, and appears indeed to be intermediate between it and the common Quata.

7. *A. hypoxanthus* (Kuhl), the Mono, or Miriki, inhabits the forests in the interior of Brazil, and, as has just been observed, approaches very nearly to the *A. Arachnoïdes*, as well in the colour of its fur as in the general form and proportions of its body and members; but it is readily distinguished from that species as well as from all the other *Ateles* hitherto described, by the presence of a small rudimentary thumb on the fore hands. The face also is more uniformly covered with hair than in the generality of the other species, being naked only about the region of the eyes; the hairs which compose the eyebrows are long, black, and directed upwards: the cheeks, lips, nose, and a narrow line descending from the forehead, are covered with short hairs of a pale yellowish-white colour; the chin also is furnished with short hair of the same colour and quality, but intermixed with thinly scattered long black hairs, forming a species of beard, and extending over the upper lip in the form of thin moustaches. The ears are small and nearly concealed by the hair of the head, which though not very long is thickly furnished, and of a pale gray colour slightly tinged with yellow. The whole body and members are of a uniform grayish-fawn colour, only differing in the greater degree of intensity which distinguishes the back and upper parts from those beneath, and in the lighter gray tinge which predominates on the extremities. The backs of the fingers are hairy down to the very nails, and there is a rudiment of a thumb on the fore hands, covered with a short compressed nail.

The Mono (*Ateles hypoxanthus*).

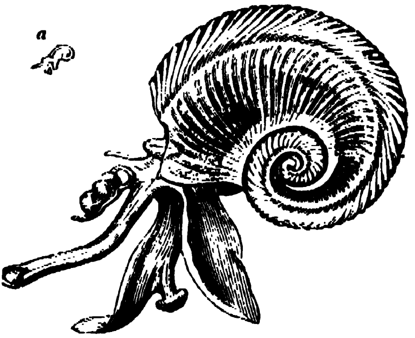
The Mono was discovered by Prince Maximilian of Neuwied, during his travels in Brazil. It is the largest species of the Quadrumanes which inhabit the part of the country through which that scientific traveller passed, and though sufficiently common in particular districts, appears to have upon the whole but a very limited geographical range. Its hide is said to be more impervious to moisture than any other description of fur known in that part of the world, and for this reason the Brazilian sportsmen have cases of the skin of the Mono made to protect the locks of their guns from the rain.

8. *A. subpentadactylus* (Geoffrey), the Chameck, the last species of the genus distinctly known at present, resembles the Mono in having a small rudimentary thumb on the anterior extremities, but it is without a nail, and in other respects the two animals are sufficiently distinguished by their difference of colour and habitat. The Chameck indeed approaches more nearly in external form and appearance to the Quata than to any other of its congeners, being furnished with a similar coat of long dense hair, of an intense and uniform black colour; but it may be readily distinguished from that species by the presence of the rudimentary thumb on the anterior members, as well as by its size, which considerably exceeds that of the Quata. It has a protuberant muzzle, and its lips, like those of the Quata, are capable of prolongation; the forehead is high; the face, cheeks, ears, and chin,

are naked and of a brown colour, with a few long black hairs thinly scattered over them; the hair of the head is long, matted, and directed forwards over the forehead, that of the body and members very long and thick; the fingers, both upon the anterior and posterior extremities, are long, slender, and nearly naked; the tail is considerably longer than the body, very thick and covered at the base with close shaggy hair, but attenuated towards the point, where it is more sparingly furnished with shorter hair, and entirely naked underneath.

This species inhabits Guyana and some of the neighbouring provinces of Brazil. Von Sack, in his 'Voyage to Surinam,' gives the following account of its manners under the name of Quata, with which species its general appearance probably causes it to be frequently confounded. "The Quata," says this author, "is of a very docile disposition, and capable of being quite domesticated. I have seen a pair of them at a gentleman's house at Paramaribo which were left quite at liberty. When the female negroes were employed at their needlework, they used to come and sit amongst them, and play with a piece of paper, and afterwards go out to gambol upon the trees, but never went over to the neighbouring gardens; and they knew well the usual hour of dinner at their master's, when they would come to the gallery, look in at the windows, though without attempting to enter into the room, being aware that this was a liberty not allowed them; they therefore patiently waited for their dinner on the outside."

ATHANAS (Leach), a genus of the *Long-Tailed Crustacea*, bearing much resemblance to *Lysmata* (Risso), from which it differs in having the first pair of feet of larger size than the rest, while the second pair of *Lysmata* are the largest. It is small in size, and has been taken on the south coast of England and on the shores of France.



Atlanta Peronii. *a*, natural size.

ATLANTA, a genus of the *Heteropodous Mollusca* of Lamarck, which Cuvier places next to *Carinaria*. The animal is very small, and the shell very delicate. Lamanon thought that he had discovered in one of these shells the original of the fossil Ammonites, or *Cornua Ammonis*, which however must have belonged to the class of Cephalopodous Mollusks, or cuttle-like animals. *Atlanta* inhabits the Indian seas. [GASTEROPODA.]

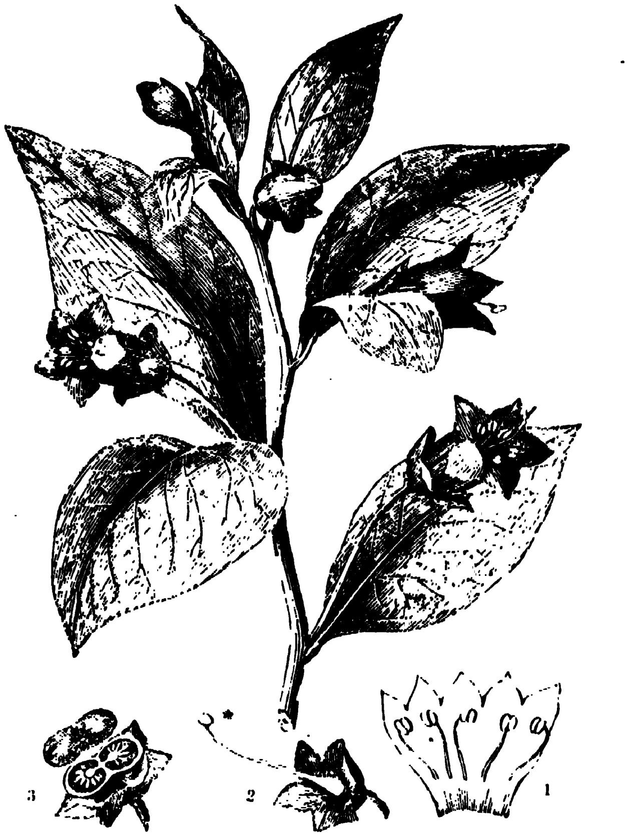
Lesueur describes another marine genus, *Atlas*, which must not be confounded with the above. *Atlas* has no shell; and Cuvier confesses his inability to class it, "so confused," says he, "is the description." De Blainville thinks that it belongs to the same family as *Gasteroptera*, and places it accordingly under *Akera*, though he confesses that it is not entirely known.

ATLAS, the first vertebra of the neck, so named because it sustains the globe of the head. It differs in several important circumstances from all the other vertebræ that enter into the composition of the spinal column, because it has distinct and peculiar offices to perform. It has to support the head, and to allow it the power of exercising two different kinds of motion, namely, a motion forwards and backwards, or that of flexion and extension; and a rotatory motion, or the power of describing a certain portion of a circle, as it does when it turns from side to side. These motions are accomplished by the peculiar mode in which the head is connected to the atlas, and the atlas to the second vertebra of the neck, the *Vertebra dentata*, or axis. The head is so united with the atlas as to form a perfect hinge-joint, that is, a joint which admits of flexion and extension, or a motion forwards and backwards. The second vertebra, the dentata, forming a pivot on which the atlas turns, and therefore called axis, is united with the atlas in such a manner as to constitute a perfect rotation-joint, or a joint which admits of a rotatory motion. The head being firmly connected with the atlas and carried round with it whenever the latter turns upon its axis, it is plain that by the combination of the two joints, namely, the hinge-joint and the rotation-joint, the head can be moved in every direction—forwards, backwards, and from side to side. In the construction of these joints such is the perfection of the mechanism that these combined motions are attained to the utmost extent, and are performed with the greatest ease. The connection of the different parts with each other forms a union of amazing strength and security, and at the same time certain organs of extreme delicacy and of vital importance are effectually guarded from injury. [*Spinal Column*, under SKELETON.]

A'TRIPLEX, a genus of plants belonging to the natural order *Chenopodiaceæ* and the tribe *Atripliceæ*. It has monœcious rarely perfect flowers, the perigone of two more or less connected parts, two stigmas, a free membranous pericarp, a crustaceous testa; the seed is vertical, attached by a lateral hilum, either near the base or by means of an elongated funiculus in the middle of the side; the radicle basal; the stamens five, continuous. Most of the species of this genus are insignificant weeds, and are sometimes troublesome pests in corn-fields. Babington, in his 'Manual of British Botany,' enumerates ten species as inhabitants of Great Britain. The most common forms of the genus on cultivated lands are *A. angustifolia*, *A. erecta*, and *A. patula*. Mr. Babington has described a new species, which is also found not uncommonly in the United Kingdom. This is *A. deltoidea* (Babington): it has an erect stem with ascending branches; opposite leaves, all hastate-triangular, with two descending lobes unequally dentate or sinuate-dentate; the perigone of the fruit ovate-triangular, dentate, tunicated on the back, rather longer than the fruit, collected into a many-flowered, branched, dense panicle; seeds smooth, shining. *A. rosea*, *A. laciniata*, *A. littoralis*, are frequent plants on the sea-shore. *A. prostrata* is a coast plant, but is rare in Great Britain, and Babington suspects that it may be a maritime form of *A. patula*.

A'TROPA, a genus of Dicotyledonous Plants belonging to the natural order *Solanaceæ*, and consisting for the most part of poisonous species. It is distinguished from other genera of the same natural order by its regular bell-shaped corolla, its 5-parted permanent calyx, which never acquires a bladdery appearance, and by its succulent fruit.

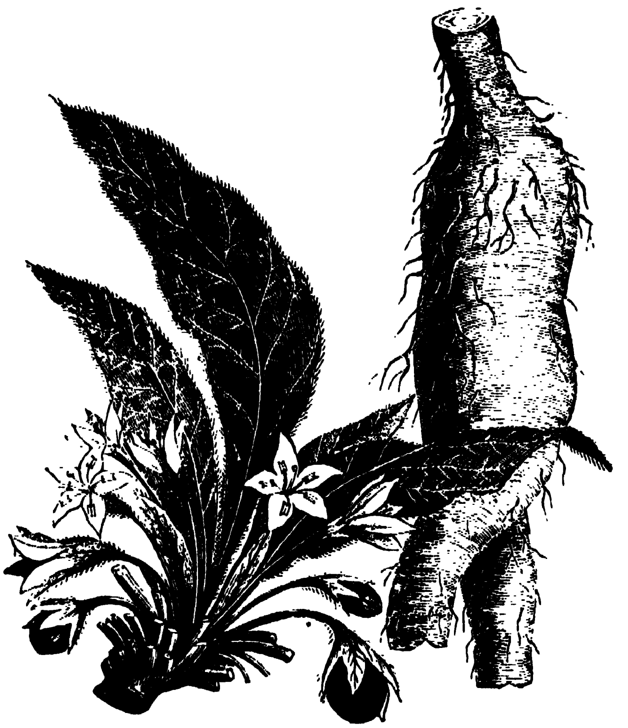
Atropa Belladonna, Deadly Nightshade, or Dwale, is found not unfrequently in thickets and hedges in this country. The whole plant is of a lightish green colour, except the flowers, which are large and of a dingy brownish purple, and the berries, which are of the rich deep black of black cherries. The root is perennial, the stem grows about 2 feet high, and the leaves are acute, with an oblong figure, tapering to each end. The flowers are bell-shaped, larger than those of the harebell, and placed singly in the bosom of the leaves. The border of the corolla is cut into 5 equal lobes: there are 5 stamens, a tapering pistil with 2 cells, and many seeds in the ovary, a long slender style, and a flattened stigma slightly divided into two lobes. The odour of the whole plant is nauseous and oppressive, as if to warn us of its venomous nature. It is in the leaves, root, and berries that the poison resides, and particularly in the berries, which from their resemblance to cherries have often been eaten by children with fatal consequences. The active property of Belladonna, though most commonly remarked in the fruit, exists also in the leaves, and especially in the roots, both of which have the same acrid narcotic property. They have nevertheless been frequently employed medicinally, and extract of Belladonna is one of the most energetic preparations in the modern Materia Medica.



Deadly Nightshade (*Atropa Belladonna*).

1, A corolla cut open, showing the position of the stamens; 2, the calyx, with the pistil; 3, a berry cut in half to show its two cells, in each of which are several seeds.

Atropa Mandragora, or Mandrake, is another species still more venomous and dangerous than the last. It is found in many parts of the south of Europe, particularly in the Grecian islands, where it is common. Its root is a large dark-coloured fleshy mass, often divided into two or three forks, which have been fancied to resemble a human body; this circumstance, and its well-known poisonous qualities, gave it in the days of popular ignorance and credulity the reputation of being endowed with animal feelings; the roots were said to shriek when torn from the earth, and it was accounted dangerous to disturb them.



Mandrake (*Atropa Mandragora*).

This remarkable plant has no apparent stem, but its long hairy sharp-pointed leaves rise from the surface of the ground, and form a deep green tuft, from the midst of which the flowers rise on slender stalks about two inches long. Their corolla is of a whitish colour, stained with veins of dingy purple; the fruit is pale orange-coloured, and about as large as a sparrow's egg. The smell of the whole plant is very fetid.

Atropa physaloides, a plant called Alkekengi in gardens, where it is often cultivated as a hardy annual, belongs now to the genus *Nicandra*.

A'TRYPA (Dalman), a subdivision of the great genus *Terebratula*, chiefly (if not entirely) confined to a fossil state, and to the Palæozoic Strata. Many of the *Spiriferæ* of Sowerby (as *S. glabra*, *S. fimbriata*) and some of the *Terebratulæ* of the same author (as *T. pugnus*), have been referred to this genus. *T. psittacea* is the recent analogue.

ATTALE'A, a genus of Palms, found chiefly in the tropical parts of America, where it occupies the richest soil and the hottest forests, rarely ascending the sides of mountains, or spreading from the woods into the open country. It extends, according to Von Martius, as far south as the tropic of Capricorn. It belongs to the same division of the natural order *Palmaceæ* as the cocoa-nut, from which as well as from all its immediate allies, except Areng [ARENG], it is distinguished by its nut containing three cells and three seeds. It is described by Von Martius as consisting of lofty or middle-sized or even occasionally stemless species, with a thickish trunk, the wood of which is soft and of a reddish-brown colour; it is irregularly marked externally with scars, and is terminated by large pinnated leaves, the stalks of which are broad, and the segments smoothish, rather thick, plaited, and neat-looking. The bunches of fruit are simply branched, but are often of a vast size, and hang down from the bosoms of the leaves, covered with brownish nuts, the seeds of which are eatable. Several species are known, of which the most remarkable are the two following:—

Attalea funifera, called by the natives Piaçaba, is found in the native forests of the maritime provinces of Brazil, where it is one of the most valuable gifts which the bountiful hand of nature has conferred on man. The best cordage in South America for naval purposes is manufactured from the fibres of the leaf-stalks and other parts; such ropes are of great strength, and are extremely durable in salt water: no other cables are employed in a great part of the Brazilian navy. This species does not grow more than from 20 to 30 feet high; its nuts, which are about as large as an ostrich's egg, have a hard shell like that of the cocoa-nut.

Attalea compta, another species, is equally useful, but for different purposes. This plant, the Pindova of the old writers on Brazil, and the Indajà of the modern Portuguese, forms delightful groves in the interior of the country, growing from 20 to 50 feet clear of its branch-like leaves; the latter are from 15 to 20 feet long, and about 3 feet wide. The fruit is the size of a goose's egg, and contains an eatable kernel, of which the negroes are fond. Its leaves form an excellent thatch, and are woven into hats mats, and baskets.

Attalea compta.

Attalea speciosa is the plant which, in the provinces of Maranhaõ and Para, furnishes the nuts which the Brazilians burn for the purpose of smoking the juice of *Siphonia elastica*, or Indian Rubber, until it becomes black.

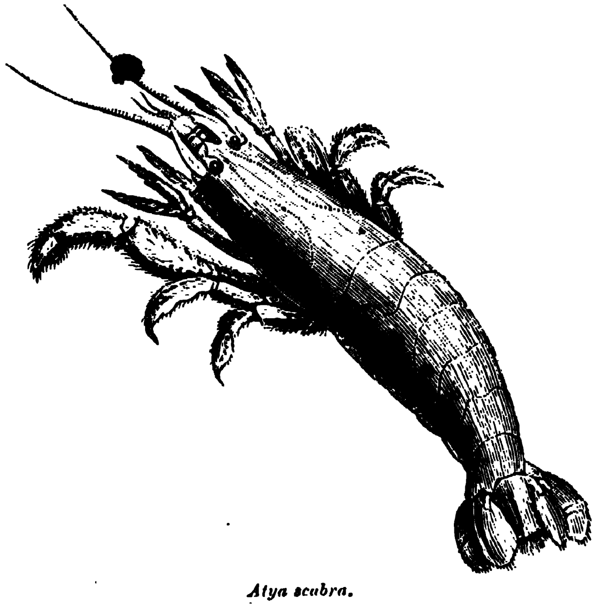
A'TYA, a genus of Crustaceous Animals, thus characterised by Leach:—

Antennæ, interior, furnished with two bristles, inserted in the same horizontal line; exterior, inserted below the interior, about the length of the body, furnished at the base with a great scale which is unidentate, or one-toothed, externally.

Pedipalpi external, the last joint shortest; flagrum elongated.

Feet: the two anterior pairs equal, penultimate joint shortest; last joint divided; laciniæ equal, furnished at the apex with long cilia; third pair large, unequal, furnished with a very short nail; two posterior pairs furnished with a moderate-sized nail.

Tail, with the exterior lamella bipartite.



Atya scabra.

"It forms," says Leach, "a peculiar subdivision of the Shrimp Family, and one species only is known."

A'TYLUS, a genus of Crustaceous Animals, thus characterised by Leach:—

Antennæ composed of four joints, the last of which is formed of several minute articulations: upper ones rather shortest, with the second joint longer than the third; under ones with the second joint rather shorter than the third.

Eyes slightly prominent, inserted on a process between the upper and lower antennæ.

Legs fourteen; first and second pair furnished with a small compressed hand, which has a moveable thumb; the other pairs having only a simple claw.

Atylus carinatus.

Tail, on each side, with a triple series of double styles; upper part on each side armed with a small spine or style.

Body (including the head) composed of twelve joints. Example - *Atylus carinatus* (*Gammarus carinatus*, Fabr.).

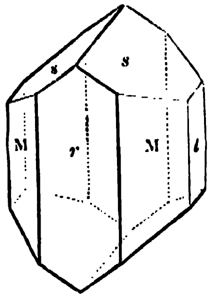
AUCHE'NIA, a genus of *Ruminating Mammalia*. [LLAMA.]

AU'CUBA, a genus of plants belonging to the natural order *Cornaceæ*. Only one species is known. It is a Japanese plant, commonly cultivated in the gardens of this country as a hardy evergreen shrub, remarkable for its shining pale-green leaves mottled with yellow, hence sometimes called Variegated Laurel. It is described by Thunberg as growing to the height of a man or higher, and as common in various places in Japan, both wild and cultivated. Its fruit, which it bears in March, is a red berry, about the size of that of a laurel, and containing a single stone, with a bitter nauseous kernel. This plant is diœcious, and in this country we have only the pistilliferous flowers. The plant, however, which is cultivated in this country is only a variety: in its natural state it is said to have brownish-green leaves without any blotches.

AUGITE. The minerals to which this name has been applied present us with some of the most interesting and at the same time most difficult investigations that can fall under the notice of the mineralogist and chemist, and have frequently occupied the attention of the most eminent men in both sciences. Nor are these bodies unworthy of such attention; for not only would a thorough knowledge of their constitution, and the relation which they bear to other minerals, particularly to the genus *Hornblende*, tend much to the perfection of the mineralogical system; but, owing to their frequent occurrence in nature, and from their forming one of the principal ingredients in many porphyritic and trap rocks, such as the Syenite, Diallage, and Schorl-Rocks, Greenstone, &c., they form a class of bodies of the highest importance to the geologist. A due regard to the circumstances which are favourable to the formation of one or other of the species, to the exclusion of the rest, would be likely to afford a safe guide in many geological inquiries into the character and formation of rocks of igneous origin. Werner was the first to divide a large class of minerals occurring commonly in basalt, lavas, and other volcanic rocks, into two species, to which he applied the names of *Augite* and *Hornblende*. This division was founded on the difference existing between the crystallised forms and structure, which, according to the experience up to that time, were never associated with each other. The same division was shortly after adopted by Haüy, who applied to them the names of *Pyroxene* and *Amphibole*, and gave the measurements, determining the oblique rhombic prisms, with their most general modifications characteristic of either species, which however we have modified by the later measurements of Rose, Mitscherlich, and Kupffer.

Augite, or *Pyroxene*.

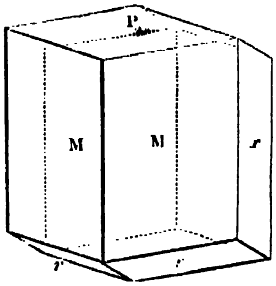
Fig. 1.



Inclination of M on M is 87° 6′
M on r 133° 33′
M on l 136° 27′
s on s 120° 57′
$\frac{s}{s}$ on r 106° 6′

Hornblende, or *Amphibole*.

Fig. 2.



Inclination of M on M is 124° 31′
M on r 117° 44′
P on M 103° 13′
P on $\frac{M}{M}$ 104° 57′
r on r 148° 25′
$\frac{r}{r}$ on $\frac{M}{M}$ 104° 57′

By $\frac{s}{s}$, $\frac{M}{M}$, is meant the edge formed by the intersection of the faces s and s, M and M, &c.

Professor Mohs, however, together with Professor Jameson of Edinburgh, has used the term *Augite* to denote the eighth genus of their respective systems, which consists of the four species designated as follows:—

First species. The *Oblique-Edged Augite*, corresponding with the *Augite* of Werner, and *Pyroxene* of Haüy.

Second species. The *Straight-Edged Augite*, corresponding to *Hornblende* and *Amphibole*.

Third species. *Prismatoidal Augite*, containing as sub-species the minerals *Epidote* or *Zoisite*.

Fourth species. *Prismatic Augite;* Tabular Spar or *Wollastonite*.

Berzelius, on the contrary, viewing the subject in a chemical point of view, has been induced to use the term Augite or Pyroxene, Hornblende or Amphibole, in the same signification as employed by Werner and Haüy. According to him, the Augites are composed of one equivalent of the bisilicate of lime united with one equivalent of the bisilicate of magnesia.

There are several varieties of this genus formed by the removal of the magnesia or lime, which are replaced either by one or both of the isomorphous substances—the protoxide of iron, and protoxide of manganese. Of these the following are the principal:—

1. *Diopside*, which may be considered as the type of the Augite Genus, is readily recognised by the form of its crystal given in *fig.* 1, and by the direction of its four cleavage planes, the most perfect corresponding with the faces M, those in the direction of r and l being less easily obtained; and by its pale-green or grayish-white colour, and vitreous lustre. Its hardness is 5·5, and its specific gravity is 3·299. Alone before the blowpipe it melts into a colourless semi-transparent glass; with borax, very readily into a transparent glass. It consists chiefly of silica, lime, and magnesia, as will be seen by the following analysis of a variety from Tammare by Bonsdorff:—

Silica	54·83	Protoxide of Iron .	0·99
Lime	24·76	Alumina	0·28
Magnesia . . .	18·55	Loss by heating . .	0·32
			99·73

Several varieties, little differing from the above, are called *Backalite* and *Fassaite*, names indicative of their locality.

2. *Hedenbergite* consists chiefly of silica, lime, and protoxide of iron, as may be seen by the following analysis by G. Rose of a variety from Lunaberg:—

Silica	49·01
Lime	20·87
Protoxide of Iron	26·08
Protoxide of Manganese with Magnesia . . .	2·98
	98·94

It is of a dark green colour, sometimes nearly black.

3. *Sahlite*, those varieties in which the magnesia is only in part replaced by protoxide of iron, and which may be regarded as consisting of one equivalent of *Hedenbergite* united with two of *Diopside*. A variety is called *Malakolith*. ('Anwendung der Löthrohrs,' by Berzelius.)

4. *Diallage*. The difference in the analysis by Köhler of two specimens, the first from Tuscany, the second from Ulthenthal in the Tyrol, were as follows:—

Silica	53·20	56·81
Lime	19·08	2·19
Magnesia	14·91	29·67
Protoxide of Iron	8·67	8·46
Protoxide of Manganese . .	0.38	0·61
Alumina	2·47	2·07
Water	1·77	0·21
	100·48	100·02

This variety is characterised by its mother-of-pearl lustre, and by its possessing the most perfect cleavage in the direction of the diagonal of the prism. It is seldom found in perfect crystals. Its most general colour is a bronze yellow.

5. *Hypersthene*, which is very similar in its general appearances and characters to *Diallage*, is a bisilicate of iron and magnesia. Both of the last-mentioned varieties may be distinguished from the former, as well as from each other, by means of the blowpipe, and by attending to the following characters as stated by Berzelius:—

Diallage alone in a matrass decrepitates, becomes of a lighter colour, and gives off a little water.

On charcoal it is with difficulty melted on the edges into a grey scoria.

With borax it is with difficulty fused into a clear glass, somewhat coloured by the protoxide of iron.

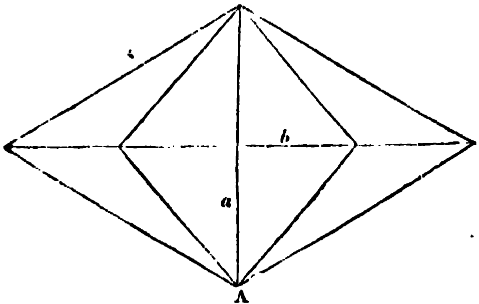
It is decomposed by the phosphate of soda and ammonia, with the development of the silica.

Hypersthene, on the contrary, when heated alone in the matrass, decrepitates slightly, gives out a little water, but does not change its appearance; while on charcoal it readily forms a green opaque glass, as is also the case when heated with borax.

The salt of phosphorus does not apparently decompose it, but the mineral at first becomes rounded on the edges, and may at length be entirely fused.

The structure also deserves particular attention, the cleavage-planes in *Hypersthene* being perfect, both in the direction of the faces *r* and M, the latter of which are obtained in *Diallage* with very great difficulty.

We have now described the various species generally considered as comprehended within the genus *Augite* or *Pyroxene*; but Professor Gustave Rose has endeavoured to prove the necessity of uniting *Augite* and *Hornblende* (*Pyroxene* and *Amphibole*) into one genus. His arguments for this union are the following:—He first shows that the two prisms of *Augite* and *Hornblende*, however different in appearance, admit of being derived the one from the other, according to the laws observed to connect the crystallographic forms of varieties of the same genus in other minerals. To show this, let the accompanying parallelogram, whose semi-diagonals are *a* and *b*, represent the horizontal section of the prism of *Augite*; since the whole angle of this prism at A is 87° 6′, *b* is the tangent of an angle of 43° 33′; if this tangent be doubled, the corresponding angle will be found to be 62° 15′ 25″, the double giving 124° 30′ 50″, an angle agreeing most closely with 124° 31′, the angle obtained by Mitscherlich in a species of *Hornblende* when measured by Wollaston's reflecting goniometer. The larger parallelogram, therefore, formed by doubling the diagonal *b*, is the horizontal section of the prism of *Hornblende*.



A similar relation is also approximately true for the inclination of the faces *s* in *Augite* and *r* in *Hornblende*; for if the angle 120° 57′ of *Augite* be halved, and its tangent doubled, the corresponding angle is 74° 11′ 21″, and by doubling this we obtain 148° 22′ 42″, not much differing from 148° 25′, as found between *r* in *Hornblende* of Vesuvius by Rose.

His argument drawn from the chemical constitution of these minerals is by no means so satisfactory; for though in *Hornblende* we find a series of bisilicates of the same bases, and as it were running parallel with those already described as *Augites*, the circumstance observed by Bonsdorff, that all the varieties of *Hornblende* contain fluorine, while Gustave Rose has been unable to detect that element in *Augite*, weakens the connection between these minerals, and renders the determination of what part the fluorine acts in their constitution a most desirable object. Our ignorance on this point, however, and the difficulty of determining what is the action of the alumina, which occurs in considerable quantity in some *Hornblendes*, prevent us from forming any opinion from the results of chemical analysis.

The observations of Rose, however, on the Greenstone of the Uralian Mountains, tend to prove the existence of that connection between the forms of *Augite* and *Hornblende* which is essential to their constituting one genus, in a more satisfactory manner than any remark hitherto made. He discovered in a soft grayish Greenstone, near the village of Mostowaja, which is situated north of Katharinenburg, and on the road to Newiansk, and also at the gold-washings of Cavellinski, near Miask, in a Greenstone somewhat harder and darker than the former, imbedded crystals, having the form of *Augite*, but not its cleavage planes, these last being found to coincide with those of *Hornblende*. This mineral was therefore either *Hornblende* in the form of *Augite*, or *Augite* with the cleavage planes of *Hornblende*.

At the village of Muldakajewsk, near Miask, he discovered still more interesting crystals embedded in a Greenstone similar to that last described. They were abundant, and possessed the form of *Augite*: the smaller crystals had cleavage-planes parallel to the sides of the prism of *Hornblende*, and were similar in their appearance and colour to those obtained from Cavellinski. The larger crystals, however, possessed a kernel of a grass-green colour, and of a lighter tint and greater lustre than the exterior. This kernel differed from the darker exterior portion of the crystal, the latter giving the cleavage of *Hornblende*, while the former presented those of *Augite*, with faces sufficiently bright and perfect to admit of measurement by the reflecting goniometer.

The observations of Mitscherlich and Berthier on the formation of *Augite* as an artificial product, are so interesting in themselves and throw so much light on the nature of *Augite* in general, and on those crystals we have just described, for which Rose proposes the name of *Uralite*, that we cannot omit to notice them in this place. Mitscherlich has observed that at many foundries in Sweden and Germany the scoriæ possessed the form, structure, and chemical composition of certain minerals found in nature. From this source he has obtained upwards of forty varieties; and among these specimens possessing the form and structure of *Augite* are frequently found, whereas *Hornblende* has never been discovered. Guided by these observations, a mixture of silica, lime, and magnesia, in the proportion indicated by the formula of *Diopside*, given below, was submitted to fusion in the porcelain-ovens of Sèvres, near Paris. On examination, the mass was found to have been completely fused: it possessed cleavage-planes corresponding with those of *Augite*, and a hollow formed in the centre from the contraction in cooling contained crystals of the form of *fig.* 1. By these processes they failed in obtaining crystals either of the form or structure of *Hornblende*.

Professor G. Rose, in accounting for this production of *Augite* to the exclusion of *Hornblende*, was led to consider that it was not the absence of the fluorine, or any error in the proportion of the elements, which prevented the production of *Hornblende*, but that it was the effect of the rapid cooling. This he fully confirmed by the following experiments:—A light-green variety of *Hornblende*, the *Strahlstein* of the Germans, from Zillerthal in the Tyrol, was submitted in a platinum crucible to the heat of a porcelain oven. It was completely fused, and in cooling had formed fibrous tufts of dark crystals, which however admitted of measurement by Wollaston's goniometer, when the angles were found to correspond with those of *Augite*. A specimen of *Diopside*, of the same locality, was also fused; it cooled into a dark mass, but regained its former structure.

We may therefore consider it to be demonstrated that *Augite* is formed whenever the process of cooling, and consequently of crystallisation, is rapid; and *Hornblende*, when it is conducted more slowly. Many circumstances confirm this view: the *Uralites* of Rose appear to be its natural consequence; for as by the laws of caloric we know that the quantity of heat lost during equal portions of time varies with the temperature, the exterior portions of the crystal from this cause alone must have crystallised under a more gradual loss of heat than the interior, while at the same time the temperature would be maintained by the specific heat given out by the parts first consolidated. The general localities of *Augite* and *Hornblende*, and the minerals with which they are found associated, afford another argument in favour of this supposition; for *Hornblende* is usually met with in Syenite, Trachyte, and Lava, accompanied by Quartz, Felspar, Albite, &c.,—minerals which decidedly require a slow process of cooling for their formation; on the contrary, *Augite* occurs in Basalt and Lava with *Olivine*, which Mitscherlich has recognised in the scoriæ of various foundries, and which is therefore formed by a process of rapid cooling. We are thus able to account for H. von Buch's remark in his observations on volcanoes, that those Lavas which contain Felspar have *Hornblende*, but no *Augite*.

Induced by these circumstances Rose, in a tabular view of the minerals which he has added to his 'Elements of Crystallography,' published at Berlin in 1833, has united into one genus the following species.

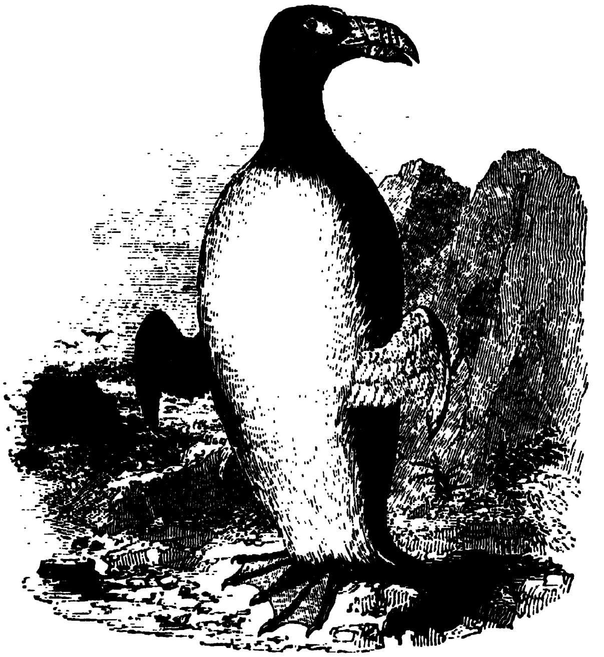
1. *Diopside*	$\dot{\mathrm{Ca}}\,\dot{\mathrm{Si}}^{2} + \dot{\mathrm{Mg}}\,\dot{\mathrm{Si}}^{2}$.
2. *Sahlite*	$\dot{\mathrm{Ca}}\,\dot{\mathrm{Si}}^{2} + \left.\begin{matrix}\dot{\mathrm{Mg}}\\ \mathrm{Fe}\end{matrix}\right\}\dot{\mathrm{Si}}^{2}$.
3. *Hedenbergite* . . .	$\dot{\mathrm{Ca}}\,\dot{\mathrm{Si}}^{2} + \dot{\mathrm{Fe}}\,\dot{\mathrm{Si}}^{2}$.
4. *Basaltic Augite* . .	$\dot{\mathrm{Ca}}, \dot{\mathrm{Mg}}, \dot{\mathrm{Fe}}, \dddot{Al}, \dot{\mathrm{Si}}$.
5. *Rothbraunsteinerz* .	$\dot{\mathrm{Mn}}\,\dot{\mathrm{Si}}^{2}$.
6. *Acmite*	$3\,\dot{\mathrm{Na}}\,\dot{\mathrm{Si}}^{3} + 2\,\ddddot{Fe}\,\dot{\mathrm{Si}}^{6}$.
7. *Diallage*	$\dot{\mathrm{Mg}}\,\dot{\mathrm{Si}}^{2} + \left.\begin{matrix}\dot{\mathrm{Ca}}\\ \dot{\mathrm{Fe}}\end{matrix}\right\}\dot{\mathrm{Si}}^{2}$.
8. *Bronzite*	$\dot{\mathrm{Mg}}\,\dot{\mathrm{Si}}^{2}$.
9. *Hypersthene* . . .	$\dot{\mathrm{Mg}}\,\dot{\mathrm{Si}}^{2} + \dot{\mathrm{Fe}}\,\dot{\mathrm{Si}}^{2}$.
10. *Uralite*	
11. *Tremolite*	$\dot{\mathrm{Ca}}\,\dot{\mathrm{Si}}^{3} + 3\,\dot{\mathrm{Mg}}\,\dot{\mathrm{Si}}^{2}$.
12. *Antophyllite* . . .	$\dot{\mathrm{Fe}}\,\dot{\mathrm{Si}}^{3} + 9\,\dot{\mathrm{Mg}}\,\dot{\mathrm{Si}}^{2}$.
13. *Strahlstein*	$\dot{\mathrm{Ca}}, \dot{\mathrm{Mg}}, \dot{\mathrm{Fe}}, \dddot{Al}, \dot{\mathrm{Si}}$.
14. *Basaltic Hornblende*	$\dot{\mathrm{Ca}}, \dot{\mathrm{Mg}}, \dot{\mathrm{Fe}}, \dddot{Al}, \dot{\mathrm{Si}}$.

AUK, the common name for certain sea-birds of the family *Alcadæ*, including species of the sub-genera *Alca*, *Fratercula*, *Mergulus*, and *Phaleris*.

Alca. [ALCA.]

The true Auks, though they are strictly oceanic birds, scarcely ever leaving the water except for the purposes of reproduction, will sometimes proceed swiftly though awkwardly on foot when pursued on land. They breed in large companies, in caverns and rocky cliffs, laying only one disproportionately large egg. Their food, which they obtain by diving (an operation in which they are materially assisted by their wings as well as by their feet), consists of small fishes, crustaceans, and other marine animals. The young are said to be fed from the crops of their parents, not only before they are able to leave the place of their birth, but also for some time afterwards.

The genus *Alca*, as it is reduced by modern ornithologists, includes but two species. The first of these, the Great Auk (*Alca impennis*, Linnæus), is remarkable for the imperfect development of its wings. It seldom leaves the Arctic Circle and the regions bordering on it, and is a rare visitant to the British Isles. Dr. Fleming however gives an account of one taken alive at St. Kilda, where they are sometimes known to breed, which, even with a long and heavy cord tied to its leg, swam under water with extraordinary speed. The power of the apparently useless wings as organs of progression was still more strongly shown in the Great Auk chased ineffectually by Mr. Bullock during his tour to the Northern Isles; for the four oars of the bird are said to have left the six-oared boat of his pursuers far behind. According to the same authority, only a single pair had been known to breed in Papa Westra for several years. Newfoundland is recorded as one of their breeding places, and Pennant relates that the Esquimaux who frequented the island made clothing of their skins. In the ocean that washes the Faroe Isles, Iceland, and Greenland, where they dwell in great numbers, they may be frequently seen on the floating ice; but Pennant says that they are observed never to wander beyond soundings, and that seamen direct their measures according to their appearance.



Great Auk (*Alca impennis*).

The food of the Great Auk consists principally of fish; and the Lump-Fish (*Cyclopterus lumpus*) is said to be its favourite morsel.

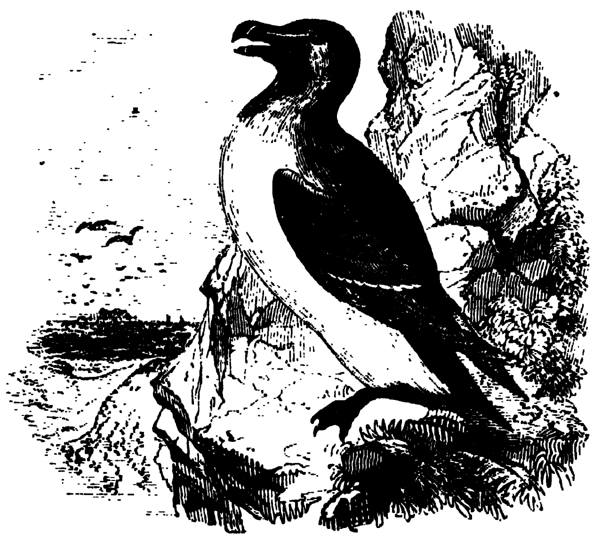
The length of the bird is somewhat under three feet. The winter plumage, which begins to appear in autumn, leaves the cheeks, throat, fore part and sides of the neck white. In spring the summer-change begins to take place, and confines the white on the head to a large patch, which extends in front and around the eyes; the rest of the head, the neck, and upper plumage is of a deep black. There is a specimen of the bird in its summer dress in the British Museum. The Great Auk breeds in June and July, laying one egg, about the size of a swan's, of a whitish-yellow, marked with numerous lines and spots of black, which have been supposed to bear some resemblance to Chinese characters.

In the Black-Billed Auk, Razor-Bill, or Murre (*Alca torda*, Linnæus), the development of the wings is carried to the usual extent necessary for the purposes of flight, though the bird uses them with great effect as oars when swimming under water.

The northern hemisphere, where they are widely diffused, is the region allotted to these birds; but it is in the higher latitudes that they swarm. In England, the Needles and other adjacent precipitous cliffs have a fair share of them; and here, as in other places, the 'dreadful trade' of taking their eggs, which are esteemed a delicacy for salads especially, is carried on. In Ray's ed. of Willughby the habits of the Razor-Bill are thus described:—"It lays, sits, and breeds up its young on the ledges of the craggy cliffs and steep rocks by the sea-shores that are broken and divided into many as it were stairs or shelves, together with the Coulter-Nebs and Guillemots. The Manksmen are wont to compare these rocks, with the birds sitting upon them in breeding-time, to an apothecary's shop—the ledges of the rocks resembling the shelves, and the birds the pots. About the Isle of Man are very high cliffs broken in this manner into many ledges one above another from top to bottom. They are wont to let down men by ropes from the tops of the cliffs, to take away the eggs and young ones. They take also the birds themselves when they are sitting upon their eggs, with snares fastened to the ends of long poles, and put about the necks of the birds. They build no nests, but lay their eggs upon the bare rocks."

On the coast of Labrador they abound, and the thousands of birds there killed for the sake of the breast-feathers which are very warm and elastic, and the quantities of eggs there collected, amount to almost incredible numbers.

The summer and winter dress of the Razor-Bill, though different, do not vary so remarkably as the plumage of many other birds. In the summer dress, the white streak which goes to the bill from the eyes becomes very pure; and the cheeks, throat, and upper part of the front of the neck are of a deep black, shaded with reddish. In winter the throat and fore part of the neck are white.



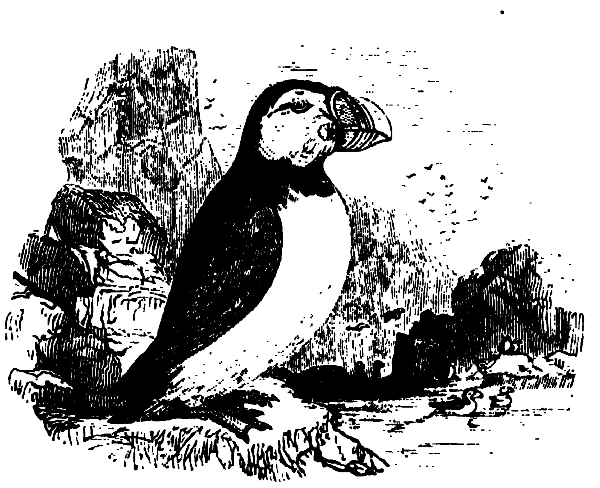
Razor-Bill (*Alca torda*).

The young of the year is by the best authorities supposed to be the *Alca Pica* of Gmelin.

The Razor-Bill is little more than 15 inches long. The egg (for they lay but one) is very large in proportion to the bird, being about the size of that of a turkey, but of a longer shape, pointed towards the smaller end, white or sometimes yellowish, blotched, and streaked with dark brown, chiefly towards the larger end.

Fratercula.

Leaving the true Auks we come to the genus *Fratercula*, Briss. (*Mormon*, Illiger), of which the Labrador Auk, Common Puffin, or Coulter-Neb (*Fratercula Arctica*, *Mormon fratercula*, Temm., *Alca Arctica*, Linn.), may be taken as an example.



Common Puffin (*Fratercula Arctica*).

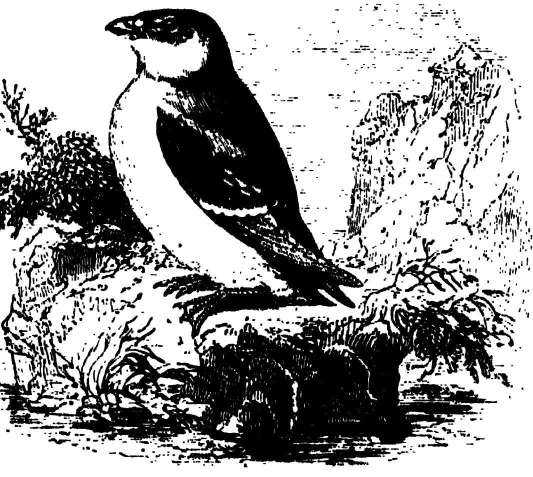
Selby gives the following account of the habits of this bird, and is corroborated by others who have written on the subject:—"Although the Puffin is found in very high latitudes, and its distribution through the Arctic Circle is extensive, it is only known to us as a summer visitant, and that from the south, making its first appearance in the vicinity of its breeding stations about the middle of April, and regularly departing between the 10th and 20th of August for the southern coasts of France, Spain, and other parts of Europe, where it passes the remainder of the year. It breeds in great numbers upon Priestholm Island, off the coast of Anglesey, on the Isle of Man, and most of the islands indeed of the English and Scottish coasts. Many resort to the Faroe Islands, selecting such as are covered with a stratum of vegetable mould; and here they dig their own burrows, from there not being any rabbits to dispossess upon the particular islets they frequent. They commence this operation about the first week in May, and the hole is generally excavated to the depth of three feet, often in a curving direction, and occasionally with two entrances. When engaged in digging, which is principally performed by the males, they are sometimes so intent upon their work as to admit of being taken by hand, and the same may also be done during incubation. At this period I have frequently obtained specimens by thrusting my arm into the burrow, though at the risk of receiving a severe bite from the powerful and sharp-edged bill of the old bird. At the farther end of this hole the single egg is deposited, which in size nearly equals that of a pullet, and, as Pennant observes, varies in form; in some instances one end being acute, and in others both equally obtuse. Its colour when first laid is white, but it soon becomes soiled and dirty from its immediate contact with the earth, no materials being collected for a nest at the end of the burrow. The young are hatched after a month's incubation, and are then covered with a long blackish down above, which gradually gives place to the feathered plumage; so that at the end of a month or five weeks they are able to quit the burrow, and follow their parents to the open sea. Soon after this time, or about the second week in August, the whole leave our coasts, commencing their equatorial migration. At an early age the bill of this bird is small and narrow, scarcely exceeding that of the young Razor-Bill at the same period of life; and not till after the second year does this member acquire its full development, both as to depth, colour, and its transverse furrows."

In rocky places (Dover cliffs for instance) they deposit their single egg, as Montagu observes, in the holes and crevices. The length of the bird is about 12 inches. The half of the bill nearest the head is bluish; the rest red. The corners of the mouth are puckered into a kind of star. The legs and feet are orange. The plumage is black and white, with the exception of the cheeks and chin, which are sometimes gray. The young pickled with spices are by some considered dainties; they are also occasionally potted in the north.

Sprats are supposed to be the principal food of the Puffin, but there is little doubt that other fishes and crustaceans are acceptable to the bird.

Mergulus.

The Little Auk, Common Rotche, or Sea-Dove (*Mergulus melanoleucos* of Ray, *Uria Alle* of Temminck, and *Alca Alle*, Linnaeus), is an example of the genus *Mergulus* of our countryman Ray.



Little Auk (*Mergulus melanoleucos*).

The Little Auk braves the inclemency of very high latitudes, and congregates in great flocks far within the Arctic Circle. The inhospitable coasts of Greenland and Spitzbergen are the dwelling-places of these birds, and thousands have been seen at Melville Island. In those dreary regions they are said to watch the motion of the ice, and when it is broken up by storms down they come in legions, crowding into every fissure to banquet on the crustaceans and other marine animals which there lie at their mercy. It can hardly be called an occasional visitant to this country, for those which have appeared here have been evidently exhausted birds, buffeted by storms and driven by contrary winds far from the spot congenial to their habits. The Little Auk is between 9 and 10 inches in length; the bill is black, and the legs inclining to brown; the plumage is black and white, and in winter the front of the neck, which is black in summer, becomes whitish: the change takes place in the autumn.

The bird lays only one egg of a pale bluish-green, on the most inaccessible ledges of the precipices which overhang the ocean.

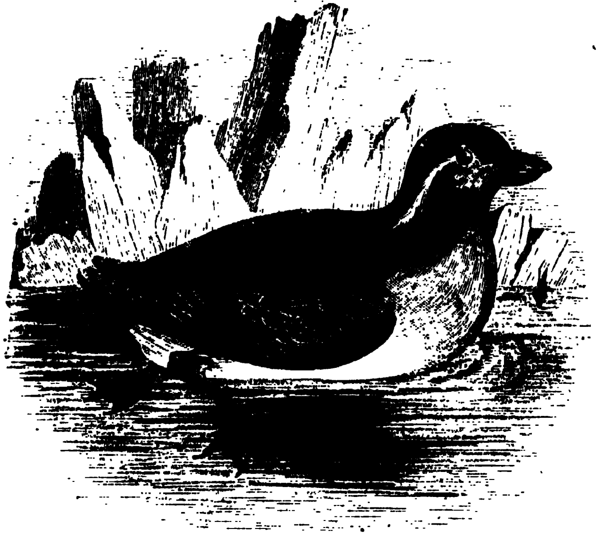
Phaleris.

The Perroquet Auk (*Phaleris psittacula*, Temminck, *Alca psittacula*, Pallas), may be taken as an illustration.

Kamtchatka and other northern regions shelter these birds in abundance. They swim and dive admirably. Stories are told to prove their unsuspicious character; and it is said that the natives place a dress with large sleeves near their holes and burrows, into which the artless birds, mistaking the sleeves aforesaid for their own retreats, creep and are taken.

About midsummer they lay one large egg nearly of the size of a hen's, with brown or dusky spots on a whitish or yellowish ground.

The Perroquet Auk is about 11 inches in length. From behind the eye a tuft of white feathers, which hang on either side of the neck, shoots forth. The head, neck, and upper parts are black, blending into ash-colour on the fore part of the neck; the under parts from the breast are white; the legs are yellowish. In the old bird the bill is red, while the young one has it of a yellowish or dusky colour.



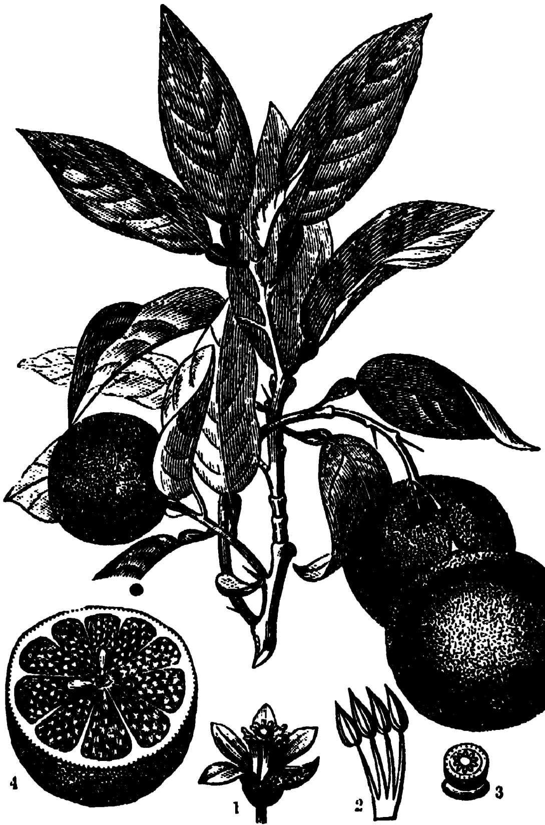
Perroquet Auk (*Phaleris psittacula*).

(Yarrell, *British Birds.*)

AU'LOLEPIS, a genus of Fossil Cycloïd Fishes, from the Chalk of Sussex and Kent. (Agassiz.)

AULO'PORA (Goldfuss), a genus of Fossil *Polypiaria*, from the Silurian Strata.

AURANTIA'CEÆ, *Citron Worts*, or the Orange Tribe, are Dicotyledonous Polypetalous Plants, with dark-green jointed leaves, filled with fragrant essential oil collected in little transparent dots, and a superior ovary changing to a succulent berry, the rind of which is



Common Orange (*Citrus Aurantium*).

1, A flower with its calyx, corolla, stamens, and style; 2, a portion of the stamens; 3, an ovary cut through transversely; 4, a fruit cut through in the same direction.

also filled with fragrant essential oil. No natural order can well be more strictly defined than the Orange Tribe, and none have properties more uniform and definite. It consists of trees or shrubs found exclusively in the temperate or tropical parts of the Old World, and unknown in a wild state in America. Their flowers are usually odoriferous, and their fruits subacid; the rind has some shade of yellow. They principally differ from each other in the number and proportion or arrangement of their stamens, in the number of cells or seeds in the fruit, and in the texture of the rind of the fruit, which does not always pull off as in the orange, the lemon, the citron, and their congeners, but is frequently a mere skin inclosing the pulp. [CITRUS.] The natural order which is most nearly allied to the Orange Tribe is that called *Xanthoxylaceæ*, into which the oranges pass by their climbing genus, *Lavanga*, and which differ principally in having a hard dry fruit which splits into several carpels.

The Orange, Lemon, Lime, Shaddock, Pompelmoose, Forbidden Fruit, and Citron, are the produce of this order. The Wampa, a fruit highly esteemed in China and the Indian Archipelago, is produced by *Cookia punctata*. The fruit of *Glycosmis citrifolia* is delicious; that of *Triphasia* is very agreeable. The *Ægle Marmelos* is used in medicine: a perfume is prepared from the rind of the fruit, which itself is delicious to the taste, and acts as a laxative medicine. The leaves of *Feronia elephantum* have a very agreeable smell. Orange flowers yield a delicious odour, and the oils of Bergamot and Lemon are obtained from the rind of the fruit of species of Citrus.

(Lindley, *Vegetable Kingdom.*)

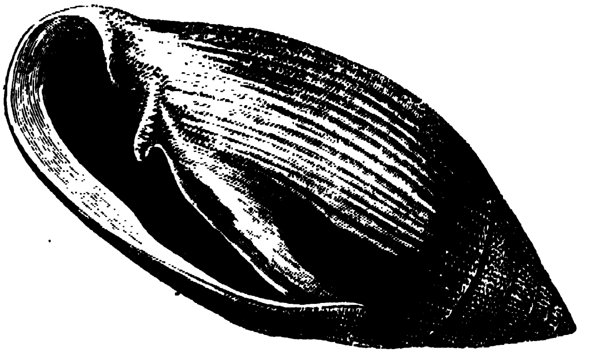
AURE'LIA, in Entomology, a name given to that state of an insect which is between the caterpillar and its final transformation, and is commonly called a Chrysalis or Pupa. The term Aurelia was first applied by the Romans, and that of Chrysalis by the Greeks, to certain butterfly pupæ which have a golden colour. In England, those of the Peacock-Butterfly (*Vanessa Iö*) and the small Tortoise-Shell Butterfly (*Vanessa Urticæ*) are beautiful examples, and may be seen in abundance hanging to the common stinging nettles about the latter end of the month of June. [PUPA.]

AURICHA'LCITE, a carbonate of Copper and Zinc. It occurs amorphous, sometimes granular, or in radiating masses. The colour is green. It is slightly transparent. Hardness but slight. It is found at Loktewsk in the Altai. The analysis by Böttger gives—

Oxide of Copper	28·19
Oxide of Zinc	45·84
Carbonic Acid	16·06
Water	9·91
	100

AURI'CULA, the name given to a commonly-cultivated species of the genus *Primula*. [PRIMULA.]

AURI'CULA, a genus of Phytophagous or Plant-Eating *Trachelipodous Mollusca*, whose organs of respiration are formed for breathing air. Cuvier observes, that the species of this genus differ from all the Pulmoniferous Aquatic Mollusks which precede them in his system, in having the columella or pillar of the shell marked by large plaits. The species of *Auricula* appear to live in the neighbourhood of rivers, lakes, or morasses, and their respiratory system, though formed for breathing air, is so framed as to enable them to sustain any vicissitudes to which such a locality might render them liable. *Auricula Midæ* (Lam.), *Voluta Auris Midæ* (Linn.), the Midas's Ear of collectors, is a good example of the genus.



Midas's Ear (*Auricula Midæ*).

It is said to be an inhabitant of the East Indies. Lamarck also names the Moluccas as its locality.

The following is the generic character:—Shell somewhat oval, or ovate-oblong; aperture longitudinal, narrowed above, and with the base entire; pillar with one or more plaits; outer lip either reflected or simple and acute.

The true *Auriculæ* are the inhabitants of warm climates. There is one in the south of France, near the shores of the Mediterranean (*Auricula myosotis* of Draparnaud), but it is a small species.

AUROTELLINITE, a mineral containing Gold combined with Tellurium.

AUST CLIFF. In the Bone-Bed of this famous locality, usually classed with the Lias Formation, occur a few organic remains which appear to belong also to the Keuper deposits. This has been thought a sufficient reason for removing these beds out of the Lias. But if we regard their mineralogical and geological relations, this displacement will hardly be allowed.

AUTOMALITE. [GAHNITE.]

AUTOMOLITE, a variety of *Spinel* [SPINEL] containing 34 per cent. of oxide of zinc. It is infusible alone, and nearly so with borax. It occurs in granite at Haddam, in Connecticut, together with Beryl, Chrysoberyl, Garnet, &c.; also near Falun in Sweden, in Talcose Slate.

AUTONO'MEA (Risso), a genus of Long-Tailed Decapodous *Crustacea*, founded on *Autonomea Olivii*, which is a little more than an inch in length, and bears great resemblance in form to *Nika* and *Alpheus*. *Autonomea* lives solitarily in sea-weed, &c., and the female produces red eggs, which she carries with her about the middle of summer. It is found in the Adriatic Sea. [SHRIMPS.]

AVANTURI'NE, a variety of Quartz, remarkable for the brilliancy with which it reflects light, the effect being in general produced by fine points of Mica imbedded within the crystalline mass. From this circumstance it is sometimes used in jewellery, but is of little value.

AVE'NA, the botanical name of the genus to which the cultivated Oat belongs. As understood by Linnaeus and the writers of his school, it comprehended many very distinct forms of Grasses, as well as the common cultivated kinds; but by other botanists it is more correctly limited to the species that yield corn, and to such as are closely allied to them. They are known by their lax panicles, their two loose membranous glumes, and by the small number of their florets, each of which has one of its husks or paleæ armed with a strong twisted beard or awn. The grain is generally, but not uniformly, closely invested with the hardened husk.

The Common Oat (*Avena sativa*), is that which is most generally cultivated for the use of man. Like most other corn-plants its native country is unknown; it cannot however be supposed to be the offspring of cultivation or of chance, but is more likely to be an inhabitant of some of the northern provinces of Asia to which Europeans have little access. [OAT, in ARTS AND SC. DIV.]

The Tartarian Oat is considered a distinct species, on account of its more compact and one-sided panicle, and of both its florets having a beard; it is however doubtful whether it can be regarded as anything more than a variety of *A. sativa*. Botanists call it *A. orientalis*, but its native country seems as uncertain as that of the last.

The Naked Oat (*A. nuda*), so called because its grain is loose in the husk, is found wild in many parts of Europe, and by some is thought to be a mere degeneration of the Common Oat. It is common in Austria, where it is cultivated for its grain, which is however small, and not much esteemed.

The Chinese Oat (*A. Chinensis*), is another species, the grain of which is loose in the husk. It is said to have been procured by the Russians from the north of China along with their tea. This species is the most productive of all the known kinds, every flower producing from three to five grains, which are large and of excellent quality. It is however said to be difficult to harvest on account of the grains not adhering to the husks, but being very easily shaken out.

Besides the species cultivated for the corn which they yield, there is another that deserves to be noticed on account of its remarkable hygrometrical action. This plant, the Animal Oat of gardeners, the *A. sterilis* of systematic writers, is something like the Common Oat when young; but when ripe its grains are inclosed in hard hairy brown husks, from the back of which rises a stout bent and twisted awn. Usually two such husks grow together, and separate from the stalk by a deep oblique scar. Taking the scar for the head of an insect, the husks with their long stiff brown hairs resemble its body, and the two bent awns represent its legs. In this state fishermen use a smaller but nearly allied species, called Havers (*A. fatua*) instead of artificial flies for catching trout. When the Animal Oat is ripe it falls out of its glumes, and in warm dry weather may be seen rolling and turning about on its long ungainly legs, as they twist up in consequence of their hygrometrical quality. It necessarily advances as it turns over, because the long stiff hairs upon its body catch against every little projecting point on the surface of the soil and prevent its retreat. Nothing can be more curious than to see the path of a garden-walk covered with these things tumbling and sprawling about in different directions, until their awns are so twisted that they can twist no further. They then remain quiet till the dews fall, or they are moistened by a shower, when they rapidly untwist and run about with renewed activity, as if anxious to get out of the wet.

AVENS. [GEUM.]

AVE'RRHOA, a genus of plants belonging to the natural order *Oxalidaceæ*. It consists of two species, both of which form small trees in the East Indies. They are remarkable for their leaves, which are pinnated, possessing in a slight degree the kind of irritability found in the sensitive plant, and for their fleshy oval fruits with five thick longitudinal wings. From the other genus of *Oxalidaceæ* they are known by this character, independently of all others.

In the Carambola (*A. carambola*) the leaves are smooth, the flowers of a violet-purple, and the fruit about the size of a goose's egg; it is of a pale yellow colour, and is said to be agreeably acid in the East Indies. It was expected that it would prove worth cultivating in the hothouse for the dessert, but it proves upon trial to be insipid, and much inferior to the common fruit of the European markets.

The other species, called the Beimbing (*A. bilimbi*), has downy leaves, and fruit resembling a small cucumber. The fruit is intensely acid, and cannot be eaten raw. It is pickled or candied, or a syrup is obtained from it by boiling with sugar, and its juice is found an excellent agent for removing iron-moulds or other spots from linen. To the Malays it answers the same purposes as the citron, the gooseberry, the caper, and the cucumber of Europe.

AVES. [BIRDS.]

AVES (Fossil). Fossil Birds have been recognised by bones and foot-prints in the Red-Sandstone of Connecticut (Hitchcock), in the Wealden of Sussex (Mantell), in the Chalk of Maidstone (Owen), in the Tertiary Beds of England and France (Cuvier), in the bone-caves of Kirkdale (Buckland), and in many late deposits. From New Zealand comes the *Dinornis* of Owen. [DINORNIS.]

AVICE'NNIA, a genus of plants belonging to the natural order *Myoporaceæ*. The calyx is 5-parted, persistent, the segments erect, subovate, obtuse, concave; the corolla monopetalous, 2-lipped, upper lip square, emarginate, flat, lower bifid, with ovate, equal, flat divisions, tube bell-shaped, short; the stamens 4, didynamous; ovary 2-celled; style, subulate, erect, length of stamens; the stigma bifid, acute, the lower division bent down; the seed single, large, albuminous. The species are natives of Australia and America.

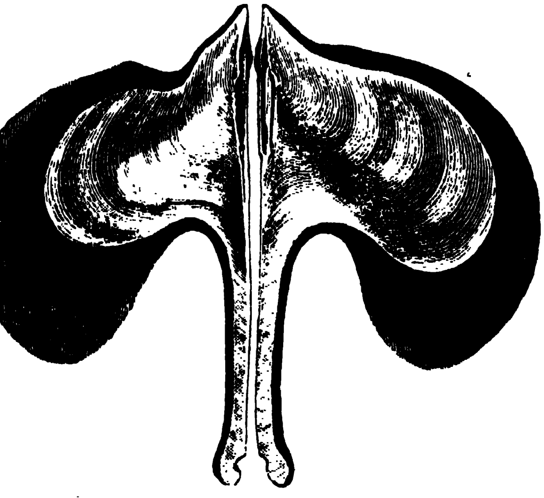
A. tomentosa, White Mangrove, has cordate ovate leaves, tomentose beneath. It puts forth twigs from the stem, resembling those of the common mangrove. The bark is found to contain tannin, and is used in Rio Janeiro for tanning.

A. resinifera is a native of New Zealand, and is said by Forster to yield a green resinous substance that is eaten by the New Zealanders as food. It is remarkable also for its clusters of large flowers. *A. nitida* is a native of Martinique.

(Burnett, *Outlines*; Lindley, *Natural System*.)

AVI'CULA, a genus of *Marine Conchifera*, or Bivalves with unequal valves, in which Sowerby, with much show of reason, includes the genus *Meleagrina*, also formed by Lamarck. The shell in both is foliaceous externally; and internally, of a brilliant pearly lustre. The left-hand valve is contracted and notched posteriorly; and so is the right, but very slightly. Through this sinus passes the byssus, by which they are moored to rocks and other marine bodies. The ligamental area is marginal, and broadest in the centre; and there is generally a small tooth in each valve near the umbones. This is most conspicuous, generally speaking, in *Avicula* (Lam.), but is not always found, while it is often present in Lamarck's *Meleagrinæ*, though it is sometimes absent. The muscular impression is nearly central, somewhat orbicular, and large.

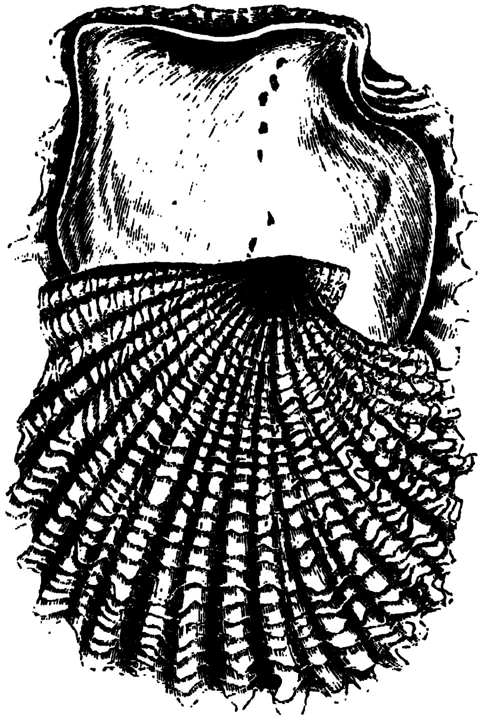
Avicula, then, as characterised by Sowerby, will comprise two sections; the first including those species which have their base, or hinge-line, considerably prolonged; the second embracing those which are without that prolongation—in other words, the *Meleagrinæ*. Both sections are the inhabitants of warm climates. *Avicula macroptera* may be taken as an example of the first section.



Avicula macroptera.

Avicula margaritifera (*Meleagrina margaritifera*, Lam., *Mytilus margaritiferus*, Linn.), commonly known as the Pearl-Oyster, the source whence the most precious pearls are derived, will afford an illustration of the second section.

The shell itself is imported in great quantities, for the manufacture of the nacre, or mother-of-pearl, into buttons, knife-handles, paper-knives, &c.; but its great commercial value rests on the pearls which it contains. For these beautiful productions, which may be considered as extravasated nacre, there are fisheries in both hemispheres. The pearl of great price, however, is found in the East, where the principal fisheries, at Ceylon, Cape Comorin, and in the Persian Gulf, are carried on by means of divers. Captain Percival, in his 'Account of Ceylon,' has given the best description of the pearl-fishery there. [SHELL.]



Pearl-Oyster (*Avicula margaritifera*).
The figure represents a young individual. The shell grows to a large size, and then the delicate foliations disappear.

A'VOCET, the common name of the *Recurvirostra Avocetta*. It belongs to the order of *Grallatores*, or Waders, and the family *Scolopacidæ*.

The Avocet (*Recurvirostra Avocetta*).

The genus *Recurvirostra* includes other species besides the Avocet. The muddy shores of the ocean and the banks of æstuaries are their favourite haunts, where they feed on aquatic animals, such as the smaller conchifers and mollusks, and the spawn of fishes. They are deep waders, but do not seem to be adepts at swimming. The Avocet is the only European species, and has been long remarked for the singularity of the shape of the bill. "There needs no great pains be taken, or time spent in exactly describing this bird," says Ray in his edition of Willughby, "for the singular bill reflected upwards is sufficient alone to characterise and distinguish it from all other birds we have hitherto seen or heard of." It is widely diffused through the temperate climates of Europe. Siberia, the shores of the Caspian, and the salt-lakes of Tartary, are also stated to be plentifully supplied with these birds, and it is said to be met with in Egypt and other parts of Africa. In England they were formerly found on the eastern coast below the Humber, and in Romney Marsh, but recently they have become much more scarce. Mr. Yarrell says that some years ago "more than twenty specimens were received at Leadenhall Market for sale within one month; but now scarcely an example appears once in a year."

Pennant well describes the Avocet's bill as "very thin, flexible, and of a substance like whalebone." Buffon makes it the subject of one of his lamentations upon the errors of nature and her niggard disposition in providing for some of the less favoured of the animal creation. But in truth no organ could have been devised more admirably adapted for the function which it has to perform than the bill of the Avocet, as he who has seen the bird scooping, probing, or apparently patting and beating the water and soft mud with it, while the mandibles act as a strainer and retain the prey, will readily acknowledge. The Avocet frequently wades up to the breast, and its long legs are well formed for this purpose; for they are compressed laterally, and present but a thin edge, so as to offer hardly any resistance to the medium through which they have to make their progress. Though the feet are palmated, they appear to be adapted not for swimming, but for supporting the bird upon the ooze, after the manner of the mud-boards used by fowlers, and figured by Colonel Hawker; this office the feet of the Avocet execute in perfection. Montagu says, "We remember one of this species being wounded in the wing, and floating with the tide for near a mile, when it was taken up alive without ever attempting to swim; so that the palmated feet seem only intended to support it on the mud."

The nests of the Avocet, which are very inartificial, are generally formed in the spring, in marine marshes, where the driest point is selected. They breed in the fens of Lincolnshire and Norfolk. The eggs are greenish, spotted with brown or black. When disturbed soon after the young are hatched, they fly round and round, repeating their peculiar cry 'twit twit' incessantly, and are said to feign lameness like the lapwing, to decoy the intruder away.

AWLWORT. [SUBULARIA.]

AWN, or ARI'STA, in Botany, the beard of grasses, is a rigid bristle, often hairy, and frequently twisted, proceeding from the back of some of the envelopes of the flower. It is often employed for systematic purposes in consequence of the number of modifications to which it is subject. It appears to be one of the veins or ribs of the envelopes, unusually lengthened, and separated from the cellular substance to which it belongs.

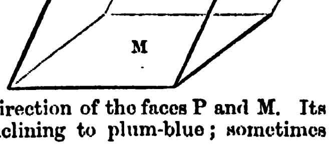
AXE-STONE, a silicate of alumina and magnesia. It is a hard tough stone, of a greenish colour. Also called *Jade*, *Nephrite*, and *Ceraunite*.

AXI'LLA, in Botany, is the angle formed by the separation of a leaf from its stem; hence the term 'axillary' is applied to anything which grows from that angle. It is at this point that buds appear, whether they are to be developed as branches or as flowers; and it is a remarkable circumstance that they never appear anywhere else except when they are adventitious and unconformable to the usual order of growth. For this reason the position of buds upon a branch will show in what position the leaves have grown, notwithstanding the leaves themselves may have fallen off, and the scars whence they fall have disappeared.

The axillæ of all leaves contain rudiments of a bud in a greater or less degree of perfection, and are capable, under favourable circumstances, of bringing it to full development. Gardeners sometimes profit by a knowledge of this law, to propagate plants in which, from the close manner in which the leaves are arranged upon the stem, it would be impossible to increase them by the ordinary modes. Thus a hyacinth bulb is a short branch with rudimentary leaves, called scales, growing closely over all its surface; and consequently at the axilla of each rudimentary leaf there exists a bud either latent or manifest. Under ordinary circumstances, two or three only of those buds develop near the outside of the bulb, in the form of cloves, or young bulbs; but if at the time the bulb is just beginning to grow, the central shoot is destroyed, either by cutting it across or searing it with a hot iron, the nutritive matter which was laid up in a bulb, not being expended upon producing flowers and leaves, will be diverted into other channels, and exercising its vital force upon the axillary buds, will cause them to develop in great numbers; and thus the hyacinth will be increased with rapidity, instead of by the slow production of two or three cloves yearly.

Although buds, or bulbs, which is the same thing, are universally axillary to leaves, and indeed to every part which is theoretically a modification of a leaf, yet one leaf cannot be axillary to another leaf, although it may seem so in consequence of the incipient development of an axillary branch to whose system it belongs. Thus in pine-trees, the clustered needle-shaped leaves seem to be axillary to the withering rudimentary leaf that grows round their base; but in reality each cluster of leaves is a small branch without perceptible axis, as is proved by the Cedar of Lebanon, where the axis sometimes lengthens and sometimes does not.

AXINI'TE. This mineral usually occurs crystallised in flat prismatic crystals, with very sharp edges, from which it has received its name. The fundamental form is a double oblique prism, from which Neumann has obtained the following angles:—



M on T = 135° 24′ and 44° 36′
P on M = 134° 48′ and 45° 12′
P on T = 115° 39′ and 60° 21′

It is imperfectly cleavable in the direction of the faces P and M. Its colour is clove-brown, sometimes inclining to plum-blue; sometimes transparent, at other times only translucent on the edges; its lustre is vitreous. The specific gravity of a crystallised variety from Cornwall is stated by Mohs to be 3·271, and its hardness 6·5 to 7.

Before the blowpipe it readily fuses with intumescence into a dark-green glass, which in the oxidising flame becomes black on account of the presence of super-oxides of manganese. With borax the glass is either green from iron, or of an amethyst tint from manganese, according as it has been exposed to the interior or exterior flame of the blowpipe. By fusing it with sulphate of ammonia and fluor-spar, the presence of boracic acid may be detected. The following is an analysis by Wiegmann of a variety from Treseburg, Harz:—

Silica	45·00
Alumina	19·00
Lime	12·50
Peroxide of Iron	12·25
Peroxide of Manganese	9·00
Magnesia	0·25
Boracic Acid	2·00
	100·00

Berzelius, however, has marked the iron and manganese as protoxides.

This mineral is not very abundant; it is found at Thum in Saxony, whence it is sometimes called Thumerstone. It occurs at Botallach, near the Land's End, Cornwall, both crystallised and forming a rock with Tourmaline and Garnet.

AXI'NUS (Sowerby), a genus of Fossil *Conchifera*, of which some species occur in the Magnesian Limestone, and one in the London Clay. To those which are found in the Magnesian and other Palæozoic Limestones Mr. King applies the title of *Schizodus*.

AXIO'TIMA. [ACALEPHÆ.]

AXIS, in Anatomy, the second vertebra of the neck, on which the Atlas, the first vertebra, moves. [ATLAS.]

AXIS, in Botany, a term that is applied to the root and stem of the whole plant. The result of placing the seed of a plant in a place fitted for its growth is the development of the embryo. The plumule ascends into the air, whilst the radicle descends towards the earth. The former is said to be the ascending axis of the plant, the latter the descending axis. It is around these axes of growth that all other parts of the plant are arranged. Those which are found upon the ascending axis, or stem, are collectively termed the appendages of the axis, and individually constitute the scales, leaves, bracts, flowers, sexes, fruit, and modifications of those parts of the plant; all these parts are in connection with the vascular system of the axis, and must not be confounded with mere expansions of the epidermis and the like, such as ramenta, thorns, &c., which have no real connection with the axis.

The cause of the direction taken by the ascending and descending axes of plants has been variously explained. This is evidently a complicated question, and one which involves the great mass of facts in the organisation of plants, and probably animals, which determine their peculiar forms, habits, and movements. Dutrochet says "The downward direction of the roots may appear easy of explanation: it may be said that, like all other bodies, they have a tendency towards the centre of the earth, in consequence of the known laws of gravity (as is the opinion of Knight in 'Phil. Trans.' for 1806); but on what principle then is to be explained the upward tendency of the stem, which is in direct opposition to those laws? And here lies the difficulty. Dodart is the first who appears to have paid attention to this circumstance; he pretends to explain the turning backward of seeds sown in an inverted position by the following hypothesis: He assumed that the root is composed of parts that contract by humidity; and that the stem, on the contrary, contracts by dryness. For this reason, according to him, it ought to happen that when a seed is sown in an inverted position, the radicle will turn back towards the earth, which is the seat of humidity; and that the plumule, on the contrary, turns to the sky, or rather atmosphere, a drier medium than the earth. The experiments of Du Hamel are well known, in which he attempted to force a radicle upwards and a plumule downwards by inclosing them in tubes which prevented the turning back of these parts. It was found that as the radicle and plumule could not take their natural direction, they became twisted spirally. These experiments, while they prove that the opposite tendencies of the radicle and the plumule cannot be altered, still leave us in ignorance of the cause of such tendencies." The well-known fact of the stems of plants seeking the light when confined in dark places, has led De Candolle and other observers to attribute the tendency of the stem to an upward growth to the influence of light. Another well-known fact, that of the tendency of the roots of plants to grow towards water or moisture, might have suggested water as a cause of the tendency of the root to grow downwards. Observing that the ascending axis of plants is always coloured, and that the descending axis is white, Dutrochet suspected that the action of light on the coloured parts of the plant was the cause of its growing upwards. He found by experiments on the *Mirabilis Jalapa* and other plants, that although roots have in general no tendency towards the light, yet such a disposition does become manifest provided the terminal shoot of a root becomes slightly green, as occasionally happens. He found that the ends of the roots of *Mirabilis Jalapa* became occasionally coloured, and on placing the plants in damp moss, he found these roots had a tendency to come to the surface towards the light. Not only is this the case, but the colourless stems of such plants as *Sagittaria sagittifolia* are known to assume the directions of roots. In this plant "shoots are produced from the axillæ of all the radical leaves which grow at the bottom of the water. These shoots have their points directed towards the sky, like those of all vegetables. The young stems which are produced by these shoots are entirely colourless, like roots; and instead of taking a direction towards the sky, as coloured stems would do, they lead downwards, pointing towards the centre of the earth. This subterranean stem next takes a horizontal course, and does not assume any tendency towards the sky until the points become green."

(Meyen, *Pflanzen-Physiologie*; Lindley, *Introduction to Botany*; Dutrochet, *Ann. des Sciences Naturelles*, xxix., 1833.)

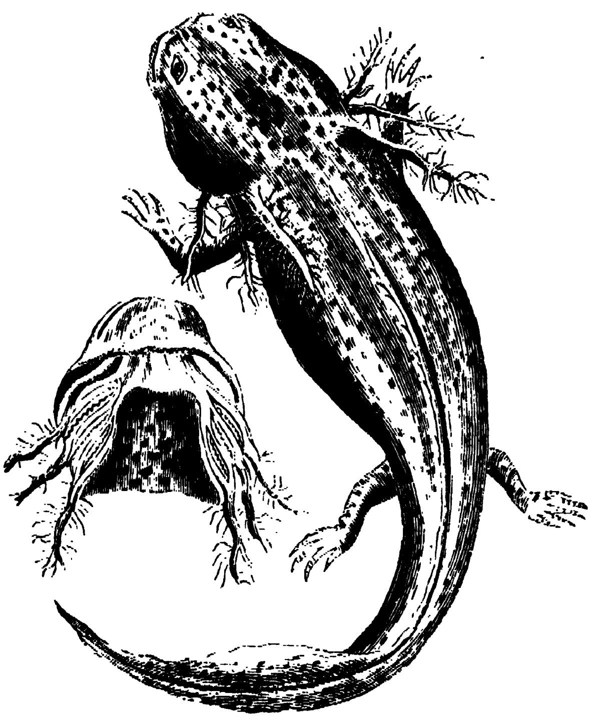
AXIS, a species of Indian Deer. The word is also used generically to denote a small group or sub-genus of solid-horned ruminants, presenting the same characters and inhabiting the same climate as the Common Axis. [CERVIDÆ.]

A'XIUS, a genus of Long-Tailed Decapodous *Crustacea*, founded by Leach on *Axius stirhynchus*, which is about 3 inches or 3½ inches in length, and rarely found on our coasts. It has been taken near Sidmouth and Plymouth. Desmarest, with much reason, considers this genus entirely artificial; and thinks that it ought not to be separated from *Callianassa*. [CALLIANASSA.]

AXOLO'TL (*Gyrinus*, Hernandez and Shaw), a genus of *Amphibia* belonging to a group called Perennibranchiate, as they retain their gills throughout life. They are distinguished from other genera of the same family by having four feet furnished with four toes before and five behind. This group contains the genera—*Axolotes*, *Menobranchus*, *Proteus*, and *Sirenus*; and comprises animals which possess at the same time both lungs and gills, and which are consequently organised to live either on land or in water. [AMPHIBIA.]

The Axolotl was the earliest observed of these remarkable animals. At the period of the Mexican conquest the Spaniards found this animal in great abundance in the lake which surrounded the city of Mexico, to the inhabitants of which capital it then furnished, as it still continues to furnish to their successors, an agreeable and much-esteemed article of food. Hernandez, who seems to be the first writer who actually described the Axolotl, expressly mentions it having been thus used by the ancient Mexicans; and adds that the flesh was considered as an aphrodisiac, that it was wholesome and agreeable, and tasted not unlike eel. Succeeding authors, without taking the trouble of observing for themselves, were content to copy what Hernandez had said before; but distorting his short description by absurd comments of their own, and adding the figures of far different species, the whole subject became at length involved in such inextricable confusion that finally all memory of the Axolotl was lost, or the animal itself considered as a fictitious being. The late Dr. Shaw however, who received a specimen of the animal direct from Mexico, recognised in it the Axolotl of Hernandez, as is proved by his having used the generic term *Gyrinus* in his account of it published in the 'Naturalist's Miscellany,' which had been originally applied to it by its first describer, though Baron Cuvier seems disposed to deprive the British naturalist of this credit, and to ascribe the sole honour of re-discovering the Axolotl to Baron Humboldt. It is indeed true that Dr. Shaw subsequently described the same animal in the third volume of his 'General Zoology' under the very different name of *Siren pisciformis*; but this only proves that he considered it, as Baron Cuvier was himself afterwards inclined to do, not as a perfect animal, nor in fact as the type of a new genus, but rather as the immature state of some species belonging to a genus already known. To Baron Cuvier himself however we are indebted for the complete description and elucidation of the form and organic structure of this curious reptile. Two specimens brought by M. Humboldt from Mexico were submitted to the examination of the French naturalist, whose researches on the subject of their anatomy, compared with that of the kindred genera, are recorded in his 'Recherches sur les Reptiles Douteux,' inserted in the zoological part of Messrs. Humboldt and Bonpland's Travels. A detailed examination of all the Batrachian Reptiles, and more particularly a careful investigation into their anatomical structure during the tadpole state, and the gradual change which they undergo in passing from this state to their mature and perfect form, led Baron Cuvier to establish as an unquestionable fact that certain of these animals retain both lungs and gills throughout the entire period of their existence; but whilst he unhesitatingly announced this fact with regard to the Siren and Proteus, he was disposed to consider the Axolotl as the tadpole of some of the larger species of American salamanders—an error induced as well by the general similarity which these animals bear to one another as by the immature age of the specimens of the Axolotl which were submitted to his observation. Succeeding naturalists adopted M. Cuvier's views upon this subject; but that great zoologist himself subsequently altered his original opinion, and candidly confesses in the second edition of the 'Règne Animal' that the concurrent testimony of all original observers overbalances the mere deductions of the physiologist, however plausible or apparently well founded.

The generic characters of the genus *Axolotl*, Cuvier (*Axolotes*, Owen, *Gyrinus*, Hernandez), in addition to those above mentioned, consist in having the gills formed of three long ramified or branch-like processes on each side of the neck, four toes on the anterior extremities and five on the posterior, and teeth in the vomer as well as in both jaws. The tail is compressed on the sides like that of the common Water-Newt (*Salamandra palmata*), and surrounded both on the upper and under surfaces by a thin erect membranous fin, which is prolonged upon the back, but becomes gradually narrower as it approaches the shoulders, between which it finally ceases. The head is broad and flat; the nose blunt; the eyes situated near the muzzle; the tail nearly as long as the body; and the toes unconnected by intermediate membranes. The singular form of the gills will be best understood from the accompanying figure, which represents the under jaw and throat of the animal as seen from beneath.



Axolotl (*Gyrinus edulis*, Hernandez).

The *Axolotl* of the Mexicans (*Gyrinus edulis*, Hernandez), when full grown, measures about 8 or 9 inches in length; its ground colour is a uniform deep brown, thickly mottled both on the upper and under surfaces of the head and body as well as on the limbs, tail, and dorsal and caudal fins, with numerous small round black spots. The head and body are larger and broader than in the generality of reptiles, and but for the long tail which terminates the latter the whole animal might be not inaptly compared in form to a large frog; the gills are prolonged into three principal processes, with numerous smaller ramifications from the sides of each, the whole being as long as the fore legs, and resembling three small branches; the legs are short, though fully developed; and the toes are long, slender, separate, and without claws. The communications which open from the gills into the mouth are four in number, and of a size considerably larger than those of the kindred genera; they are covered externally by a species of operculum formed by a fold in the skin of the head.

The Axolotl is very common in the lake of Mexico, and, according to Baron Humboldt, likewise inhabits the cold waters of mountain-lakes at much greater elevation above the level of the sea than the plains surrounding that city. It is commonly sold in the markets of Mexico, and esteemed a luxury by the inhabitants. It is dressed after the manner of stewed eels, and served up with a rich and stimulating sauce.

Professor Owen has described a second species under the name of *Axolotes maculata*, which also is an inhabitant of Mexico.

AYE-AYE. [CHEIROMYS.]

AYMESTRY LIMESTONE, one of the calcareous bands in the Upper Silurian series which has been produced by coral and shell accumulations amidst the masses of argillaceous sediments. It is not traceable beyond the districts of Ludlow, Abberley, Malvern, Woolhope, May Hill, and Usk. It is partially characterised by *Pentamerus Knightii*.

AZA'LEA, in Botany, is the name of a genus belonging to the natural order *Ericaceæ*, and consisting of shrubs remarkable for the beauty and fragrance of their flowers; on which account they are very generally cultivated in Europe. By some botanists the genus is esteemed the same as *Rhododendron*, in which it is accordingly sunk; and it must be confessed that it is difficult to point out any positive character except the thin and generally deciduous leaves by which *Azalea* can be distinguished from *Rhododendron*.

The forms of *Azalea* may be reduced to four principal heads, to one or other of which all the species are referrible—namely, 1, those with glutinous flowers and short stamens; 2, those with glutinous flowers and stamens much longer than the corolla; 3, those with flowers that are scarcely at all glutinous, and stamens much longer than the corolla; and 4, those with flowers that are scarcely at all glutinous, and short stamens.

Section I.—*Flowers covered with numerous glutinous hairs. Stamens little or not at all longer than the tube of the corolla.*

1. *Azalea viscosa*, Linn. (*A. odorata, vittata, fissa, lucida* of various authors). Leaves shining, green on both sides, fringed at the edge. A native of swamps, copses, and wet and shady woods, throughout the United States of North America, from Canada to Georgia. It is a shrub from 3 to 8 feet high, with the young branches covered with numerous stiffish brown hairs. The leaves are bright green, shining, and smooth on the upper side; paler but not at all glaucous on the under side. The flowers are deliciously fragrant, usually white or nearly so, with a long narrow tube, and a contracted limb with narrow sharp-pointed divisions; they are covered all over externally with glutinous brownish-purple glands. The stamens are not so long as the segments of the corolla, but longer than its tube. It is one of the most common species and the most fragrant.

2. *Azalea glauca*, Lamarck. Leaves dull green, somewhat wrinkled and wavy at the edge, glaucous on the under side, fringed at the edge. Found in clayey swamps in the middle states of North America, where it flowers rather earlier than the last. In a wild state it is a much rarer plant, and does not grow so tall; its white flowers appear in the utmost profusion, and are very like those of *A. viscosa*, but the stamens are a little longer. In the nurseries it is called *A. viscosa floribunda.*

Section II. *Flowers covered with numerous glutinous hairs. Stamens much longer than the corolla.*

3. *Azalea nitida*, Pursh. Branches with very few hairs. Leaves small, rather leathery, shining, and smooth on both sides. Found in deep mossy swamps on the mountains of North America, from the state of New York to Virginia, flowering in June and July. The leaves of this plant, which appear a little earlier than the flowers, are dark-green, shining, and smaller than in any other species: the only parts which are hairy are the midrib and the margin. The flowers are white, with a red tinge, and glutinous; their tube is a little longer than the segments; the calyx is very short; the stamens are longer than the corolla. It is doubtful whether this is to be met with in cultivation.

4. *Azalea hispida*, Pursh. Branches clothed with numerous stiffish hairs. Leaves long-lanceolate, covered with bloom on both sides, hairy on the upper surface, and smooth on the lower. A native of the borders of lakes; and on the highest part of the Blue Ridge in the state of Pennsylvania, flowering in July and August. An upright shrub, growing 10 or 15 feet high, with a bluish aspect, by which it may be recognised at a distance.

5. *Azalea pontica*, Linn. Leaves large, not shining, puckered, reflexed and wavy at the edge, green and slightly hairy on both surfaces. Flowers yellow, long-stalked, covered with long hairs and glutinous glands. Common in the Crimea, the Caucasus, and the eastern parts of Poland, rendering the whole country a brilliant garden with its golden fragrant flowers during the month of May. Although found on the mountains, it is by no means an alpine plant, but disappears in the higher regions of the air, where the Pontic Rhododendron takes its place. Its flowers abound in a fluid nectar, which is said to render poisonous the honey collected by the bees at the time of its blooming. It is readily known by its large yellow corolla from all the American species: in the gardens it deviates to a pale straw colour, which is called white by collectors.

Section III.—*Flowers with scarcely any glutinous hairs. Stamens much longer than the corolla.*

6. *Azalea periclymena*, Persoon (*A. nudiflora*, Willd.; *periclymenoides*, Michaux; *coccinea, speciosa, rubra, rutilans, carnea, alba, papilionacea, partita, polyandra*, of the Gardens). Leaves flat, nearly hairless, except the midrib, which is bristly. Tube of the corolla much longer than the limb, which is white. Found wild on the sides of hills, in woods all over North America, where it is called Upright Honeysuckle—a name which it well merits for its fragrance and beauty. It is a smaller plant than *A. viscosa*, rarely exceeding the height of a man, and being generally much shorter, and exceedingly branched. By botanists it was formerly distinguished by its flowers appearing before its leaves, whence it was called *A. nudiflora*; but as this is an uncertain circumstance, the name we have adopted from Persoon deserves the preference. Its leaves are bright green, and nearly smooth on the upper side, flat, and by no means puckered or wavy; their under side and the branches are slightly downy, and their margin covered with stiff hairs.

7. *Azalea canescens*, Michaux (*A. bicolor*, Pursh). Leaves hoary, especially beneath, where they are also downy; their midrib without any stiff hairs. Tube of the corolla of about the length of the limb, which is white. On barren sandy hills, in the southern parts of the United States, on the banks of rivers in South Carolina, and on the mountains of Virginia, this species grows wild; it resembles *A. periclymena* very much, but is a tenderer plant, and has the same gray appearance which renders *A. glauca* so conspicuous an object. Its flowers are small and white, with a deep rosy-red tube; they appear the earliest of the American species.

8. *Azalea calendulacea*, Michaux. Leaves convex, shining, bright green, slightly hairy on both sides, reflexed and wavy at the edge; their midrib without stiff hairs. Tube of the corolla not longer than the broad orange-coloured or scarlet limb. A native of moist places in the southern states of North America; sometimes inhabiting the banks of rivers, but more frequently adorning the mountains with a garment of living scarlet.

9. *Azalea arborescens*, Pursh. Leaves covered on the under side by a glaucous bloom, and smooth on both sides. Tube of corolla longer than the segments. Calyx with leafy divisions. The only botanist who has described this remarkable plant is Pursh, who says it grows on rivulets near the Blue Ridge in Pennsylvania, flowering from May to July. He speaks of it thus: "This beautiful species has, to my knowledge, not yet been introduced into the gardens. I have only seen it in its native place, and in the garden of Mr. John Bartram, near Philadelphia. It rises from 10 to 20 feet high, and forms, with its elegant foliage and large abundant rose-coloured flowers, the finest ornamental shrub I know. The flowers are not so much pubescent as the rest of the species; the scales of the flower buds are large, yellowish-brown, surrounded with a fringed white border."

Section IV.—*Flowers entirely destitute of glutinous hairs. Stamens short. Corolla bell-shaped.*

10. *Azalea Sinensis* (*A. pontica*; *A. Sinensis*, 'Botanical Register,' plate 1253). Leaves downy on both sides, sharp-pointed, glaucous beneath, reflexed and wavy at the edges. Flowers covered externally only with a fine silkiness; their tube much shorter than the bell-shaped limb, the divisions of which are acute. Introduced from China by the late Mr. W. Wells, of Redleaf, about the year 1826, and supposed to be a native of that country. Its leaves are very like those of *Azalea pontica*, except that they are glaucous underneath, and its flowers are of a bright clear ochry yellow; it is even supposed to be a mere variety of that species. Its bell-shaped corolla, however, without any glandular or other conspicuous hairs on the outside, and with scarcely any tube, distinguishes it sufficiently. The segments of the corolla are broadly ovate, slightly wavy, and the upper one is distinctly dotted in the manner of a rhododendron.

11. *Azalea Indica*, Linnaeus. Leaves obovate, flat, green on both sides, and very abundantly clothed with stiffish brown hairs. Flowers quite smooth externally; their tube much shorter than the bell shaped limb, the divisions of which are rounded. Calyx small and very hispid; stamens five. This and the following are the most beautiful plants which exist in the rich flora of China, where they far exceed in splendour of appearance the camellias, moutans, chrysanthemums, and roses of that favoured climate. This forms a bush varying in height from two to six feet, with the branches usually drooping, and covered when young with rigid brown hairs. The leaves are deep green, flat, and half evergreen, usually tinged with brown, in consequence of the many brown hairs with which they are clothed. The flowers are large and showy, and gaily marked with brilliant colours. The calyx is very small, and closely covered with stiff hairs. There are many varieties, of which the Brick Red, the Double Purple, and the Variegated are the principal.

12. *Azalea ledifolia*, Hooker. Leaves obovate, flat, evergreen, green on both sides, and clothed with brown hairs. Flowers quite smooth externally; their tube much shorter than the bell-shaped limb, the divisions of which are dilated and wavy. Calyx with leafy acute sepals; stamens ten. A native of China, and less impatient of cold than the last, from which it chiefly differs in its leafy calyx, evergreen less rusty shining leaves, larger flowers, and more numerous stamens. There are two varieties in the gardens, the White and the Royal Purple, or Phœnicea.

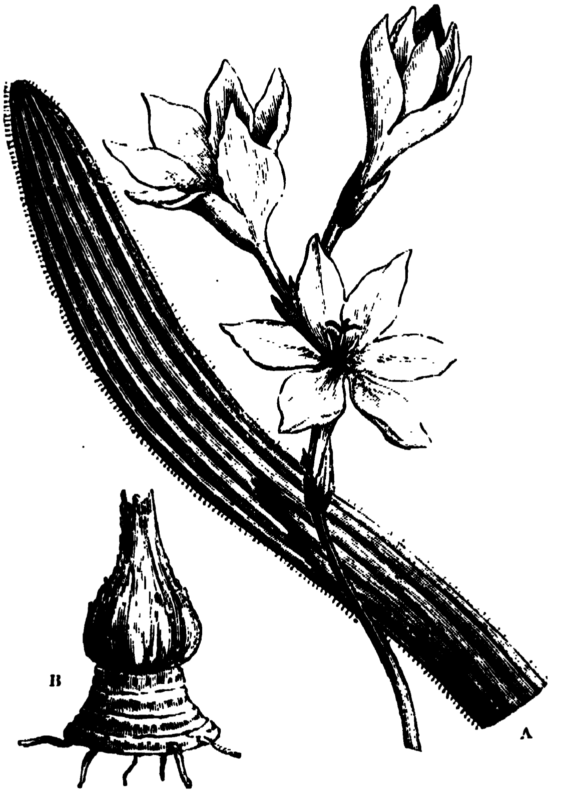
A'ZURITE, a term used by Phillips to denote *Lazulite*, under which name this mineral is most generally described by mineralogists. [LAZULITE.] It is different from Azure-Stone, by which name Lapis Lazuli, the Ultramarine of painters, is sometimes known.

B

BABIA'NA, a genus of plants belonging to the natural order *Iridaceæ.* It derives its singular name from Babianer, which the Dutch colonists call these plants, because their round subterranean stems are greedily eaten by baboons. It differs from *Gladiolus* in its round leather-coated seeds, and in the flowers having the tube of *Ixia*, and from *Ixia* in their having the irregular limb of *Gladiolus.* Fourteen or fifteen species are known, among which are some of the handsomest of the Cape Bulbous Plants, as they are commonly though incorrectly called. Of these all have narrow, plaited, sword-shaped leaves, rising from a cormus which is covered with rigid, netted, brown scales; this part, which is sometimes called the bulb, sometimes the root, but which is in reality a short underground stem, is propagated by one or more young buds near its point, which shoot up at the season of growth, feed upon the old cormus till they have sucked it quite dry, and by that time become new cormi themselves elevated upon the point of the original one. In this way the underground cormi gradually rise towards the surface of the earth, and afford an instance of vegetable progression which by some has been adduced as extremely remarkable, but which is in fact, if the phenomenon be rightly considered, precisely analogous to the progression of the stem of a tree into the air by the formation of fresh branches year after year.

The flowers of *Babiana* are yellow, purple, and even scarlet, of considerable size, and extremely handsome. They are produced in perfection, provided the plants are so cultivated as to be exposed abundantly to air, light, warmth, and moisture, when in a state of growth, and preserved cool and dry while in a state of repose. It is in the plains of the Cape of Good Hope that these plants are found, where they are exposed for two or three months, at the most, to rain; and where, during the remainder of the year, they are buried beneath a soil so dry that even succulent plants themselves can scarcely contrive to exist upon it.

Babiana sulphurea, one of the commonest species, grows about a foot high, with oblong, plaited, hairy leaves, and a one-sided spike of four or five flowers. The latter are about two inches long, of a pale sulphur-yellow, with a short sky-blue tube and eye; the segments are oblong, slightly wavy, nearly equal in size, and spreading nearly equally round three short erect stamens. The style and stigma are sky-blue; the latter very narrow and channeled.



Babiana sulphurea.

A, a diminished figure of the flowering spike; B, one of the cormi, showing how they gradually ascend by rising annually upon the remains of cormi of former years.

BABINGTONI'TE, a mineral which occurs crystallised. Its primary form is a doubly oblique prism; the colour is black or greenish-black; the fracture uneven; hardness, 5·5 to 6·0; lustre, vitreous; it is faintly translucent; the specific gravity is 3·5. It has been found at Arendal in Norway, the Shetland Isles, and in the United States at Charles-town, Massachusetts. The following is the analysis by Arppe of a specimen from Arendal:—

Silica	54·4
Protoxide of Iron	21·3
Lime	19·6
Magnesia	2·2
Protoxide of Manganese	1·8
Alumina	0·3
Volatile matter	0·9

BABIROU'SSA is sometimes called the Horned Hog by travellers, from the great length and curved form of its upper tusks, which pierce through the upper lip and grow upwards and backwards like the horns of the *Ruminantia.* It is a species of wild hog which inhabits the woods of Java, Celebes, and others of the larger Sunda Isles. From its more slender proportions and longer limbs, compared with other species of the same genus, this animal has been likewise called the Stag-Boar, and was not altogether unknown to the ancients; at least it seems probable that it is the *Sus tetraceros* of Ælian (lib. xviii., cap. 10), and is plainly referred to by Pliny (lib. viii., cap. 52). [SUIDÆ.]

BABOON (*Cynocephalus*, Cuvier), a genus of *Quadrumana*, or Four-Handed Mammals, which forms the last link in the chain that unites the *Simiadæ*, properly so called, with the lower animals. The zoological or technical name of this genus, *Cynocephalus*, is from a Greek word used by Aristotle and other ancient writers to designate the common species of Egypt and Arabia, the *C. Hamadryas* of modern writers, and is plainly derived from the marked resemblance which the head and face of these animals bear to those of a dog, and which, in truth, constitutes the most distinctive character of the genus. The origin of the common name Baboon is a subject of greater doubt. Skinner and other British etymologists are content with deriving it from our vernacular word Babe, without considering that the German Pavian, the Dutch Baviaan, the French Babouin, and the Italian Babbuino, are manifestly but so many different modes of writing the same term. A more probable origin of all these terms appears to be the Italian Babbuino, from which is likewise derived, according to the opinion of Aldrovandus, the vulgar Latin word Papio, applied by the writers of the 15th and 16th centuries to these animals, and which is itself a diminutive of the common Italian word Babbo, which answers to our Papa.

Though the Baboons differ widely from the other groups of quadrumanous animals, and may be readily distinguished at sight even by those who are not much in the habit of observing them, yet it has been found not a little difficult to form such a simple definition of the genus as will comprehend all the species properly belonging to it, and also distinguish them from those which appertain to the proximate genera, *Macacus* and *Cercopithecus.* The most marked and prominent of the characters which more immediately distinguish the Baboons from the other *Simiadæ* consists in the great prolongation of the face and jaws, and in the truncated form of the muzzle, which gives the whole head a close resemblance to that of a large dog, and from which, as already observed, the Greeks and Romans very appropriately denominated them *Cynocephali*, or Dog-Headed Monkeys. In the ordinary *Quadrumana*, which have the head and face round, as in the human species, the nose is flat, and the nostrils situated about half-way between the mouth and the eyes, the whole bearing no unapt resemblance to that of a man who has lost the greater part of his nose: but in the Baboons this organ is prolonged uniformly with the jaws; it even surpasses the lips a little in length, and the nostrils open at the end of it exactly as in the dog. Here there is a marked difference in form and development from what we observe in the Apes and other higher groups of *Quadrumana.* The great length of the face detracts from the size of the skull; the organs of mastication are strongly developed to the prejudice of the brain and intellectual functions; the facial angle, which has been generally regarded as a pretty accurate measure of the mental capacity, is reduced to 30°, whilst it is never less than 45° in the Monkeys, and among the Apes amounts even to 60° or 65°; and the character of the Baboons, as might be readily suspected from these indications, is less docile and intelligent than that of the kindred genera. To the same prolongation of the face, and preponderance of the anterior part of the head, is to be attributed, at least in a great measure, the fact that the Baboons less frequently assume an erect posture than any of the other *Quadrumana*, and are less capable of maintaining it for any length of time. The weight of the long nose, to which the small size of the skull forms but a very inefficient counterbalance, fatigues the muscles of the neck, and constantly tends to make the animal seek for support upon all fours, as may be observed in a dog or a bear; and in fact the Baboons are but very little superior to these animals in the facility with which they maintain themselves in an upright posture.

In their native mountains the ordinary food of the Baboons is berries and bulbous roots, but in the vicinity of human habitations they make incursions into the cultivated fields and gardens, and destroy a still greater quantity of grain and fruits than they carry away with them. In well-inhabited countries where they are likely to meet with resistance, their predatory incursions are usually made during the night, and travellers assure us that, taught by experience of the risks to which they expose themselves during such expeditions, they place sentinels upon the surrounding trees and heights to give them timely warning of the approach of danger; but in wilder and more solitary districts, where the thinness of the population and the want of fire-arms place them on some degree of equality with the inhabitants, they make their forays in the open day, and dispute with the husbandman the fruits of his labour. "I have myself," says Pearce, in his 'Life and Adventures in Abyssinia,' "seen an assembly of large monkeys [baboons] drive the keepers from the fields of grain, in spite of their slings and stones, till several people went from the village to their assistance, and even then they only retired slowly, seeing that the men had no guns." Some travellers even assert that if the troop happens to be surprised in the act of pillaging, the sentinels pay with their lives for their neglect of the general safety; but however this may be, it is certain that individuals are frequently met with which exhibit marks of ill-usage from their companions, and which even sometimes appear to have been expelled from their society. Others assure us that the troop sometimes forms a long chain extending from the vicinity of their ordinary habitation to the garden or field which they happen to be engaged in plundering, and that the produce of their theft is pitched from hand to hand till it reaches its destination in the mountains. By this means they are enabled to carry off a much larger booty than if every individual laboured for his own peculiar benefit; but notwithstanding this attention to the general interest, each takes care before retiring to fill his cheek-pouches with the most choice fruits or grains which he can procure, and also, if not likely to be pursued, to carry off quantities in his hands. After these expeditions the whole troop retire to the mountains to enjoy their booty. They likewise search with avidity for the nests of birds, and suck the eggs; but if there be young, they kill them and destroy the nest; as, notwithstanding the evident approximation of their organisation and appetites to carnivorous animals, they are never known to touch a living prey in a state of nature, and even in captivity will eat no flesh but what has been thoroughly boiled or roasted. In this state we have seen various baboons enjoy their mutton-bone and pick it with apparent satisfaction; but it was evidently an acquired habit, like that of drinking porter and smoking tobacco, which they had been taught by the example of their keepers.

Of all the *Quadrumana* the Baboons are the most frightfully ugly. Their small eyes deeply sunk beneath huge projecting eyebrows, their low contracted forehead, and the very diminutive size of their cranium compared with the enormous development of the face and jaws, give them a fierce and malicious look, which is still further heightened by their robust and powerful make, and by the appearance of the enormous teeth which they do not fail to display upon the slightest provocation. The fierceness and brutality of their character and manners correspond with the expression of their physiognomy. These characters are most strongly displayed by the males; but it is more especially when, in addition to their ordinary disposition, they are agitated by the passion of love or jealousy that their natural habitudes carry them to the most furious and brutal excess. In captivity they are thrown into the greatest agitation at the appearance of young females. It is a common practice among itinerant showmen to excite the natural jealousy of their baboons by caressing or offering to kiss the young females who resort to their exhibitions, and the sight never fails to excite in these animals a degree of rage bordering upon frenzy. On one occasion a large baboon of the species which inhabits the Cape of Good Hope (*Cynocephalus porcarius*) escaped from his place of confinement in the 'Jardin des Plantes' at Paris, and far from showing any disposition to return to his cage, severely wounded two or three of the keepers who attempted to recapture him. After many ineffectual attempts to induce him to return quietly, they at length hit upon a plan which was successful. There was a small grated window at the back part of his den, at which one of the keepers appeared in company with the daughter of the superintendent, whom he appeared to kiss and caress within view of the animal. No sooner did the baboon witness this familiarity than he flew into the cage with the greatest fury, and endeavoured to unfasten the grating of the window which separated him from the object of his jealousy. Whilst employed in this vain attempt the keepers took the opportunity of fastening the door and securing him once more in his place of confinement. Nor is this a solitary instance of the influence which women can exert over the passions of these savage animals: generally untractable and incorrigible whilst under the management of men, it usually happens that baboons are most effectually tamed and led to even more than ordinary obedience in the hands of women, whose attentions they even appear to repay with gratitude and affection. Travellers sometimes speak of the danger which women run who reside in the vicinity of the situations which these animals inhabit, and affirm that the negresses on the coast of Guinea are occasionally kidnapped by the baboons, and carried off to their fastnesses: we are even assured that certain of these women have lived among the baboons for many years, and that they were prevented from escaping by being shut up in caves in the mountains, where however they were plentifully fed, and in other respects treated with great kindness. It is to be observed however that these accounts rest upon authority which is by no means unexceptionable. Credible and well-informed modern travellers do not relate them, and even their older and more credulous predecessors give them only from hearsay.

In addition to the mental and physical characters already mentioned, the Baboons, besides the great development of their canine teeth, are distinguished by having a fifth tubercule upon the posterior molar of the under jaw, in which respect they differ from the Apes and *Cercopitheci*, and resemble the *Macaci* and *Semnopitheci*. They are furnished with large callosities and capacious cheek pouches, and their tails, always shorter than those of the Macacks and Monkeys, are carried erect at the root, and then hang pendant perpendicularly, like that of a horse which has not been truncated. Those species which have very short tails carry them upright and erect. The bones of their cheeks also are protuberant and form large swellings on each side of the nose; and though this character is more strongly marked in the Mandrill and Drill than in the other species, yet all exhibit it in a greater or less degree. It is only since the labours of Messrs. Geoffroy and F. Cuvier have developed the true generic characters of the different groups which compose the family of *Quadrumana*, that we have become acquainted with the geographical distribution of these animals, and the habitats of the different genera. We have thus learned that the *Quadrumana* of the African continent are as distinct from those of Asia in their zoological characters as they are in the localities which they inhabit; in fact, among upwards of fifty species of *Simiadæ* belonging to the Old World there are only two known instances of an Asiatic genus occurring in Africa, or of an African genus occurring in Asia. One of these instances is even doubtful, since the animal to which it refers, the Common Magot or Barbary Ape, though generally considered as a Macack, is in reality an intermediate species between that genus and the Baboons, which it resembles equally in its habitat as it does in its powerful and muscular frame, and in its general habits and character, and from which it only differs in the comparative shortness of its face and the less truncated form of its nose. These, to be sure, are very essential characters in the true Baboons; but in all departments of zoology we find intermediate species, which partake as it were equally of the characteristic forms and organisation of two or even three conterminous genera, and which it is often impossible to include in either without a considerable relaxation in the strict import of their respective definitions. The other instance to which we have alluded regards a real species of Baboon, the *Cynocephalus Hamadryas* of authors, which is found in Asia and Africa, and which forms the only indisputable instance of any quadrumanous animal being common to both these continents. In other respects the Baboons are a strictly African genus. They inhabit all the great mountain ranges of that continent, from the shores of the Mediterranean to the Cape of Good Hope, and are capable of supporting a much lower degree of temperature than any of the other *Quadrumana*. The lofty mountains of Samen in Abyssinia, and the bleak and desolate range of the Sneeuwbergen in South Africa, are both tenanted by numerous troops of these animals, which appear to prefer the more rigorous climate of these elevated regions to the hot and sultry forests of the lower plains. Fischer enumerates eleven different species of baboons, but it is evident that some of those which he describes are the females or young of other species; and in fact the most judicious naturalists, those who describe from their own original observations, do not reckon more than five or six. The following are very distinctly marked, and have been universally admitted:—

1. *C. porcarius* (Desmarest), the Chacma. The colour of this species is a uniform dark brown, almost black, mixed throughout with a dark green shade, deepest on the head and along the ridge of the back, and paler on the anterior part of the shoulders and on the flanks. The hair over the whole body is long and shaggy, more particularly on the neck and shoulders of the males, where it forms a distinct mane; each hair is of a light gray colour for some distance from the root, and afterwards annulated throughout its entire length, with distinct rings alternately black and dark green, sometimes though but rarely intermixed with a few of a lighter and yellowish shade. The green predominates on the head more than on other parts; the face and ears are naked, as are likewise the palms of the hands and soles of the feet; the interior surfaces of the arms and thighs are but thinly covered with hair, which is long and of a uniform dark-brown colour; the hair on the toes is short, bristly, and uniformly black; the neck and shoulders of the male are furnished with a mane of long shaggy hair, which is wanting in the females and young; and the cheeks of both sexes have small whiskers directed backwards, and of a grayish colour. The tail is rather more than half the length of the body, and is terminated by a tuft of long black hair; the skin of the hands, face, and ears, is of a very dark violet-blue colour, with a paler ring surrounding each eye; the whole of the upper eyelids are white, as in the Mangabey (*Cercopithecus fuliginosus*); the nose projects a little beyond the upper lip, the nostrils are separated by a small depression or rut, as

in the dog and other carnivorous animals, and the callosities are less strongly marked than in most other species of this genus. In the adult animal the muzzle is extremely prolonged in comparison with the skull, which is proportionately contracted and flattened: the young on the contrary have the region of the brain much larger in proportion to the length of the face, the head considerably rounder, and in form resembling that of the adult Monkeys (*Cercopitheci*).

The Chacma (*C. porcarius*).

The Chacma, so called from the Hottentot word T'Chackamma, the aboriginal name of this baboon in South Africa, is one of the largest species of the present genus, and when full grown is equal in size, and much superior in strength, to a common English mastiff. This animal inhabits the mountains throughout the colony of the Cape of Good Hope, and associates in families more or less numerous. They are still found on the Table Mountain above Cape Town, though they do not exist in such numbers as they appear to have done formerly. Still however they pay occasional visits to the gardens at the base of the mountains, and with such skill and caution, that even the most watchful dogs, as we are assured by Professor Lichtenstein, cannot always prevent them. "Although," he remarks, "Kolbe somewhat exaggerates the regular and concerted manner in which their robberies are carried on, yet it is very true that they go in large companies upon their marauding parties, to support each other reciprocally, and carry off their plunder in greater security." Their common food consists of the bulbous roots of different plants, particularly of the *Babiana* [BABIANA]; these they dig up with their fingers, and peel them with their teeth, and heaps of the parings are frequently seen near the large stones upon which the baboons delight to sit and look round them. In ascending the kloofs or passes in the mountains of South Africa, which are frequently steep, narrow, and dangerous, travellers often disturb troops of these animals which have been sunning themselves on the rocks: if not attacked they scamper up the sides of the mountains yelling and screaming; but if fired at and wounded, they no sooner get beyond the range of the gun than they commence rolling and throwing down stones, and otherwise resenting the injury. A full-grown Chacma is more than a match for two good dogs, and though there is no animal which hounds pursue with so much fury, yet the boers of the interior would rather set their dogs upon a lion or panther than upon one of these baboons.

2. *C. Hamadryas* (Linnæus), the Derrias, the most celebrated of all the Baboons, and probably the only species of this genus known to the ancients, inhabits the mountains of Arabia and Abyssinia, and grows to the size of a large pointer, measuring upwards of 4 feet when standing erect, and 2½ feet in a sitting posture. The face of this species is extremely elongated, naked, and of a dirty flesh-colour, with a lighter ring surrounding the eyes; the nostrils, as in the dog, are separated by a slight furrow; the head, neck, shoulders, and all the fore part of the body as far as the loins, are covered with long shaggy hair; that on the hips, thighs, and legs, is short, and contrasted with the former has the appearance of having been clipped, so that the whole animal bears no unapt resemblance to a French poodle. The hair of the occiput and neck is upwards of a foot in length, and forms a long mane which falls back over the shoulders, and at a distance looks something like a full short cloak. The whiskers are broad and directed backwards so as to conceal the ears; their colour, as well as that of the head, mane, and fore part of the body, is a mixture of light gray and cinereous, each hair being marked with numerous alternate rings of these two colours; the short hair of the hips, thighs, and extremities is of a uniform cinereous brown colour, rather lighter on the posterior surface of the thighs than on the other parts; a dark-brown line passes down the middle of the back, the hands are almost jet black, and the feet are rusty brown. The tail is about half the length of the body, and is carried drooping as in other baboons; it is terminated by a brown tuft of long hair; the callosities are large and of a dark flesh-colour; the palms of the hands and soles of the feet dark-brown. The female when full grown is equal to the male in point of size, but differs considerably in the length and colour of the hair. This sex wants the mane which ornaments the neck of the male, and is covered over the whole body with short hair of equal length, and of a uniform deep olive-brown colour, slightly mixed with green. The throat and breast are but sparingly covered with hair, and the skin on these parts, as well as on the face, hands, and callosities, is of a deep tan-colour. Hemprich and Ehrenberg in their 'Symbolæ Physicæ' compare the female Derrias to a bear, whilst the copious mane which adorns the fore quarters of the male gives to that sex much of the external form and appearance of a small lion. The young of both sexes resemble the female, and the large whiskers and manes of the males only begin to make their appearance when the animals arrive at their full growth and mature age, that is, when they have completed their second dentition. At this period they undergo as great a change in their mental propensities as in their physical appearance. While young they are gentle, docile, and playful, but as soon as they have acquired their full development, they become sulky, malicious, and morose.

This species inhabits Arabia and Abyssinia, but is not found either in Egypt or Nubia, though its figure is often sculptured on the ancient monuments of both these countries. Hemprich and Ehrenberg found large troops of them in Wadi Kanun and in the mountains near the city of Gunfud in the country of the Wahabees, as well as in the mountains above Arkeeko on the Red Sea; and we learn from Salt and Pearce that they are extremely common upon all the high lands in Tigré. The travellers above-mentioned found troops of 100 and upwards in the neighbourhood of Eilet, in the chain of the Taranta. These were usually composed of ten or twelve adult males, and about twenty adult females; the remainder of the troop was made up of the young of the four or five preceding years. When seen at a distance approaching a small stream for the purpose of quenching their thirst, they bore a close resemblance to a flock of wild hogs; and it was observed that the young ones always led the van, and that the old males brought up the rear, probably for the purpose of having the whole family continually under their immediate observation. The Arabic name of this animal is Robah or Robba; the Abyssinians call it Derrias, according to Pearce's orthography, or Karrai, according to the spelling of Hemprich.

The name of this species in the ancient Ethiopic or Geez, the learned language of the Abyssinians, is Tot or Tota. The figure of this animal in a sitting posture is common upon the ancient monuments of Egypt and Nubia; small metal images of it have been dug up among the ruins of Memphis and Hermopolis, and mummies containing the embalmed body of the animal are still found among the catacombs. Strabo indeed (p. 812), in mentioning Hermopolis as the centre of the adoration paid to the *Cynocephalus*, says that the Babylonians in the vicinity of Memphis paid divine honours to the *Cepus:* yet though the geographer makes use of very different names, and though these in reality apply to very different animals, there is good reason to believe that they both refer in the present instance to the same species; no quadrumanous animal is ever found represented upon the sacred monuments of ancient Egypt except the Baboon nor have the images of any other species ever been dug up in searching for antiquities. One or two instances, indeed, occur in the representations of profane subjects, such as the procession of a returning conqueror, in which Monkeys (*Cercopitheci*) are introduced, as for instance the painting discovered at Thebes by the late Mr. Salt and represented by Minutola (tab. xii., fig. 9), in which a monkey is represented riding on the neck of a cameleopard; but this was manifestly intended merely to fix the locality of the country or people whose subjection the triumph was meant to commemorate, and by no means indicates a participation in the divine honours which were paid to the baboon. Neither does the female ever appear to be represented as an object of worship; all the figures and images seem to be those of males, as is proved by the mane which covers the neck and shoulders, and which gives a fullness to the fore part of the body in this sex which is wanting in the other.

3. *C. papio* (Desmarest), the Common Baboon, is of a uniform yellowish-brown colour, slightly shaded with sandy or light red upon the head, shoulders, body, and extremities; the whiskers alone are of a light fawn-colour; the face, ears, and hands are naked and entirely black, the upper eyelids white and also naked, and the tail about half the length of the body, but not terminated by the tuft which distinguishes it in the last two species. The hair of the occiput and neck is rather longer than that on the neck and shoulders, but is neither so long nor so thick as to give it any resemblance to the mane of the Chacma or Derrias; neither is the face of the present species so much prolonged as in these two animals; the nose however is advanced rather beyond the extremity of the lips, and has the nostrils opening as in the other baboons; the cheeks are considerably swollen immediately below the eyes, after which the breadth of the face contracts suddenly, giving the muzzle or nose the appearance of

having been broken in that situation by a heavy blow. The whiskers are not so thickly furnished as in the species already described; they are however equally directed backwards, but do not conceal the ears, which are black, naked, and less regularly oval than in man and the generality of the *Simiæ*. The under parts of the body, the breast, belly, abdomen, and inner face of the arms and thighs, are very sparingly furnished with long hairs of a uniform brown colour. The females and young differ in no other respect from the adult males, except in being of a lighter and more active make.

This species inhabits the coast of Guinea, and is that most commonly seen about the streets, and in menageries and museums. In youth it is gentle, curious, gluttonous, and incessantly in motion, smacking its lips quickly, and chattering when it wishes to beg contributions from its visitors, and screaming loudly when refused or tantalised. As it grows older however it ceases to be familiar, and assumes all the morose look and repulsive manners which characterise the baboons in general. The specimen observed by Buffon was full grown, and exhibited all the ferocity of disposition and intractability of nature common to the rest of its kind. "It was not," says he, "altogether hideous, and yet it excited horror. It appeared to be continually in a state of savage ferocity, grinding its teeth, perpetually restless, and agitated by unprovoked fury. It was obliged to be kept shut up in an iron cage, of which it shook the bars so powerfully with its hands as to inspire the spectators with apprehension. It was a stout-built animal, whose nervous limbs and compressed form indicated great force and agility; and though the length and thickness of its shaggy coat made it appear to be much larger than it was in reality, it was nevertheless so strong and active that it might have readily worsted the attacks of several unarmed men."

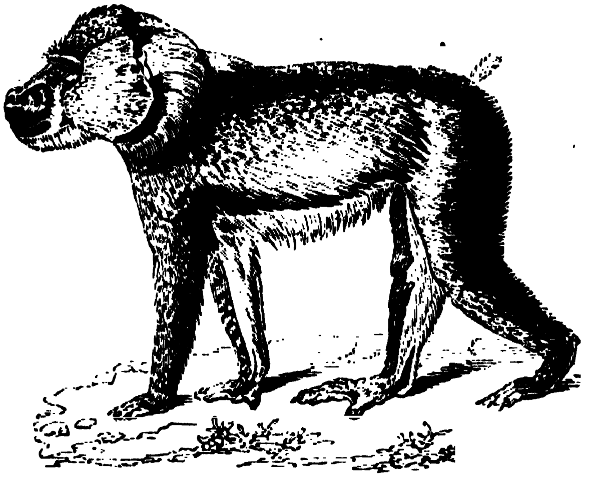
4. *C. Mormon* and *C. Maimon* (Linnæus), the Mandrill, is the largest of the whole genus, and may be readily distinguished from all the other baboons by the enormous protuberance of its cheeks, and the bright and variegated colours which mark them, as well as by its short upright tail. The full-grown Mandrill measures above 5 feet when standing upright; the limbs are short and powerful, the body thick and extremely robust, the head large and almost destitute of forehead, the eye-brows remarkably prominent, the eyes small and deeply sunk in the head, the cheek-bones swollen to an enormous size, and forming projections on each side of the nose as large as a man's fist, marked transversely with numerous alternate ribs of light blue, scarlet, and deep purple; the tail not more than a couple of inches in length, and generally carried erect; the callosities large, naked, and of a blood-red colour. The general colour of the hair is a light olive brown above, and silvery gray beneath, and the chin is furnished underneath with a small pointed yellow beard. The hair of the forehead and temples is directed upwards so as to meet in a point on the crown, which gives the head a triangular appearance; the ears are naked, angular at their superior and posterior borders, and of a bluish black colour; and the muzzle and lips are large, swollen, and protuberant. The former is surrounded above with an elevated rim or border, and truncated like the snout of a hog—a character which we have observed in no other baboon, and which leads us to suspect that the Mandrill is the species that Aristotle incidentally mentions by the name *Chæropithecus* (χοιροπίθηκος), ('Hist. Anim.,' lib. ii. cap. 2), and which may have been brought into Egypt or Greece by the merchants who kept up a regular intercourse between Egypt and the countries of the interior. There are other considerations which give a strong degree of probability to this conjecture. The short, indeed almost tuberculous, tail of the Mandrill, for instance, would have led Aristotle to compare it with the ape or *Pithecus* (πίθηκος), rather than with the other *Simiadæ*, all of which have tails of considerable length; and the truncated form of the snout would readily suggest its similarity to the hog (χοῖρος). We are aware that the *Chæropithecus* of the Greek philosopher has been generally identified with the Common Baboon or the Derrias; but neither of these species possesses any character which justifies that supposition; and besides, the Derrias is indisputably allowed to be the species designated by the much more appropriate name of *Cynocephalus* (κυνοκέφαλος). Nor does the Mandrill differ much in its general form and appearance from the *Pithecus* of Aristotle, which was the common Magot or Barbary Ape (*Macacus inuus*): there is no very great difference in the size of these animals, their colour is very nearly the same, both are equally remarkable for the powerful make of their bodies, and the sinewy character of their short stout limbs; and in fact the only striking difference which exists between them is the prolonged, truncated, swinish snout of the one, and the round head and short face of the other. Thus we can very satisfactorily account for both members of the compound name employed by Aristotle; nor can an objection be fairly taken to the approximation which we have here made of his *Chæropithecus* to the Mandrill of Guinea, on account of the extremely limited knowledge which the ancient Greeks possessed of the western coasts of Africa; since we know that they were well acquainted with other animals from the same or even a more remote locality; such, for instance, as the Gnu (*Antilope Gnu*), which is clearly the *Catoblepas* of ancient writers, and the Pecasse or buffalo of the Gold Coast.

The Mandrill (*C. Mormon* and *C. Maimon*).

The females and young Mandrills differ from the adult males in the shorter and less protuberant form of the muzzle, which is moreover of a uniform blue colour; the cheek-bones have little or no elevation above the general plane of the face, nor are they marked with the longitudinal furrows which give the other sex so singular an appearance; at least they are far from being so prominently developed. It is only indeed when they have completed their second dentition that these characters are fully displayed in the males, and that the extremity of the muzzle assumes that bright red hue by which it is so remarkably distinguished.

The Mandrill is often mentioned by travellers, and bears the different names of Smitten, Choras, Boggo, Barris, &c., according to the language or dialect of the tribes in whose territories it has been observed. Those which have been observed in a domestic state are generally remarked to have had a strong taste for spirituous and fermented liquors. A remarkably fine individual, which was long kept at Exeter Change, and afterwards at the Surrey Zoological Gardens, drank his pot of porter daily, and evidently enjoyed it. In a state of nature his great strength and malicious character render the Mandrill a truly formidable animal. As they generally march in large bands, they prove more than a match for any other inhabitants of the forests, and are even said to attack and drive the elephants away from the districts in which they have fixed their residence. The inhabitants of those countries themselves are afraid to pass through the woods unless in large companies and well armed; and it is said that the Mandrills will even watch their opportunity when the men are in the fields, to plunder the negro villages of everything eatable, and sometimes attempt to carry off the women into the woods.

5. *C. leucophæus* (F. Cuvier), the Drill, is a species only recently admitted by the most judicious modern naturalists, though long since described by Pennant, and after him by various other writers. It is likewise a native of the coast of Guinea, and like the Mandrill is distinguished by a short erect stumpy tail, scarcely two inches in length, and covered with short bristly hair. The cheeks are not so protuberant as in that species, neither are they marked with the same variety of colours; and the size and power of the animal are much inferior. The colours of the body bear some resemblance to those of the Mandrill, but they are more mixed with green on the upper parts, and are of a lighter or more silvery hue beneath. The head, back, sides, outer surface of the limbs, a band at the base of the neck, and the backs of the fore hands, are furnished with very long fine hair, of a light-brown colour at the root, and from thence to the point marked



The Drill (*C. leucophæus*).

with alternate rings of black and yellow, the two last colours alone appearing externally, and by their mixture giving rise to the greenish shade that predominates over all the upper parts of the head and body. The under parts of the body are equally covered with long fine hair, but of a uniform light-brown or silvery-gray colour, and more sparingly furnished than on the back and sides; the whiskers are thin and directed backwards; there is a small orange-coloured beard on the chin; the hair on the temples is directed upwards, and meeting from both sides forms a pointed ridge or crest on the crown of the head; and the tail, short as it is, is terminated by a small brush. The face and ears are naked, and of a glossy black colour like polished ebony; the cheek-bones form prominent elevations on each side of the nose, as in the Mandrill, only not nearly so large; neither are they marked with the same series of alternate ridges and furrows, nor with the brilliant and varied colours which render that species so remarkable; the palms of the hands and soles of the feet are also naked in the Drill, and of a deep copper-colour; the colour of the skin, when seen beneath the hair, is uniform dark-blue, and that of the naked callosities bright-red. The female differs from the male by her smaller size, shorter head, and much paler colour; and the young males exhibit the same characters up to the time of their second dentition.

The Wood-Baboon, the Cinereous Baboon, and the Yellow Baboon of Pennant, are all manifestly referrible to this species, and differ only from the difference of the age and sex of the specimens from which he took his description. The habits and manners of the Drill have not been observed in a state of nature, nor do we find the animal itself indicated in the works of any of the travellers which we have consulted. In its native country it is probably confounded with the Mandrill, at least by casual and passing observers, but it is frequently brought into this country, and is well known as a menagerie-animal. Its habits in confinement do not appear to differ in any material respect from those of its congeners.

BA'CCA, the technical name by which botanists distinguish the fruit commonly called a Berry. While however the English word is familiarly applied to all soft fruits, of whatever construction internally, it is strictly speaking made use of to designate those fruits only which have a thin skin, are pulpy internally, and have several seeds finally lying loose in the pulpy mass; such are the gooseberry, currant, grape, fruit of the potato, &c. When a fruit has only a fleshy rind, without any internal pulpiness, as is the case with the capsicum, it is not called a Berry, but a Berried Capsule. It will be seen that this definition excludes the berries of the hawthorn, the raspberry, the orange, the rose, &c. [POME; ETÆRIO; HESPERIDIUM; CYNARRHODON.]

BA'CCHA, a genus of Insects belonging to the natural order *Diptera* and family *Syrphidæ*. The species of this genus of two-winged flies are peculiar in having the two basal joints of the abdomen remarkably long and slender, with the remaining joints depressed, and suddenly increased in breadth. They are generally of a black or bronze colour, with yellow spots or markings. They are met with near London, and frequent flowers.

BACILLA'RIA, a large family of Infusorial Animalcules, constituted by Ehrenberg, who includes in it upwards of 30 genera. The silicious shields of these animalcules are amongst the most numerous of the forms of *Microzoaria* in the Cretaceous, Tertiary, and Superficial Deposits. *Xanthidia* occur in the Chalk and its included nodules of flint: *Gaillonellæ*, *Naviculæ*, *Actinocycli*, *Coscinodisci*, *Gomphonemæ*, and other genera, abound in the white Tertiary Marls of Greece, Italy, Bohemia, England, and North America. The Silicious Beds of Bohemia (Polierschiefer), which are 14 feet in thickness, contain innumerable shields of *Naviculæ*, and probably few of the superficial lacustrine deposits of Europe are wholly devoid of these exuviæ. [DIATOMACEÆ.]

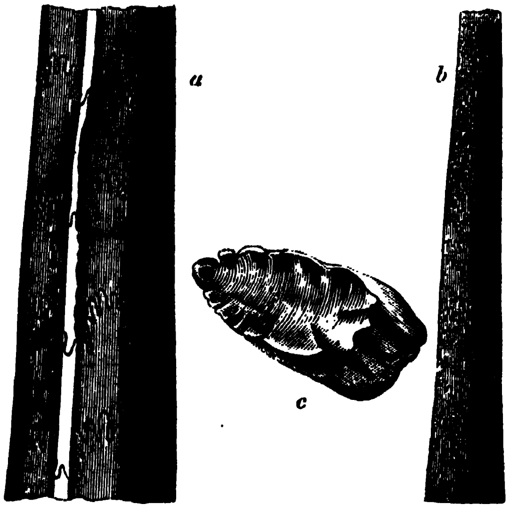
BA'CTRIS, a genus of Palms, consisting of a considerable number of species, found about rivers and in marshy places in America within the tropics, especially near the Line. Their trunk is usually of moderate height, or even dwarfish, never exceeding 20 feet; sometimes having the stout tree-like aspect of palms in general, but often more resembling reeds. They often grow in dense patches, forming impassable thickets, on account of the numerous, long, hard, black spines with which the stem is protected. The wood is generally hard and black towards the outside, but pale yellow internally, with black fibres. The leaves usually grow all over the surface of the stem, instead of being confined to the summit only. They have extremely spiny stalks, and are either pinnated after the manner of the date-palm, or merely consist of two broad, sharp, diverging, plaited lobes. The fruit is small, soft, with a subacid rather fibrous pulp inclosed in a bluish-black rind, and affords a grateful fruit to small birds.

Bactris acanthocarpa, a species which grows 12 or 15 feet high in the primæval woods about Bahia, forming patches 30 feet in circumference, and having elegant pinnated leaves 6 or 8 feet long, with stout spines on their stalks, yields an extremely tough thread, from which the natives, who call it Tucum, manufacture strong nets. Its drupes are of a kind of vermilion-red, bristling with short black prickles.

Martius mentions 17 other species.

BACULI'TES, a genus of Lamarck's Polythalamous or Many-Chambered Cephalopods, belonging to the family of *Ammonites*. *Baculites*, which was first discovered by Faujas de St. Fond in the limestone of Maestricht, is only known in a fossil state, and is comparatively abundant in the limestone of Valognes, in Normandy. The shell is straight, more or less compressed, conical, or rather tapering to a point, and very much elongated. The chambers are sinuous, and pierced by a marginal siphon, and the last chamber is several inches in length. *Baculites vertebralis*, Montfort, affords a good example of the genus. [AMMONITES.]

Bactris acanthocarpa.



Baculites vertebralis.

a, *b*, Portions of *Baculites vertebralis*; *c*, a detached piece of the same.

BADGER (*Meles*, Cuvier), a genus of Plantigrade Carnivorous Mammals included by Linnæus among the Bears, but, as well as the Gluttons, Racoons, Coatis, &c., very properly separated from that group by succeeding naturalists.

This genus, as definitely characterised by modern zoologists, is distinguished by a system of dentition which is in many respects analogous to that of the Moufettes (*Mephitis*), a genus of *Carnivora*, which indeed is scarcely to be recognised as differing from the badgers except in the plantigrade or rather semi-plantigrade formation of their extremities. There is nothing remarkable either in the size or number of the incisor or canine teeth; the grinders however are in some respects peculiar, and it is this part of the dentition which principally distinguishes the Badgers. There are 4 false molars in the upper and 8 in the under jaw, 2 and 4 on each side respectively, followed by a carnassier and a single tuberculous tooth of large dimensions. The whole system is better adapted for masticating and bruising vegetable substances than for cutting and tearing raw flesh;

and in fact the Badgers are much less carnivorous than any other animal of the order to which they belong, except perhaps the bears. The quality of the food is in all cases necessarily dependent upon the nature of the dentition. The principal character of the feet in the badgers consists in their having five toes both before and behind, short, strong, deeply buried in the flesh, and furnished with powerful compressed claws, admirably calculated for burrowing or turning up the earth in search of roots. The legs are short and muscular; the body broad, flat, and compact; the head more or less prolonged; the snout pointed; the ears small, and the tail short. Beneath the anus there is an aperture of considerable size which opens transversely, and exudes from its inner surface a greasy or oleaginous matter of very offensive odour. The same formation is observed in many other genera of carnivorous mammals, though the qualities of the substance secreted differ according to the species. In the Civets and Genets, for instance, its smell is so pleasing as to entitle it to the rank of a perfume; whilst in the Moufettes, on the contrary, its odour is so extremely fetid as to have acquired for them above all other animals the generic name of *Mephites*, or Stinkards.

The Badgers sleep all day at the bottom of their burrows, and move about during the night in search of food. They are frequently accused of destroying rabbits, game, and even young lambs; but roots and fallen fruits appear to constitute the chief part of their food, and they certainly exhibit a more marked taste for vegetable than for animal food, at least when kept in confinement. With the powerful claws of their fore feet they construct a deep and commodious burrow, generally in a sandy or light gravelly soil; this has but a single entrance from without, but it afterwards divides into different chambers, and terminates in a round apartment at the bottom, which is well lined with dry grass and hay. The habits of the badgers are extremely solitary; they are never found in company even with the females of their own species, and as they sleep all day rolled up in their bed of warm hay at the bottom of their holes, they are always fat and in good condition: their flesh is relished in many places as an article of food. They carefully remove everything of an offensive nature from their earths, never deposit their excrements in the vicinity of their habitations, and are even said to abandon them if accidentally or intentionally polluted by any other creature. In its geographical distribution the genus extends throughout the whole of Europe, Northern and Central Asia, and North America: we have no accounts of its extending into Africa or South America, in the former of which continents it appears to be represented by the Rattel (*Gulo mellivora*, Desmarest), and in the latter by various species of Moufettes (*Mephitis*). Australia possesses no species of mammal belonging to the Plantigrade Family, at least none has been hitherto discovered in that country; and in the Eastern Peninsula and Isles of India the place of the Badger is supplied by the Telagon (*Mydaus meliceps*, F. Cuvier).

The number of species which zoologists admit into the genus *Meles* is very limited indeed. All writers, without exception, have followed F. Cuvier's example in excluding the Indian Badger, for the purpose of making it the type of a new genus, though for what reason it would be difficult to say, since the dental system of this animal has never been properly described, and in all its other characters it differs in no respect from the Common Badger. Many again are disposed to consider the American Badger as only a simple variety of the European: so that according to these authors the genus includes only a single species. The observations of Sir John Richardson however have placed the distinctness of the American animal beyond a doubt; and so long as we have no definite observations to contradict the approximation, we shall continue to associate the Indian species with the genus to which its known characters so nearly assimilate it.

1. *M. vulgaris* (Desmarest), the Common Badger, is about the size of a middling dog, but stands much lower on the legs, and has a broader and flatter body. The head is long and pointed, the ears almost concealed in the hair of the head, and the tail so short that it scarcely reaches to the middle of the hind legs; the hide is amazingly thick and tough; the hair uniformly long and coarse over the whole body, and trailing along the ground on each side as the animal walks. The Badger and its congeners offer a strange intermixture of colours, which is seen in no other mammal, except those of the genera *Gulo* and *Mephitis*, which, as already remarked, approximate so nearly to it in many other respects: in general the darker shades are found to predominate upon the back and upper parts of the body, and the lighter below; but in the animals above-mentioned this general rule is reversed, and it is the light shades which occupy the back and shoulders, whilst the dark ones are spread over the breast and abdomen. The head of the Badger for instance is white, except the region beneath the chin, which is black, and two bands of the same colour, which rise on each side a little behind the corners of the mouth, and after passing backwards and enveloping the eye and ear terminate at the junction of the head and neck. The hairs of the upper part of the body, considered separately, are of three different colours, yellowish-white at the bottom, black in the middle, and ashy-gray at the point; the last colour alone however appears externally, and gives the uniform sandy-gray shade which covers all the upper parts of the body: the tail is furnished with long coarse hair of the same colour and quality, and the throat, breast, belly, and limbs are covered with shorter hair of a uniform deep black.

Though the Badger is found throughout all the northern parts of Europe and Asia, it is rather a scarce animal everywhere. Its food is chiefly roots, fruits, insects, and frogs, but it likewise destroys the eggs and young of partridges and other birds which build on the ground, and attacks the nests of the wild bees, which it robs with impunity, as the length of its hair and the thickness of its hide render it insensible to the sting of the bee. It chooses the most solitary woods for its residence, is quiet and inoffensive in its manners, but when attacked defends itself with a courage and resolution which few dogs of double its own size and weight can overcome. It bites angrily, and holds on with great tenacity, which it is enabled to do the more easily from the peculiar construction of the articulation or hinge that connects its under jaw with the skull, and which consists of a transverse condyle completely locked into a bony cavity of the cranium. The Badger is not mentioned by Aristotle, and possibly may not be found in Greece, as the ancient language of that country has not even a name for it, and as it is less common in the southern than in the northern parts of Europe. Pliny however notices it under the name of *Melis* (viii. 38), and various other Roman authors have spoken of it. More recent writers also use *Taxus*, perhaps derived, like other Roman names of northern animals, from the German language, in which the Badger is called *Zachs* or *Dachs*; in Dutch *Das*. The female brings forth her young in the early part of spring, to the number of three, four, or five; she continues to suckle them carefully for the first five or six weeks, and afterwards accustoms them gradually to shift for themselves. When taken young they are easily tamed, and become as familiar and playful as puppies; they soon learn to distinguish their master, and show their attachment by following or fawning upon those who feed them; the old however are always indocile, and continue solitary and distrustful under the most gentle treatment.

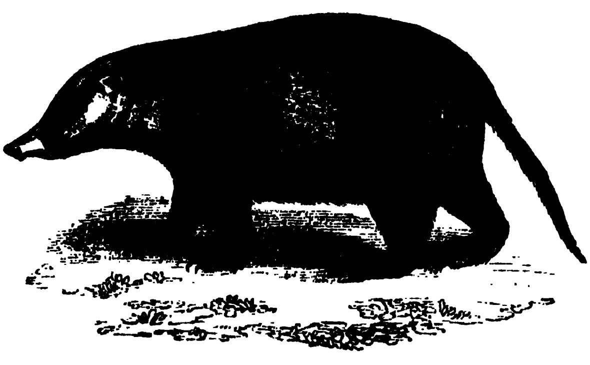
The Badger is hunted in some parts of the country during the bright moonlight nights, when he goes abroad in search of food. The hide, when properly dressed, makes the best pistol furniture; the hair is valuable for making brushes to soften the shades in painting; and the hind-quarters, when salted and smoked, make excellent hams. This kind of food indeed is not so universally esteemed in our own country as in China, where Bell informs us that he saw dozens of Badgers at a time hanging in the meat-markets of Pekin; but there is no reason why it should be inferior to the flesh of the bear, which is universally esteemed by all who have tasted it.

2. *M. Labradorica* (Sabine), the American Badger, measures, when full grown, about two feet and a half from the muzzle to the root of the tail, which is six inches more. Its snout is less attenuated than that of the European species, though its head is equally long; its ears are short and round, the claws of its fore feet much longer in proportion than those of the common species, its tail comparatively shorter, its fur of a quality altogether different, its colours also very different, and its appetites more decidedly carnivorous; the head and extremities alone are covered with short coarse hair; all the other parts of the body are furnished with remarkably soft, fine, silky fur, upwards of four inches in length, and differing only in being rather more sparingly supplied on the under than on the upper parts.

The American Badger is called Brairo and Siffleur by the Canadians, Mistonusk and Awawteekæoo, or the Digging Animal, by the Crees, and Chocartoosh by the Pawnee Indians. Its form and habits have been well described by Sir John Richardson in his admirable 'Fauna Boreali-Americana.'

"The *Meles Labradorica*," says Sir John, "frequents the sandy plains or prairies which skirt the Rocky Mountains as far north as the banks of the Peace River, and sources of the River of the Mountains, in lat. 58°. It abounds on the plains watered by the Missouri, but its exact southern range has not, as far as I know, been defined by any traveller. The sandy prairies in the neighbourhood of Carlton House, on the banks of the Saskatchewan, and also on the Red River that flows into Lake Winipeg, are perforated by innumerable badger-holes, which are a great annoyance to horsemen, particularly when the ground is covered with snow. These holes are partly dug by the badgers for habitations, but the greater number of them are merely enlargements of the burrows of the *Acctomys Hoodii* and *Richardsonii*, which the badgers dig up and prey upon. Whilst the ground is covered with snow, the badger rarely or never comes from its hole; and I suppose that in that climate it passes the winter, from the beginning of November till April, in a torpid state. Indeed, as it obtains the small animals upon which it feeds by surprising them in their burrows, it has little chance of digging them out at a time when the ground is frozen into a solid rock. Like the bears, the badgers do not lose much flesh during their long hybernation, for on coming abroad in the spring they are observed to be very fat. As they pair however at that season they soon become lean. The badger is a slow and timid animal, taking to the first earth it meets with when pursued; and as it makes its way through the sandy soil with the rapidity of a mole, it soon places itself out of the reach of danger. The strength of its fore feet and claws is so great, that one which had insinuated only its head and shoulders into a hole resisted the utmost efforts of two stout young men, who endeavoured to drag it out by the hind legs and tail, until one of them fired the contents of his fowling-piece into its body. Early in the spring however, when they first begin to stir abroad, they may be easily caught by pouring water into their holes; for the ground being frozen at that period, the water does not escape through the sand, but soon fills the hole, and its tenant is obliged to come out. The American Badger appears to be a more carnivorous animal than the European one. A female which I killed had a small marmot, nearly entire, together with some field mice, in its stomach. It had also been eating some vegetable matters." As to the southern limit of the geographical range of the species, at least in one direction, it is known to inhabit Mexico, as appears from the detailed and correct description of Fernandez, who calls it by the native name of Ilacoyotl or Coyotlhumuli; and a very fine skin was some time ago sent from California to the Zoological Society.

3. ***M. collaris***, the Indian Badger, called Bhalloo-Soor, or Bear-Pig, by the Hindoos, is about the size of the Common Badger, but stands higher upon its legs, and is at once distinguished by its attenuated muzzle ending in a truncated snout, like that of the common hog, and by its small and nearly naked tail. The whole height of this animal is about 20 inches, and the length of its tail 9 inches. It has the body and limbs of a bear, with the snout, eyes, and tail of a hog. Its ears are short, completely covered with hair, and surrounded by a slight border of white.



Indian Badger (*Meles collaris*).

The individuals, a male and female, observed in the menagerie of the Governor-general at Barrackpoor by the French naturalist Duvancel, who furnished Mons. F. Cuvier with the materials for his description, were remarkably shy and wild. The female however was less savage than the male, and showed a certain degree of intelligence, which gave reason to believe that, if taken young, this animal might be easily domesticated. They passed the greater part of the day buried beneath the straw of their den in deep sleep. All their movements were remarkably slow. Though they did not altogether refuse animal food, yet they exhibited a marked predilection for bread, fruits, and other substances of a vegetable nature. When irritated they uttered a peculiar kind of grunting noise, and bristled up the hair of their back; if still further tormented, they would raise themselves upon their hind legs like a bear, and appeared, like that animal, to possess a power in their arms and claws not less formidable than their teeth. This is confirmed by Mr. Johnson in his 'Sketches of Indian Field Sports.' "Badgers in India," says he, "are marked exactly like those in England, but they are larger and taller, are exceedingly fierce, and will attack a number of dogs. I have seen dogs that would attack a hyæna or wolf afraid to encounter them. They are scarce, but occasionally to be met with among the hills. In their nature they resemble the bear."

BADI'STER, a genus of Insects belonging to the order *Coleoptera*, and family *Harpalidæ*. This genus, together with the genera *Trimorphus*, *Licinus*, *Rembus*, and *Dicœlus*, form a conspicuous group among the *Carnivora* of the Beetle Tribe.

BAËTIS, a genus of Insects of the order *Neuroptera*, and family *Ephemeridæ*. This is one of the four genera of the British family of May-Flies. The generic characters are taken from the number of wings, and the setæ, or hair-like appendages to the abdomen. The genus *Ephemera* has four wings and three setæ; *Baëtis* has four wings and two setæ; *Brachycercus* has two wings and three setæ; and *Cloëon* has two wings and two setæ. These setæ are of great use to the little animal in steering its way through the air whilst performing that beautifully undulating flight which all must have observed. It is to the first of these genera (*Ephemera*) that the common May-Fly belongs.

BAGO'US, a genus of Insects belonging to the order *Coleoptera*, and family *Curculionidæ*. The little Beetles composing this genus are all of a mud-colour, and feed upon aquatic plants, probably both in the larva and imago states. There are six or eight species found in England.

BAGSHOT SAND. One of the higher members of the Tertiary Group of England is thus designated.

BAIKALITE, a light-green variety of Augite, deriving its name from its locality, the mouth of the river Sljumanka, which falls into Lake Baikal. [AUGITE.]

BALA LIMESTONE, one of the most interesting of the Calcareous Deposits which have been examined by Professor Sedgwick in the midst of the Schistose Rocks of North Wales. There are two bands of this rock, exhibited on the west of the Berwyn Mountains and on the east of Bala Lake. Two miles north-east of Bala the limestone and the schistose rocks in which it lies may be well seen, and numerous fossils may be gathered at this and at many other points in the vicinity of Bala, on both sides of the lake. Professor Sedgwick has satisfied geologists of the true position of those rocks with reference to the slates of the Berwyn range, and the flags and slates of Llangollen. The series is in two parts, thus:—

Upper Part. Flags and schistose beds of Llangollen, with upper Silurian fossils.

Lower Part. Schistose beds with limestone bands, the lowest of which occur at Bala, and yield lower Silurian fossils.

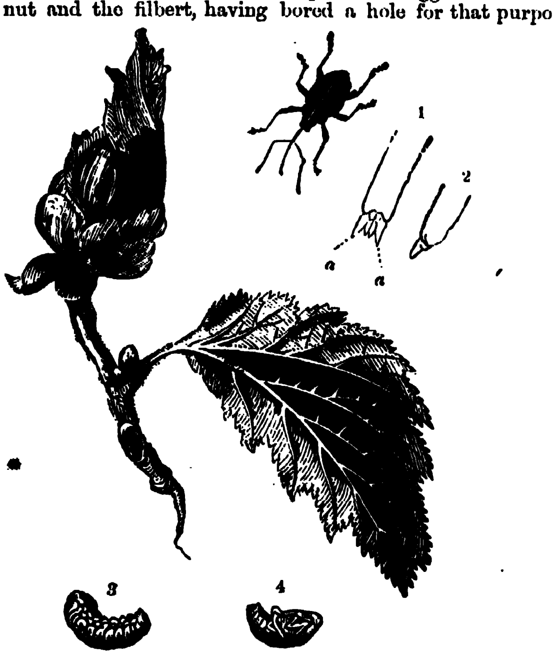
This is the view of Professor Sedgwick, and the Bala and Llandeilo limestones are thus nearly coeval.

BALÆ'NA (from the Greek φάλαινα), the Latin name of the Common or Greenland Whale, and adopted by naturalists as a generic term, to comprehend all the other species which agree with it in their zoological characters. [CETACEA.]

BALÆNO'PTERA. This term was invented by Lacépède, to denote those whales which are distinguished by having an adipose fin on the back, whence they are called Finners by sailors, and which he proposed to separate from the other *Balænæ* for the purpose of forming them into a distinct genus. The character however upon which he proposed to make this separation is utterly void of importance, and exercises no assignable influence upon the habits and economy of animal life. His division is consequently vicious, and cannot be admitted into a natural or philosophical system of mammalogy, at least for any other purpose than as a matter of simple convenience. The word itself is compounded of the terms *balæna*, a whale, and πτέρον, a wing or fin.

BALANI'NUS, a genus of Insects belonging to the order *Coleoptera*, and family *Curculionidæ*. The species of this genus are all remarkable for possessing a long slender rostrum or snout, which is furnished at the tip with a minute pair of sharp horizontal jaws: this instrument is used by the animal in depositing its eggs, which are generally placed in the kernel of some fruit.

Balaninus Nucum, the Nut-Weevil, deposits its eggs in both the common nut and the filbert, having bored a hole for that purpose while the nut is young and tender. When about to perform this operation, the little animal may be seen travelling over the nut, and feeling with its antennæ to discover a convenient situation, in selecting which it shows great care. The spot being determined on, it cuts a hole with the jaws at the top of the snout until it reaches the kernel; in this hole the egg is deposited, which in a short time is hatched and becomes a maggot or larva. The nut being but slightly injured continues to grow and ripen, while the larva feeds upon its kernel. In course of time this larva gnaws a hole in the shell, through which it makes its escape, and immediately burrows into the ground, where it assumes the pupa state, from which, in the following



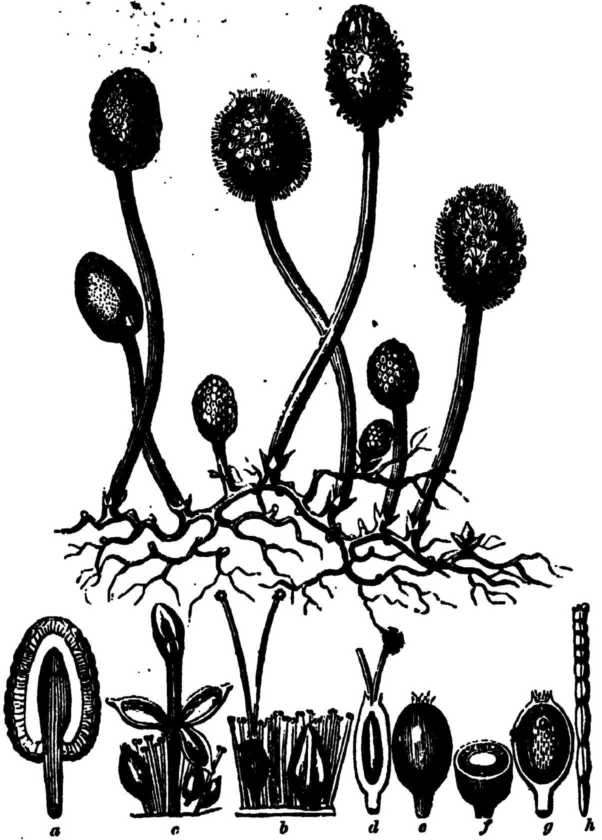
Nut-Weevil (*Balaninus Nucum*).

1, The tip of the rostrum magnified, showing the jaws, *a a*; 2, side view of the same; 3, the larva; 4, the pupa. The larva, pupa, and perfect insect, are each represented rather larger than the natural size.

summer, the perfect insect proceeds. The preceding figure represents a nut which has been pierced by the larva.

Balaninus Glandium, another species of the same genus, attacks the acorn in the same manner as the one above mentioned does the nut.

BALANOPHORA'CEÆ, *Cynomoriums*, a natural order of Parasitical Plants belonging to the sub-class *Rhizantheæ*. They grow upon the roots of woody plants, in tropical countries, rooting into their wood, from which they draw their nutriment, as the mistletoe from the branches of the thorn. None of the species have fully-formed leaves; but, in lieu of them, closely-packed fleshy scales clothe their stems and guard their flowers in their infancy. Succulent in texture, dingy in colour, and often springing from a brown and shapeless root-stock, *Balanophoraceæ* remind the observer of *Fungi* more than of flowering plants: and in fact they appear intermediate in nature between the two. If they have flowers and sexes, both are of the simplest kind; and their ovules, instead of changing to seeds, like those of other flowering plants, become, according to Endlicher, bags of spores, like those of true flowerless plants. Even their woody system is of the most imperfect kind, for it is either entirely, or almost entirely, destitute of spiral vessels. It is probable that numerous genera and species of this singular order still remain undiscovered in the depths of tropical forests, where they lurk among the herbage, and are not likely to attract the attention of the mere flower-gathering traveller. All the species, with the exception of one found in Malta, are natives of the tropics. The species have had a reputation as styptics. The *Cynomorium coccineum*, or *Fungus Melitensis*, has been employed for this purpose. Various species of *Helosis* have had a similar reputation. Pöppig says the *Ombrophyton* is eaten in Peru. The species of *Sarcophyte* have an atrocious odour.



Balanophoraceæ.

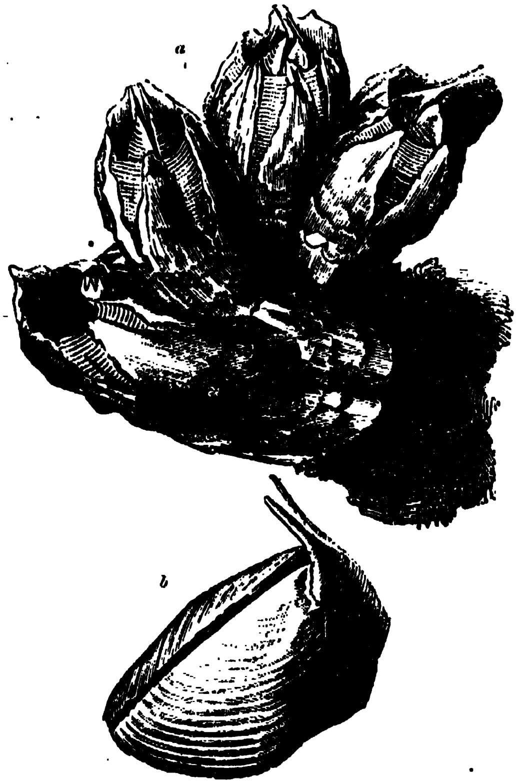
a, A head of flowers cut through vertically; *b*, a highly-magnified view of a portion of the receptacle with two fertile flowers; *c*, a male flower in the midst of some fertile ones; *d*, an ovary; *e*, a ripe fruit; *f*, a transverse section of the same; *g*, a verticle section of the same; *h*, a jointed hair of the receptacle.

BALA'NTIA, from βαλάντιον, a bag or pouch, the generic name which the German naturalist Illiger gave to the animals commonly called *Phalangers* (*Phalangista*): the latter name he reserves for the *Petaurists* (*Petaurus*) of other zoologists. [MARSUPIATA.]

BA'LANUS, a genus of Sessile Cirrhipeds or Barnacles, formed by Bruguières from some species of the genus *Lepas*, Linn. *Balanus* offers a great variety of form; but the shell will be found to consist of six valves, four of which are comparatively large, coalescing at the sides, and forming altogether a rude hollow cone, whose aperture is closed by an operculum of four valves (between the two foremost of which issue the jointed feather-like tentacula), and its base by a testaceous plate.

The genus is most widely diffused, and abounds upon almost all bodies, whether fixed or moveable, that offer an opportunity for it to attach itself to them, and are immersed in the sea. On rocks left dry at low water, on ships, on timber, whether floating or at rest, on lobsters and other crustaceans, on the shells of conchifers and mollusks, colonies of *Balani* are to be found.

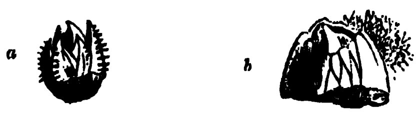
Balanus Psittacus (*Lepas Psittacus*, Molina) is described by Captain P. P. King, R.N., in his 'Description of the Cirrhipeda, Conchifera, and Mollusca, in a Collection formed by the Officers of H.M.S. Adventure and Beagle, employed between the years 1826 and 1830 in surveying the Southern Coasts of South America, including the Straits of Magalhaens and the Coast of Tierra del Fuego.'



a, *Balanus Psittacus*, about one-fourth of the natural size.
b, The opercular valves, natural size.

"This cirrhiped," writes Captain King, "which at Concepcion de Chile is frequently of a larger size than 5½ inches long and 3½ inches in diameter, forms a very common and highly-esteemed food of the natives, by whom it is called Pico, from the acuminated processes of the two posterior opercular valves. The anterior and posterior opercular valves, when in contact, present some resemblance to a parrot's beak, whence Molina's name. It is also found very abundantly at Valdivia and at Calbuco, near the north of the island of Chiloe. It occurs in large bunches, and presents somewhat of a cactus-like appearance. The parent is covered by its progeny, so that large branches are found composed of from 50 to 100 distinct individuals, each of which becomes in its turn the foundation of another colony. One specimen, in the possession of my friend W. J. Broderip, Esq., consists of a numerous group based on two large individuals. They are collected by being chopped off with a hatchet. At Concepcion, where they are found of larger size than to the southward, they are principally procured at the island of Quiriquina, which lies across the entrance of the bay; whence they are exported in large quantities to Valparaiso and Santiago de Chile, where they are considered as a great delicacy; and indeed with some justice, for the flesh equals in richness and delicacy that of the crab, which, when boiled and eaten cold, it very much resembles."

The spined and smooth varieties of *Balanus Montagui*, Sowerby (*Acasta Montagui*, Leach), afford examples of those species which live in sponges.



a, *Balanus Montagui*.
b, Variety without spines, and with a flat base.

Fossil *Balani* have been found in the later deposits, and species are recorded from the beds at Piacenza, Bordeaux, Paris, Essex, &c. [CIRRHIPEDA.]

BALAS RUBY, a term used by lapidaries to designate the rose-red varieties of *Spinel*. [SPINEL.] It should be carefully distinguished from *Oriental Ruby* (the *Sapphire*), a gem of much greater rarity and value. [ADAMANTINE SPAR.]

BALBUSARDUS HALIÆTUS, a name for the Bald Buzzard or Osprey. [FALCONIDÆ; OSPREY.]

BALD BUZZARD, one of the English names for the Osprey or Fishing Eagle, the *Falco Haliætus* of Linnæus, *Pandion Haliætus* of Savigny. [FALCONIDÆ; OSPREY.]

BALIO'STICHUS. A fossil plant in the Laminated Lithographic Limestone of Pappenheim, is named *Baliostichus ornatus* by Sternberg.

BALISTES, a genus of Fishes belonging to the order *Plectognathes*, and family *Sclerodermes* of Cuvier. These groups are intermediate in point of structure between the common or osseous tribes and the cartilaginous tribes; for though the skeleton is in reality of a fibrous or bony texture, it ossifies very slowly, and is never entirely complete; the ribs in particular usually remain imperfect throughout the whole period of the animal's life. The maxillary and intermaxillary bones, again, form but a simple piece, distinguished only by a slight suture or furrow at the point of junction, and the palatal arch is soldered firmly to the skull, and consequently devoid of individual motion. The opercula and gill-rays are concealed beneath the skin, which gave origin to an opinion, at one time common even among professed naturalists, that these fishes wanted the branchial apparatus altogether.

The *Balistes* are particularly distinguished by the vertical compression of the body, by having eight teeth arranged in a single row in each jaw, and a scaly or granulated skin. They have two dorsals; the first composed of numerous powerful spines, articulated to a peculiar bone, itself articulated to the skull, and furnished with a longitudinal furrow for the reception of the spines, which can be erected or depressed at the will of the animal; the second large, soft, or without spines, and placed opposite to an anal fin of similar structure. Like other genera of the same order, the *Balistes* have no ventral fins; notwithstanding which, however, their skeleton is furnished with a complete pelvis, suspended from the bones of the shoulder. The intestinal canal is large, but without cæca, and the air-bladder of considerable size. These fish abound in all the seas of the torrid zone, where they swim on the surface of the water, particularly in the neighbourhood of rocky coasts and coral reefs, feeding with avidity upon the polypi of the reefs, and shining with the most brilliant and varied colours. Their flesh is at all times very indifferent food, and is said to be actually poisonous during the period that the coral-worms are in season. The species are very numerous. They are easily distinguished by the rhomboidal form of their large and hard scales, which are disposed in regular rows, not overlapping one another as in the generality of fishes, but merely touching at their edges, and thus giving the whole body the appearance of being divided into so many regular compartments. Though, as already observed, they have no real abdominal fins, yet a few isolated spines are often found in the vicinity of the pelvis, which have been generally considered as representing these organs; and the greater number have the sides of the tail armed with one or more rows of strong spines curved forwards.

BA'LLOTA, a genus of plants belonging to the natural order *Labiatæ*, and the tribe *Stachydeæ*. It has the anthers approximating in pairs, the cells diverging, bursting longitudinally. The upper lip of the corolla is erect, concave, the lower three-lobed, the middle lobe cordate. The calyx is funnel-shaped, with five equal teeth. There are two British species of this genus, *B. fœtida* and *B. ruderalis*. *B. fœtida* is the most common plant, and goes by the name of Horehound. The White Horehound is the *Marrubium vulgare*. [MARRUBIUM.]

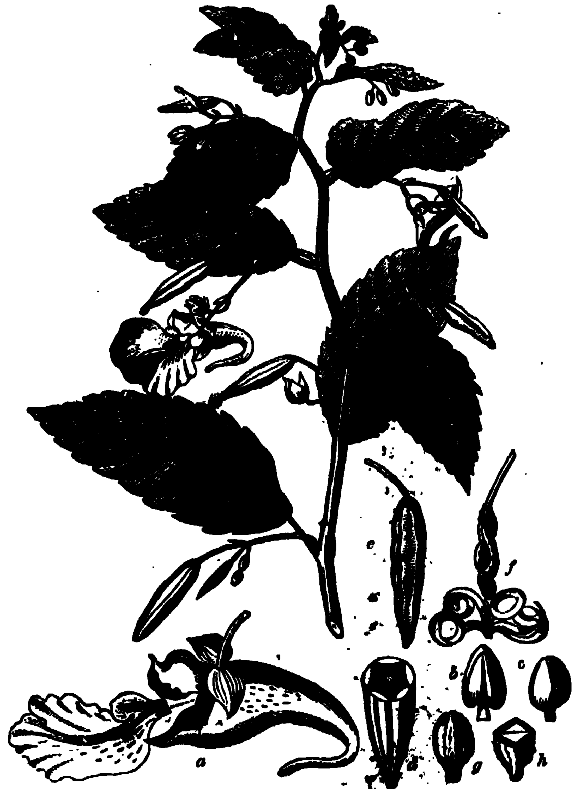
BALM. [MELISSA.]

BALSAM. [IMPATIENS.]

BALSAMI'FLUÆ, *Liquidambars*, a natural order of plants consisting of only one genus, *Liquidambar*, first indicated by Theodore Nees von Esenbeck, defined by Dr. Blume in his 'Flora Javæ,' and adopted by Lindley in his 'Vegetable Kingdom' under the name of *Altingiaceæ*. It is intermediate between the Willow and Plane Tribes, from the former of which it differs in having a 2-celled fruit and downless seed, and from the latter in having numerous seeds. It consists of lofty trees, flowing with balsamic juice, bearing the flowers in small scaly heads, without either calyx or corolla, and having the stamens in one kind of head and the pistils in another. The different species yield the resinous fragrant substance called Liquid Storax, which is so much prized by the inhabitants of the East. [LIQUIDAMBAR; STORAX, in ARTS AND SC. DIV.]

BALSA'MINA, one of the two genera of which the natural order *Balsaminaceæ* consists. It differs from *Impatiens* in having all its anthers 2-celled, its stigmas distinct, and the valves of its fruits curling inwards when bursting. There are numerous species, several of which have very handsome flowers. They are chiefly found in the damper parts of the East Indies; but the only one that is much known in Europe is the common Garden Balsam (*Balsamina hortensis*), which in its double state has been an object of cultivation since the earliest records of modern horticulture. This plant, which is supposed to be found wild in the mountainous parts of Silhet, in the form of what botanists call *Balsamina tripetala*, is one of those species which not only has a tendency to vary with double flowers, but has also the power of continuing to produce them when renewed from seeds. On this account it particularly deserves the attention of the cultivator, especially as it may be brought by art to a state of beauty equalled by few plants. All that is necessary in order to secure fine Balsams, is, first to save the seed with great care from the finest and most double flowers only, throwing away all whole-coloured and single blossoms; and secondly, to cultivate the plants with a due regard to the natural habits of the species. A native of the hot damp shady woods of Silhet, it is incapable of bearing much drought or bright sunshine. It should therefore be raised in a hot-bed, treated with great care as a tender annual, grown in rich soil, sheltered from excessive sunlight, and kept constantly in a damp atmosphere, but freely and fully ventilated. It should not however be stimulated into extremely rapid growth until the plants have become stout bushes and the flowers have grown to the size of small peas. At that time the plants should have all the heat and moisture they can bear, and the most brilliant flowers the plant is capable of producing will be the result. In the latter stage of growth great care is still to be taken to expose the plants fully to air.

BALSAMINA'CEÆ, a small natural order of plants belonging to the Gynobasic group of Dicotyledons, and principally distinguished from *Geraniaceæ* by their many-seeded fruit and unsymmetrical flowers. They are succulent herbs, most abundant in hot countries, with simple opposite or alternate leaves, and showy flowers, with a spur to their calyx. They have no sensible properties of importance, but are the ornament of the damp or swampy places in which they grow wild. The order is remarkable for the elastic force with which the valves of its fruit contract and reject the seeds.



Impatiens Noli-tangere.

a, a calyx magnified, with one of the petals; *b*, the front of an anther; *c*, the back of the same; *d*, an ovary cut across; *e*, the ripe fruit; *f*, the same in the act of bursting and scattering its seeds; *g*, a seed; *h*, the same cut transversely.

BALSAMODE'NDRON, a genus of oriental trees belonging to the natural order *Amyridaceæ*, and remarkable for their powerful balsamic juice. They have small green axillary diœcious flowers, a minute 4-toothed persistent calyx, four narrow inflected petals, eight stamens inserted below an annular disk, from which eight little excrescences arise alternating with the stamens, and a small oval drupe with four sutures, and either one or two cells, in each of which is lodged a single seed. The leaves are pinnated, with one or two pairs of leaflets, and an odd one.

B. Opobalsamum, the Balessan of Bruce, has a trunk from six to eight feet high, furnished with a number of slender branches ending in a sharp spine. The leaves consist of from five to seven sessile, obovate, entire, and shining leaflets, within which are placed the small flowers, which grow in pairs on short slender stalks, and are succeeded by small oval plums. From this is distinguished the

B. Gileadense, supposed to be the *βαλσάμον δένδρον* of Theophrastus, which is described as a middle-sized tree, with the leaflets growing in threes, and the flowers singly. But it is probable that, as these balsam-trees are found in the same places, and produce the same substance, they are in fact nothing but varieties of the same species. They both produce three different substances: 1, Balm of Mecca, or Balm of

Gilead, or Opobalsamum; 2, Xylobalsamum; and 3, Carpobalsamum; the first obtained from the trunk of the balsam-trees by simple incision; the second by boiling the branches and skimming off the resin as it rises to the surface of the water; and the third by simple pressure of the fruit. They are no longer met with, even in gardens, about Gilead in Palestine.

B. Myrrha is a small scrubby tree found in Arabia Felix, near Gison, scattered among species of *Acacia, Euphorbia,* and *Moringa.* Both its wood and bark have a strong and remarkable odour. The branches are stiff, short, and spiny; the leaves composed of three obovate unequal leaflets, with distinct crenatures, and the fruit a narrow, oval, furrowed plum, surrounded at the base by the persistent calyx.

B. Katof has fewer spines, and downy and more distinctly serrated leaves. Its wood, which is red and resinous, is a common article of sale in Egypt.

Whatever may be the product of the last species, which Forskäl states to produce the myrrh of commerce, it is now certain that this substance is yielded by *Balsamodendron Myrrha,* which Ehrenberg found on the frontiers of Nubia and Arabia, bearing a substance identical with the myrrh of the shops. It is therefore no longer to be doubted that the suggestion of Bruce, that it is the produce of a kind of Mimosa—a most improbable circumstance, by the way—originated in some incorrect observation.

B. Zeylanicum is mentioned as a fifth species, producing oriental Elemi, which is very different from the American kind; but of this too little is known to enable us to do more than advert to its existence.

Balsamodendron Myrrha.

Myrrh, a natural gum-resin, the source of which was long doubtful, was observed by Ehrenberg to exude from the bark of the above-mentioned species of balm, much in the same way as gum tragacanth exudes from the *Astragalus verus.* It is at first soft, oily, and of a yellowish-white colour, then acquires the consistence of butter, and by exposure to the air becomes harder, and changes to a reddish hue. As met with in commerce it is of two kinds, that which is called Myrrh in Tears, and that called Myrrh in Sorts.

Dr. Von Martius mentions a White Myrrh, which has a very bitter taste like colocynth, and an external appearance like ammoniacum; it is probably ammoniacum treated with tincture of colocynth. Another false myrrh may be distinguished by its transparency and less bitter taste. [BALSAMS; MYRRH, in ARTS AND SC. DIV.]

BALTIMORITE, a mineral which is a variety of Serpentine, and is composed of longitudinal fibres adhering to each other. It has a silky lustre, is opaque, but in thin pieces translucent on the edges. Its hardness is less than that of calcareous spar. It is found at Baltimore, United States. The following is the analysis by Dr. Thompson:—

Silica	40·95
Magnesia	34·70
Protoxide of Iron	10·05
Alumina	1·50
Water	12·60

BAMBU'SA, the *Bamboo,* a genus of Grasses, well known for its great economical importance, but consisting of species which are very imperfectly understood by botanists. It is remarkable in structure, among other things, for having only one style, which is more or less deeply two- or three-parted, three minute scales at the base of its ovary, and six stamens.

It is doubtful whether nature has conferred upon the inhabitants of hot countries any boon more valuable than the Bamboo, unless it be the Cocoa-Nut; to such a multitude of useful purposes are its light, strong, and graceful stems applicable. These are universally pushed forth by a strong, jointed, subterranean, creeping rootstock, which is the true trunk of the Bamboo, the shoots being the branches. The latter are hard externally and coated with flint; in the inside they are hollow, except at the nodes, where strong partitions stretch across the inside, and cut off the interior into a number of closed-up cylinders. In the cavity of these cylinders water is sometimes secreted, or, less commonly, an opaque white substance, becoming opaline when wetted, consisting of a flinty secretion, of which the plant divests itself, called Tabasheer, concerning the optical properties of which Sir David Brewster has made some curious discoveries.

In their manner of growth they exhibit a beautiful example of a contrivance by which they are enabled to grow into the dense tufts which they usually form. When full-grown a bamboo is a straight rod, bearing a number of stiff branches, which shoot at nearly right angles from the main stem; and it is difficult to conceive by what arrangement such a stem elevates itself through the dense mass of rigid branches which cross each other in every direction. This is however contrived by nature in a very simple manner. The young shoot of a bamboo, whatever its length may be, when it is first produced, is a perfectly simple sucker, like a shoot of asparagus, but having a sharp point, and in this state it pierces readily the dense overhanging branches; it is only when it has arrived at its full length and has penetrated through all obstacles, that it begins to form its lateral shoots; and these, which are emitted horizontally, readily interpose themselves between the horizontal laterals of the bamboo stems among which they grow. In the words of Dr. Roxburgh, the shoots, on their first appearance, resemble a large straight elephant's tusk invested in stout leathery sheaths.

The purposes to which different species of Bamboo are applied are so numerous that it would be difficult to point out an object in which strength and elasticity are requisite, and for which lightness is no objection, to which the stems are not adapted in the countries where they grow. The young shoots of some species are cut when tender, and eaten like asparagus. The full-grown stems, while green, form elegant cases, exhaling a perpetual moisture, and capable of transporting fresh flowers for hundreds of miles: when ripe and hard they are converted into bows, arrows, and quivers, lance-shafts, the masts of vessels, bed-posts, walking-sticks, the poles of palanquins, the floors and supporters of rustic bridges, and a variety of similar purposes. In a growing state the spiny kinds are formed into stockades, which are impenetrable to any but regular infantry, aided by artillery. By notching their sides the Malays make wonderfully light scaling-ladders, which can be conveyed with facility where heavier machines could not be transported. Bruised and crushed in water, the leaves and stems form Chinese paper, the finer qualities of which are only improved by a mixture of raw cotton and by more careful pounding. The leaves of a small species are the material used by the Chinese for the lining of their tea-chests. Cut into lengths and the partitions knocked out, they form durable water-pipes, or by a little contrivance are made into excellent cases for holding rolls of paper. Slit into strips they afford a most durable material for weaving into mats, baskets, window-blinds, and even the sails of boats. Finally, the larger and thicker truncheons are exquisitely carved by the Chinese into beautiful ornaments. It is however more especially for building purposes that the bamboo is important. According to Marsden, in Sumatra the frame-work of the houses of the natives is chiefly composed of this material. In the floorings, whole stems, four or five inches in diameter, are laid close to each other, and across these stems laths of split bamboo about an inch wide are fastened down with filaments of the rattan-cane. The sides of the houses are closed in with the bamboo opened, and rendered flat by splitting or notching the circular joints on the outside, chipping away the corresponding divisions within, and laying it in the sun to dry, pressed down with weights. Whole bamboos often form the upright timbers, and the house is generally roofed in with a thatch of narrow split bamboos, six feet long, placed in regular layers, each reaching within two feet of the extremity of that beneath it, by which a treble covering is formed. Another and most ingenious roof is also formed by cutting large straight bamboos of sufficient length to reach from the ridge to the eaves, then splitting them exactly in two, knocking out the partitions, and arranging them in close order with the hollow or inner sides uppermost; after which a second layer, with the outer or convex sides up, is placed upon the other in such a manner that each of the convex pieces falls into the two contiguous concave pieces, covering their edges; the latter serving as gutters to carry off the rain that falls upon the upper or convex layer.

The different species of *Bambusa* may be conveniently distributed in three sections.

I. *Asiatic Bamboos, with the Flowers either in Spikes or Panicles.*

1. *B. arundinacea,* Roxburgh. Spiny. Leaves very narrow, covered with asperities on the margin and upper surface. (Called *Bans* in Bengal.) 'Common in rich, moist soil, among the mountains of India. The stems grow in clusters, from 10 to 100, from the same root-stock, and are straight for 18 or 20 feet. When in flower it is usually destitute of leaves, and as the extremity of every ramification is covered with blossom, the whole tree seems one entire immense panicle. Its seeds are used as rice. Tabasheer is found in its joints.

2. *B. stricta,* Roxb. Somewhat spiny. Flowers in extremely compact whorls. Said to be a smaller species than the last: it grows in a drier situation, has a much smaller cavity, and is very straight. Its great strength, solidity, and straightness render it much fitter for many uses. From this the shafts of lances are made in India.

3. *B. vulgaris,* Wendl. Not spiny; leaves very narrow, covered at the edge and on the upper surface with asperities. Found in the East Indies, whence it is thought to have been carried to the West. Its stems are from 20 to 30 feet long, and as thick as a child's arm.

4. *B. spinosa,* Roxb. Strongly armed with both single and compound spines; leaves very narrow, rarely more than six inches long. (*Behor Bans,* in Bengal.) Common about Calcutta, and in the south of India, forming an impenetrable jungle; also often cultivated round Indian villages. It has a smaller hollow than most of the others, and is consequently stronger than many of them. Dr. Roxburgh describes it as rising in such dense tufts as to appear like a single trunk at some

distance; and by help of their spiny branches so bound together that it is a most arduous task to cut down an old clump of them. The stems are from 30 to 50 feet long.

5. *B. Tulda*, Roxb. Not spiny; leaves broad, rounded or heart-shaped at the base. (*Tulda Bans* in Bengal; *Peka Bans* of the Hindoos.) Common all over Bengal. Its growth is so rapid that the stems, which are sometimes as much as 70 feet long and 12 inches in circumference, rise to their full height in about 30 days. Before their lateral shoots are formed, they are described as resembling fishing-rods of immense size. The young thick shoots, when about two feet high, are tender, and form an excellent pickle. It is chiefly used for scaffolding and for covering the houses of the natives; it is found to last much longer if steeped in water some time before being used. Of this species Dr. Roxburgh mentions several varieties. *Jowa Bans* is a larger variety, with longer and thicker joints; *Basini Bans* has a larger cavity, and is chiefly used to make baskets. *Behoor Bans* is of a small size, very solid and strong, much bent to one side, and armed with numerous strong thorns. A staff of it is placed in the hand of every young Brahmin when invested with the sacerdotal robe. It is probably a distinct species.

6. *B. Balcooa*, Roxb. Not spiny; leaves narrow, heart-shaped at the base. (*Balcoo Bans* in Bengal.) A native of Bengal, and even more gigantic than the last. It is reckoned by the workers in bamboo the very best for building purposes. Previously to being used, it is immersed in water for a considerable time. Two varieties are distinguished: *Dhooli Balcoo*, the larger, and *Balcoo Bans*, which is smaller and stronger, with a less cavity.

7. *B. Blumeana*, Schultes. Armed with triple recurved spines: leaves very narrow, quite smooth, suddenly tapering into a short stalk. A native of Java. Stems about as thick as a child's arm.

8. *B. agrestis*, Poir. Stems crooked, at the lower part very spiny; leaves narrow, small, smooth. On mountains, and in dry and desert places in all China and Cochin China; it is common also in various islands in the Malay Archipelago. Its crooked sometimes creeping stems and rugged aspect distinguish it. The trunk is a foot thick, and the joints (we presume near the base) a foot and a half long, and often nearly solid.

9. *B. Thouarsii*, Kunth. Stems very much branched. Found wild in Madagascar, where however it is not believed to be indigenous.

10. *B. mitis*, Poir. Stems perfectly unarmed; leaves very narrow, and clasping the stems at their base. Cultivated in the fields and hedges of Cochin China, and found wild in Amboyna, where several supposed varieties exist. Its stems grow 30 feet long, and are said by Rumphius to be the strongest of all the species, although its sides are thin. It is sometimes as thick as a man's leg.

11. *B. maxima*, Poir. Stems very straight, branching only near the summit, and densely covered with spines. The most gigantic of all the species, from 80 to 100 feet high, and sometimes as thick as a man's body. Its wood is however very thin. It is found wild in Cambodia, Bally, Java, and various islands of the Malayan Archipelago.

12. *B. aspera*, Schultes. Stems covered all over with a sort of white mealy down. Found at the foot of mountains in Amboyna, with stems from 60 to 70 feet high, and as thick as a man's thigh. It does not branch, but emits little hard spine-like roots at its nodes.

13. *B. apus*, Schultes. Leaves very large, taper-pointed, and gradually narrowing to the base, extremely scabrous at the edge. Another gigantic species, with the dimensions of the last, growing on Mount Salak, in Java.

14. *B. Bitung*, Schultes. Leaves very large, taper-pointed, narrowed at the base into a sort of bristly very short stalk, very scabrous at the edge and on the upper surface. Found in Java with the last, and remarkable for its extremely broad and scabrous leaves. Its dimensions are not stated.

15. *B. nigra*, Loddiges. Not spiny. Stems slender, swelled at the nodes, dark-brown, and polished, not more than a man's height. Leaves narrow, very smooth, rounded and narrowed at the base into a short stalk; ligule with long stiff fringes. A native of the neighbourhood of Canton, where its beautiful slender stems are cut for the handles of parasols, walking-sticks, &c. It is by far the most patient of cold, having been living for several years without protection in a morass in the garden of the London Horticultural Society, and is no doubt capable of being acclimated in the south-west of England or on the west coast of Ireland.

16. *B. aristata*, Loddiges. Stems slender, smooth, not spiny. Leaves very smooth, narrowed gradually at the base into a short stalk; with downy fringed sheaths. Ligules divided into very long coarse fringes. Nodes mealy when young. Native of the East Indies. A very elegant species, related to the last.

17. *B. nana*, Roxb. A native of China. It makes most beautiful close hedges.

18. *B. pubescens*, Loddiges. Not spiny. Young shoots, leaf-sheaths, and leaves on the under side, covered with short down. A very remarkable species, obtained by the English from the collections of France. Its native country is unknown. The stems are 30 feet long, and an inch and a half in diameter.

19. *B. striata*, Loddiges. Not spiny. Stems slender, polished, yellow with green stripes. Leaves narrow, rather glaucous on the under side, tapering into a short stalk at the base, quite smooth, except a few short black hairs on the sheaths. A native of China. Often cultivated in the hot-houses of England on account of its beautiful variegated stems. Grows about 20 feet high.

20. *B. glauca*, Loddiges. Not spiny. Stems very slender, pale green. Leaves very small, not downy, taper-pointed, almost heart-shaped at the base, covered on the under surface with very close bright glaucous bloom. Leaves scarcely above an inch long, and not more than two lines broad. A native of India, whence it was procured by the Messrs. Loddiges. A very remarkable species, not growing above 2 feet high, with entangled branches.

II. *Asiatic Bamboos, with the Flowers not Panicled, but in simple Terminal Whorled Spikes.*

21. *B. verticillata*, Willd. Leaf-sheaths covered with stinging hairs. Stems whitish. Fifteen or sixteen feet high, and when full-grown of a pale colour, which becomes nearly white in drying. The hairs of the leaves occasion so much itching, that this kind is troublesome to collect. It is the *Leleba alba* of Rumphius, who says the edges of its leaves are so sharp as to wound the gatherers. It is found in Amboyna.

22. *B. atra.* Leaf-stalks covered with stinging hairs. Stems black and shining. Very like the last, and found also in Amboyna. It chiefly differs in the colour of the stems. It is the *Leleba nigra* of Rumphius.

23. *B. prava.* Leaves very large, stiff, and broad, extremely hispid with stinging hairs. The most common in Amboyna, forming large woods, which come down to the coast. It flourishes equally in dry and moist situations, and is readily known from the others of this section by its very large leaves, which are as much as 18 inches long and 3 or 4 inches broad.

24. *B. picta.* Joints very long, variegated with white and green. Leaves narrow and not very hairy. Common in Cerama, Kelanga, Celebes, and some other Malayan islands. Its joints are as much as 4 feet long and about 2 inches thick: the wood is thin, and it is consequently used principally for light walking-sticks; it is however extremely strong.

25. *B. Amahussana.* Joints short. Leaves with stinging hairs on the upper part of the stem, but smooth near the ground. Less straight, and more short-jointed than any of the preceding species of this section. Its wood is very thick. In Amboyna and Manipa.

26. *B. multiplex*, Lour. Stems long-jointed, not spiny. Leaves stingless, narrow, and clasping the stems at their base. Cultivated in the north of Cochin China for hedges. Its leaves are very narrow, and of a brownish-green. The stems are about 12 feet long and an inch thick.

27. *B. tabacaria*, Poir. Stems slender, very straight, of nearly equal thickness, branched; with very long rough joints. Wild in the black and argillaceous soil of Amboyna, Manipa, and Java, in the plains and moister parts of the mountains. Its stems are nearly solid, and excessively tough and hard. The joints are 3 or 4 feet long, and not thicker than the little finger. When polished they make the finest pipe-sticks. The outside is so hard, that it emits sparks of fire when struck by the hatchet. The species runs very much at the root.

III. *American Bamboos.*

28. *B. Guadua*, Humb. Leaves very narrow, covered with asperities at the edge and on the under-surface. Found in warm and temperate places, on the western side of the Cordilleras of New Granada and Quito, growing like a tree 30 or 40 feet high, with a knotted, shining trunk 16 inches in diameter. The leaves, which are 6 or 7 inches long, are not more than 5 lines broad.

29. *B. latifolia*, Humb. Leaves narrow, but oblong; extremely smooth. About 25 feet high, drooping at the point, with shining joints 2 feet long and about 4 inches thick. The leaves are the same length as in the last, but thrice as broad. It is found in the damp shady woods on the banks of the river Cassiquiare in tropical America.

30. *B. Tagoara*, Nees. Leaves oblong-lanceolate, rounded at the base, and then narrowed into a very short stalk. Stems 20 to 30 feet long, and 4 to 6 inches in diameter, with joints from 6 to 18 inches long; the leaves are 9 or 10 inches long and full 2 inches wide. Found by Von Martius in woods 1800 feet above the sea, on the mountain called Serra do Mar, towards Guarantinqueta, in the province of St. Paul's, Brazil.

31. *B. parviflora*, Schultes. An obscure species, found on the mountains of Peru, in Huanoco, by Hænke. The stem is said to be branched, and the leaves lance-shaped, taper-pointed, with a scabrous

re can be no doubt that many other species of this curious genus are to be found in the tropical parts of Asia and America. It is also not improbable that some of the foregoing may be repetitions. Travellers who have opportunities of procuring wild specimens of bamboos should dry a small branch with the leaves, and if possible the flowers, and should, at the same time, put by a portion of the lower part of the stem, 6 or 7 feet long, marked so as to correspond with the dried specimen.

(Roxburgh, *Flora Indica*, vol. ii.; Rumphius, *Herbarium Amboinense*, vol. iv.; Römer and Schultes, *Systema Vegetabilium*, vol. vii.)

BAMLITE, a mineral of a white or grayish-white colour. It is columnar; has a hardness=6 and specific gravity=2·98. It occurs in Norway, and consists of—

Silica	59·6
Alumina	42·0
Peroxide of Iron	1·0

BANCHUS, a genus of Insects belonging to the order *Hymenoptera*.

BAND-FISH. [Cepola.]

BANDICOOT (*Perameles*, Geoff. St. Hilaire), a genus of Marsupial Mammals, which appears to occupy, in Australia, the situation which the Shrews, Tenrecs, and other *Insectivora* fill in the Old World.

The species of *Perameles* called Bandicoots by the colonists (a name which properly belongs to the Great Rat of India, *Mus giganteus*, but which, from a vague resemblance in size and appearance, the early colonists of Sydney applied to the animals at present under consideration), though they agree in the most prominent characters of their dentition with some of the *Marsupiata*, and in the form of their extremities and the number of their toes with others, yet differ essentially from all in their habits and economy. [Marsupiata.] In the number, form, and arrangement of their canine and molar teeth they agree in all respects with the Opossums of America and the Dasyures of Australia; that is to say, that they have 2 canines and 14 molars in each jaw; but they differ widely in the number of their incisors, and in this respect offer a unique combination which is found in no other known genus of mammals. Of the incisor teeth there are 10 in the upper jaw, and only 6 in the lower; and the external on each side, particularly in the upper jaw, is insulated, and stands apart both from the canine and from the other incisors; it is likewise much larger than the intermediate incisors, and its form is that of an ordinary canine tooth, of which indeed it appears to exercise all the functions.

The hind legs are considerably longer than the fore, and the number and form of the toes are in all respects similar to those of the kangaroos. It was this similarity that induced M. Geoffroy St. Hilaire to suppose that the pace of the Bandicoots also resembled that of the kangaroos. This, however, is far from being the case. The disproportion between their anterior and posterior extremities is by no means so great as to compel the Bandicoots to hop upon the hind legs only, like the kangaroos, though it is certainly sufficiently so to prevent them from walking like ordinary quadrupeds. Their actual pace resembles that of the hare, and consists of a succession of leaps from the hind to the fore feet, but it is not very rapid, nor can they maintain it for any great length of time. On the fore feet there are five toes, of which the three middle are long and stout, but the lateral ones are so short that they do not touch the ground, and are consequently useless in walking, though they may be of great service in burrowing. The hind feet have but four toes each, and of these the third is the largest of all, whilst the two internal are united under the same skin, and appear externally like a single toe armed with two claws.

This is precisely the arrangement and form which we find in the kangaroos; but the feet of the Bandicoots differ, in being provided with broad powerful claws, which enable them to burrow with astonishing facility, and to scratch up the ground in search of roots. They likewise differ from the kangaroos in having a small fleshy tubercle, in lieu of a thumb, upon the hind feet, and in having the last or ungual phalange of all the toes divided in front by a small incision, as in the pangolins and ant-eaters, a structure which gives a much firmer attachment to the claw, and vastly increases their power of burrowing. In other respects the Bandicoots are chiefly characterised by their long attenuated muzzles, short upright ears, lengthened bodies, and moderate rat-like tails, which are not prehensile, as is the case with many genera of this order, nor have these animals the power of ascending trees. With regard to the period of gestation, the number of young, and the mode of their introduction into the abdominal pouch, it is only known that they resemble the other marsupials in the premature production of their young, and in nourishing them for some time afterwards in the abdominal pouch of the mother, and that this pouch contains the mammary organs for that purpose.

Three or four of the species are well made out, but with regard to the rest there is still some doubt.

1. *P. nasuta* (Geoff. St. Hilaire), the Long-Nosed Bandicoot, measures about a foot and a half in length from the extremity of the muzzle to the origin of the tail; the head is 4 inches long, the tail 6 inches, the hind legs also 6 inches, and the fore legs only 3 inches. The ears are erect, pointed, and covered with short hair; the eyes are particularly small; the nose remarkably long, pointed, and naked at the extremity; and the tail attenuated, and, though better covered with hair, bearing some resemblance to that of a large rat. This organ is not used by the Bandicoot to support the body in a sitting posture, like that of the kangaroo, as has been imagined by M. Geoffroy St. Hilaire, to whom we owe the first description of this species as well as the establishment of the present genus; neither are the progressive movements of these animals similar to those of the kangaroos, as the same eminent zoologist conceived, from the form and proportions of the extremities, that they might be. The pace of the Bandicoot as already observed resembles that of our hares and rabbits, which certainly approximates more nearly to the saltigrade pace of the kangaroos, gerboas, and helamys, than any other kind of locomotion with which we are acquainted. So far M. Geoffroy's conjecture was well founded, and he has certainly good reason in his observation that analogous structures rarely deceive us in reasoning upon their functions. The external coat of the Long-Nosed Bandicoot is composed of coarse bristly hair, in colour very nearly resembling that of the common Rat (*Mus decumanus*), except that it is of a more sandy shade on the upper parts of the body, and of a more clear silvery white beneath; under this long outer hair there is an interior coat of soft ash-coloured wool or fur, which protects the animal from the cold and variations of temperature, for it appears to be an inhabitant of the mountainous parts of Australia, principally if not exclusively. The tail is of a rather darker colour than the body, and the whole animal, except in the great length and pointed form of the nose, has much the appearance of an overgrown rat. The form and characters of its teeth would lead us to suppose that it fed upon insects and other similar animal substances. In the neighbourhood of human habitations they frequently enter into the granaries, and do as much mischief to the corn as the rats and mice of our own country.

Long-Nosed Bandicoot (*P. nasuta*).

2. *P. obesula* (Geoff.), the Blunt-Nosed Bandicoot, first described by Dr. Shaw under the names of the Porcupine Opossum and *Didelphys obesula*, is readily distinguished from the last species by the shortness and bluntness of its snout, and by the broad round form of its ears. The arrangement of the teeth also differs in some degree from that of the Long-Nosed Bandicoot. The external incisors are more nearly in contact with the canines and central incisors on each side of them; the molars immediately succeeding the canines, and answering to the false molars of the carnivora, are contiguous to one another and of a triangular form; and the posterior molars are more flattened on the crowns. This latter character would seem to intimate that the present species was more purely herbivorous than the last, and future observation may probably confirm this conjecture. The colour and quality of the hair and fur are the same as in the Long-Nosed Bandicoot.

3. *P. Gunnii* is a native of Van Diemen's Land, where it is very generally diffused. It lives principally on bulbs, but also eats insects. *P. lagotis*, of Reid, is of a gray colour, and as large as an opossum. It has been described by Professor Owen under the generic name *Phalacomys*. [Marsupiata.]

BA'NKSIA, an Australian genus of plants belonging to the natural order *Proteaceæ*. It was named in compliment to Sir Joseph Banks. It consists of bushes or less frequently of small trees, with their branches growing in an umbellate manner. The leaves are hard and dry, and in young plants always cut at the edges, but in old specimens undivided. They have a dull green colour on their upper side, and are usually white, or very pale green, on the lower. The flowers are long, narrow, tubular, coloured calyxes, without corolla, and with only four stamens lodged in their concave points. They are collected into oblong heads, often consisting of 600 or more, closely arranged, and do not fall off when the blooming is over, but wither, become brown, and adhere to the axis of the head. Very few of them are fertile; the greater part are altogether abortive, and form a sort of coarse fibrous covering to the singular 2-valved fruit, which is thick and woody, contains two black-winged seeds, and when it sheds them opens like an oyster, or any other bivalve shell.

These plants are found in sandy forest-land, or on rocks, over the whole known continent of Australia, but chiefly beyond the tropic. They are called by the colonists Honeysuckle Trees, and are considered in New South Wales as evidence of bad land; but in the Swan River colony they occupy the most fertile tracts. Many species are now cultivated in the conservatories of Europe, where they are much esteemed for their handsome foliage and singular heads of flowers.

Banksias.

The plant in the foreground is the *Red Banksia* of King George's Sound, and the other the *Yellow Banksia* of the Gulf of Carpentaria, from sketches made on the spot.

None of them appear to be of much value for timber, although they make good fire-wood. *B. compar* and *B. serrata* (which last is said to grow 30 feet high, with a stem measuring a foot and a half in diameter) are the largest species which have been mentioned by travellers on the east coast. On the west coast, in Swan River colony, *B. grandis* reaches 50 feet in height, with a trunk 2½ feet in diameter.

A considerable quantity of honey is secreted by their flowers, and collected by the natives of King George's Sound, who are extremely fond of it.

BANSTICKLE. [GASTEROSTEUS.]

BANXRING, the Sumatran name of a small arboreal animal, discovered by the late Sir Stamford Raffles, which is intermediate in its nature and habits between the Shrews and Squirrels. [TUPAIA.]

BAOBAB. [ADANSONIA.]

BAPTA, a genus of Insects belonging to the order *Lepidoptera* and family *Geometridæ*. The species of this genus are among the thin-bodied day-flying Moths. Mr. Stephens, in his 'Illustrations of British Entomology,' confines this genus to two species: *Bapta bimaculata*, White Pinion-Spotted Bapta, which is of a beautiful white colour, and has two brown spots on the front edge of each of the anterior wings; and *Bapta punctata*, Clouded-Silver-Bapta. This differs from the first principally in having the tips of the anterior wings clouded with brown. Both species are occasionally met with in woods in the neighbourhood of London.

BARB, the name of a noble breed of horses reared by the Moors of Barbary and Marocco, and introduced into Spain during their dominion in that country, where however it has been suffered to degenerate greatly since their expulsion. The noble race of Barbary horses which we commonly call Barbs are of rare occurrence even in their own country, where the tyranny of the governors holds out no inducement to private individuals to rear an animal of which they may be deprived without scruple or compensation by the first man in power who happens to fancy it. It is only among the wild nomadic tribes of the desert, whose roving habits and inhospitable country place them beyond the control of the ordinary powers of the state, that this breed exists in perfection. The common horse of Barbary is a very inferior animal, which, if originally derived from the same source as the noble race of Barbs, has greatly degenerated. In the beauty and symmetry of their forms however even the latter are far from excelling: their valuable qualities—and in these they are perhaps unequalled by any other breed in existence—are, unrivalled speed, surprising bottom, abstinence, patience and endurance under fatigue, and gentleness of temper. Their points would not please the critical eye of a member of the Jockey Club: the head is large and clumsy; the neck short and thick; the chest broad and powerful; yet the body and legs are so long and slender as to resemble those of a greyhound, and form a perfect contrast to the rest of the animal. But the Moors do not regard the external appearance of their horses so much as their temper, speed, and capability to endure fatigue; and the animals which possess these valuable qualities are cherished with all the kindness and attention that are bestowed on children. Their mode of treatment is very different from that practised in Europe. They are very early accustomed to the saddle, are mounted at two years old, and have their manes and tails cropped till the age of six, under the supposition that it adds to their strength and bottom. After this period they are never dressed, nor are their manes and tails combed; if dirty they are washed in the next stream, and some are even said to be offended by Europeans patting their horses with the palm of the hand, from an apprehension of its injuring their coat. They are never castrated, nor have the Moors the bad taste to seek to improve upon nature by cropping the ears and tails of their horses, as is practised by some nations; a Mussulman will neither mutilate nor sell the skin of 'the beast of the prophet,' the noblest of animals. The horses alone are used for the saddle, the mares being kept for breeding, except among some of the predatory tribes of the Desert, who find that the neighing of the horses is apt to betray their approach, and give notice of their coming to the caravans which are the objects of their attack. Walking and galloping are the only paces which these animals are allowed to practise; and it is even considered vulgar to trot or canter. Generally speaking, the Moors avoid giving their horses violent exercise, or overheating them, except upon extraordinary [illegible]; and among the Desert tribes it is only in their cavalry exercises, such as throwing the lance, &c., that their speed is at all [illegible]. On these occasions however they are not spared, and it is surprising with what rapidity and precision they perform the different evolutions. These indeed are not so complicated as the tactics of more civilised nations, but they are much more severe upon the cattle, and would soon break down the best of our European breeds. The great exercise of the Moorish cavalry consists in galloping their horses at the very height of their speed for the distance of about a quarter of a mile, and then making them stop suddenly short, while the rider delivers his spear or fires his musket; and of this amusement the people are so excessively fond, that they frequently continue it for hours together without a moment's intermission to breathe or change their horses. Yet notwithstanding such violent exercises, very little care is afterwards taken of the horses; still they are said to be long-lived and remarkably free from diseases. Such distempers as farcy and glanders are unknown; spavin and mullender are of very rare occurrence.

The Moors never make hay, but feed their horses upon chopped straw and barley, which they eat out of a nose-bag put over their heads, as is the custom in England; in spring they are chiefly fed upon grass. In the stables there are no mangers, but the horses are fastened by means of two iron pins driven into the ground, one before and the other behind, to which the fore and hind legs are respectively fastened in such a manner as to prevent the animal from moving more than a foot either backwards or forwards: their collar is also made fast to the front pin, which is provided with a ring for that purpose, and they eat their provender off the ground. Formerly it was the practice for the Moors, in shoeing their horses, to cut off the front part of the hoof; a flat shoe of a triangular shape was then put on, with one of the sides in front, and the other two nearly meeting in an acute angle behind the frog: but this unnatural mode of disfiguring these noble animals was put an end to about the year 1700, by an order of the Emperor Muley Ishmael, who commanded that thenceforth all his subjects should upon pain of death, shoe their horses with round shoes. The Berbers and Kabyles, the aboriginal inhabitants of the country between the Sahara and the shores of the Mediterranean, and who are now for the most part confined to the mountainous and most inaccessible districts of North Africa, never shoe their horses at all; yet so hardy are these animals, and so much tougher are their hoofs than those of our own horses, that Windhus, who in the beginning of the last century accompanied a British embassy to the court of the emperor of Marocco, and who has left an interesting account of his journey, assures us that he saw one of them which had travelled 50 miles without resting, and that though he had been twice during the journey obliged to cross a mountain full of rocks, yet it was not perceived that he had the least crack in his hoof, nor any apparent injury of his feet.

There is a particular breed of the noble Barbs, called *Sh'rubah Er'reeh* (literally Wind-Sucker), or the Desert Horse, which is only found among the tribes of the Sahara, and which, when transported beyond the sands of the Desert, soon languishes and dies. The fleetness, temperance, and endurance of this animal, if we are to believe half the stories related by travellers, almost surpass the bounds of credibility. "When thou shalt meet a sh'rubah er'reeh," says a Moorish proverb, "and say to his rider, 'Salam Alikum,' before he can answer 'Alikum Salam,' he will be far from thee, for his speed is like the whirlwind." By the assistance of this animal, or of the *Heirie*, or Desert-Camel, the Arab can upon an emergency cross the Sahara in a short time. The Sh'rubah Er'reeh, however, is neither so useful nor so economical an animal as the desert-camel; it is true that his speed is greater, but he is neither so abstemious nor so enduring. The Heirie will travel for 15 or 20 successive days, and requires but a handful of dried dates in the morning, and a supply of water every third day; upon an extraordinary emergency he can even travel for six or seven days without this important element; but the desert-horse must have a feed of camel's milk once a day, and for this purpose there must be a couple of female camels wherever he goes. Camel's milk is his only sustenance; and indeed it would be difficult to find him any other in the parched and arid deserts which he inhabits; he does not like wheat, hay, straw, or any other kind of food, and if forced to live upon these substances, soon loses all his valuable qualities. In his native country the desert-horse is principally employed for the purpose of hunting the ostrich and gazelle, at which sports he is amazingly expert, nor is there any other being that can equal these animals in speed. When brought to Marocco, as is sometimes the case, these horses soon decline under the change of food and climate. "Alkaid Omar ben Daudy," says Jackson in his 'Account of the Empire of Marocco,' "when governor of Mogodor, had two Saharawan horses in his stables; but finding it inconvenient to feed them constantly upon camel's milk, he resolved to try them on the usual food given to Barbary horses. He accordingly had their food gradually changed, and in a short time fed them altogether with barley, and occasionally with wheat and straw; they grew fat, and looked better than before, but they lost their speed, and soon afterwards died, as if nature had designed them to be appropriated solely to that district whose arid and extensive plains render their use essentially necessary."

BARBACOU. [KINGFISHERS.]

BARBA'REA (from a former name, Herb St. Barb[illegible] [illegible]nus of plants belonging to the natural order *Cruciferæ*. [illegible] has [illegible] terete 2-edged pod, the valves convex, with a prominent lon[illegible] nerve; the stigma capitate, the seeds in a single row. *Barba*[illegible]ngs to the first sub-order of *Cruciferæ*, *Siliquosæ*, which possess a linear or linear-lanceolate pod opening by two valves. The species of *Barbarea* are perennial herbs, with fibrous roots and erect stems. The flowers are yellow, arranged in racemes; the pedicles without bracts.

B. vulgaris, Common Yellow Rocket, Common Winter Cress, Herb St. Barbara, has the lower leaves lyrate, upper pair of lobes as broad as the large roundish subcordate terminal lobe, the uppermost leaf undivided, toothed; young pods obliquely erect; seeds scarcely longer than broad. It is a native, in damp moist places, of Great Britain, and throughout Europe; also of North America. This plant has a bitter nauseous taste, and is sometimes cultivated as a spring salad. In Sweden the leaves are boiled and eaten. It is often cultivated in gardens, especially a double variety, which forms a handsome border-plant.

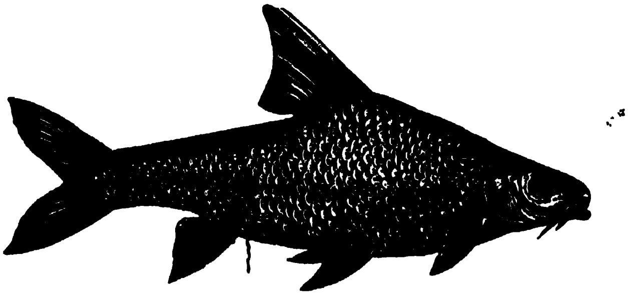
B. præcox, Early Winter Cress, has the lower leaves lyrate, upper pair of lobes as broad as the roundish subcordate terminal lobe, uppermost leaf pinnatifid, with linear oblong entire lobes. It is a native of France and Great Britain; abundant in North America. It is called in Germany Amerikanischer Kraut; in French, Cresson d'Amérique; in England, American Cress, Black American Cress, French Cress, and Belle-Isle Cress. It is used as a salad, and is more bitter than the common Water-Cress. It can be raised for eating all the year round. In cultivating, it should be grown from seeds, a quarter of an ounce of which will serve for sowing 10 feet of drill.

B. arcuata and *B. stricta* are two species described by Babington, and lately added to the British Flora. A few others are found in the northern parts of Europe and America. With the exception of the Double Yellow Rocket, none of the species are worth cultivating as ornamental. This plant may be propagated by cuttings, suckers, or dividing the plants at the root.

(Don, *Gardener's Dictionary*; Babington, *Manual*.)

BARBEL (*Barbus*, Cuvier), a genus of Abdominal Malacopterygious Fishes, belonging to the Carp Family (*Cyprinidæ*), and distinguished by the shortness of their dorsal and anal fins, by a strong spine, which replaces the second or third ray of the dorsal, by four beards or fleshy tentacula, which grow from the lips, two at the nose, and the other two at the corners of the mouth, and by having but three branchiostegous rays. Like the great majority of the abdominal soft-finned fishes, the Barbels are a freshwater genus, and certainly among the least carnivorous of the whole class. They feed almost entirely upon aquatic plants and roots, to obtain which they bore into the banks of the ponds and rivers in which they reside, using their snout for that purpose like a hog.

Barbus vulgaris, the Common Barbel, sometimes measures 3 feet in length, and weighs from 15 to 18 pounds. The section of its body forms an elongated ellipse; its scales are small, its head smooth, its eyes large and contiguous to the nostrils, and the lateral line straight and nearly parallel to the back. Its pectoral fins are of a pale brown colour, its ventral and anal tipped with yellow; the tail is slightly bifurcated, and of a deep purple, and the general colour of the scales is pale gold, edged with black on the back and sides, and silvery-white on the belly. The dorsal fin is armed with a strong serrated spine, with which it sometimes inflicts dangerous wounds on the hands of the fishermen, and does considerable damage to their nets. The barbel is found only in deep and still ponds, and in sluggish rivers which have little or no current. In the hot summer months the barbels abandon for a time the deep pools and ponds which had protected them from the severe winter frosts, and make excursions into the shallower parts of the stream in search of food. Their habits are nocturnal, and they are fond of the society of their own species, being generally found together in large companies. Their flesh is extremely coarse and unsavoury, and their roe in particular is said to produce vomiting, purging, and slight swellings in those who incautiously eat it. The barbel is a very common fish in the Thames, where it is taken rather on account of the sport for the angler than the goodness of the fish.



Common Barbel (*Barbus vulgaris*).

The Binny, or Barbel of the Nile, is so like the Common Barbel of our European rivers, that it might readily be mistaken at first sight for that fish; but a little observation will show that it is proportionally shorter and thicker, its back more arched, and it is particularly distinguished by having the first three rays of the dorsal fin so closely united as to have the appearance of almost forming but one single spine. The Binny is very common in the Nile; it grows to a large size, sometimes weighing, according to Bruce's statement, upwards of 70 pounds, and is described as being a firm, delicate, and well-flavoured fish. The traveller just mentioned gives an interesting account of the methods which the Egyptians employ for the capture of the Binny, and for preserving it alive till they require to dress it, or have an opportunity of disposing of it. Having kneaded together a quantity of oil, clay, flour, and honey, with some chopped straw or other similar material to unite the different parts of the composition, the whole is formed into a mass, in size and appearance resembling a Cheshire cheese, round the sides of which, in different parts, are stuck small pieces of dates saturated in honey. Seven or eight stout hooks, each having a separate line of strong whip-cord, and baited with a date steeped in honey, are concealed in the centre of the cake. The fisherman then, bestriding his inflated goatskin, paddles himself and his burden out into the middle and deepest part of the stream, where, having sunk the whole mass, he carries the cords attached to the hooks on shore, and fastens each of them separately to the branch of a palm stuck firmly into the ground, and having a small bell suspended from the top of it. He then goes off about his work, which, upon such occasions, is always contiguous to the river, and within hearing of the bells. In a short time the action of the water begins to dissolve the mass of paste at the bottom of the river, and the small pieces of dates getting detached from it float down the river, and are greedily caught and devoured by the Binnies. These naturally ascend the stream in the direction from which they perceive their favourite food to proceed, and having arrived at the mass of composition, begin, as is their custom, to root and bore into it, till they at length arrive at the dates inside, which they ravenously swallow, and are of course caught by the hook concealed within. In its struggles to escape the fish necessarily pulls the line and the palm branch to which it is made fast on shore, when the ringing of the bell gives notice to the fisherman.

"The fisherman," says Bruce, "runs immediately to the bell, and finding thereby the particular line, hauls his prisoner in, but does not kill him: the hook being large, it generally catches him by the upper jaw, which is considerably longer than the under. He then pulls him out of the water, and puts a strong iron ring through his jaw, ties a few yards of cord to it, and returning the fish to the river, fastens him to the shore: so he does with the rest, for very rarely is there a single hook empty. Those who want fish at Girgé, a large town opposite, or at Achmim itself, come thither as to a fish-market, and every man takes the quantity he wants, buying them alive. Fish when dead do not keep in Egypt, which makes that precaution necessary. We bought two, which fully dined our whole boat's crew; the fisherman had 10 or 12 of them fastened to the shore, all of which he pulled out and showed us."

BARBERRY. [BERBERIS.]

BARBERRY-BLIGHT. [ÆCIDIUM.]

BARBETS, the English name for a family of birds of the order *Scansores*, or Climbers; Les Barbus of the French, and the genus *Bucco* of Brisson and Linnæus. They are distinguished by their large conical beak, which appears swollen, as it were, or puffed out at the sides of its base, and is bearded (whence their name) with five tufts of stiff bristles directed forwards. One of these tufts is behind each nostril, one on either side of the lower mandible, and the fifth is under the symphysis.

Their short wings and heavy proportions do not admit of swift flight; and their prey consists of insects and young birds, which they surprise, and also of fruits. Their nests are generally built in the holes of trees. The Barbets are divided into the three following sub-genera:

Sub-genus *Pogonias.*

Pogonias (Illiger) is furnished with one or two strong teeth on each side of the upper mandible, and the beard is very strong. Africa and the Indies are the places where they are found, according to Cuvier, who says that the species of this sub-genus feed more on fruits than any of the others. *Pogonias hirsutus* (Swainson), an African species, is a good example.

Pogonias hirsutus.

Sub-genus *Bucco.*

Bucco (Cuvier), *Capito* (Vieillot), embraces the true Barbets, which have the conical bill slightly compressed and a little elevated in the middle. Their plumage is, generally speaking, gay; and they are to be found both in Africa and Asia. During the breeding season they go in pairs, but congregate in small flocks during the remainder of the year. The Buff-Faced Barbet (*Bucco Lathami*) affords an example of the true Barbets.

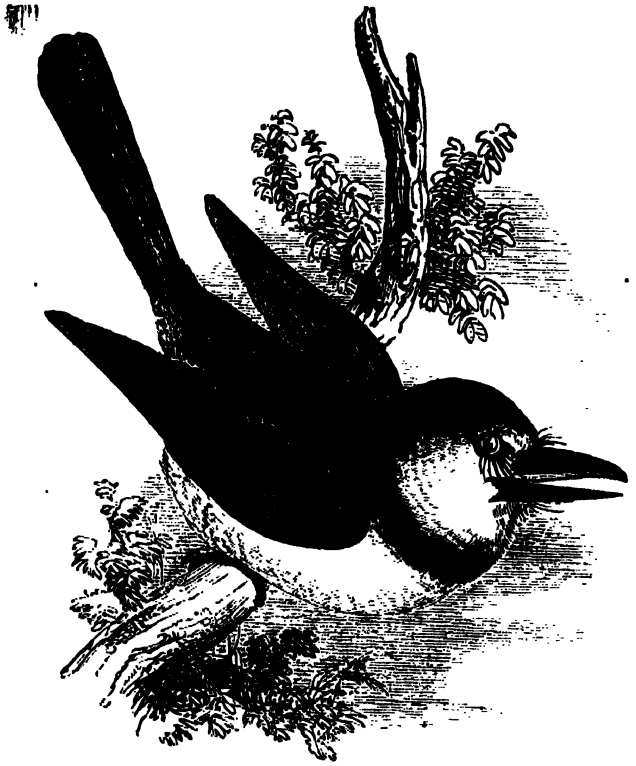
Buff-Faced Barbet (*Bucco Lathami*).

Latham refers to a specimen in the British Museum, and says that its native place is uncertain.

Sub-genus *Tamatia.*

Tamatia (Cuvier), the name by which one of these birds is known in Brazil according to Marcgrave, comprises those species which have the bill a little more elongated and compressed, and slightly curved at the extremity. The great head, short tail, and large bill of these Puff-Birds, as they are called, give them, as Cuvier observes, an air of stupidity, which their melancholy and solitary habits do not lessen. They are said to feed entirely on insects, and all the recorded species are American. In Paraguay, according to Azara, they are called Chacurus. Temminck affixes the name *Capito* to this sub-genus.

Tamatia macrorhynchos (Swainson), which that author obtained from southern Brazil, and which he is disposed to consider a variety of the greater Pied Barbet of Latham, will give a good idea of the character of these birds.



Tamatia macrorhynchos.

Swainson gives the following interesting account of their habits:—"There is something very grotesque in the appearance of all the Puff-Birds, and their habits in a state of nature are no less singular. They frequent open cultivated spots near habitations, always perching on the withered branches of a low tree, where they will sit nearly motionless for hours, unless indeed they descry some luckless insect passing near them, at which they immediately dart, returning again to the identical twig they had just left, and which they will sometimes frequent for months. At such times the disproportionate size of the head is rendered more conspicuous by the bird raising its feathers so as to appear not unlike a puff-ball; hence the general name they have received from the English residents in Brazil, of which vast country all the species, I believe, are natives. When frightened, this form is suddenly changed by the feathers lying quite flat. They are very confiding, and will often take their station within a few yards of the window. The two sexes are generally near each other, and often on the same tree."

The length of this species is about eight inches. Plumage black and white, except the belly and vent, which are tinged with buff.

BARBUS. [BARBEL.]

BARCKHAUSIA, the name of a genus of plants belonging to the natural order *Compositæ*, the tribe *Cichoraceæ*, and the sub-tribe *Lactuceæ*. It has many-flowered heads, a double involucre, the inner of one row, the outer of short lax scales; the fruits 4-cornered, all (or the inner ones only) gradually contracted into a long beak. This genus has several European species, two of which only are natives of Great Britain. The flowers are yellow or pale purple. Some of the species are cultivated in gardens, where they form a pretty and easily cultivable border-plant. The British species are—*B. taraxacifolia*, with rough runcinate-pinnatifid leaves, erect heads, bristly and downy involucre covering half the pappus, its outer scales ovate-lanceolate with a membranous margin, herbaceous bracts, the fruits all equally beaked. *B. fœtida*, with hairy runcinate-pinnatifid leaves, nodding unopened heads, hairy and downy involucre as long as the pappus, its outer scales lanceolate, acute, downy; the marginal fruits slightly beaked, shorter than the involucre, central ones with long beaks equalling it. The first species has a stem one or two feet high, yellow flowers, purple beneath, and is found in limestone districts. The second has a stem from six to twelve inches in height, with yellow flowers. It grows in chalky places in England, but is a rare plant.

B. setosa, a German species, has been lately found in several districts of Great Britain, but it appears most probable that this species has been introduced by means of clover and other seeds used for agricultural purposes.

(Koch, *Flora Germanica;* Babington, *Manual of British Botany; Phytologist*, vol. i.)

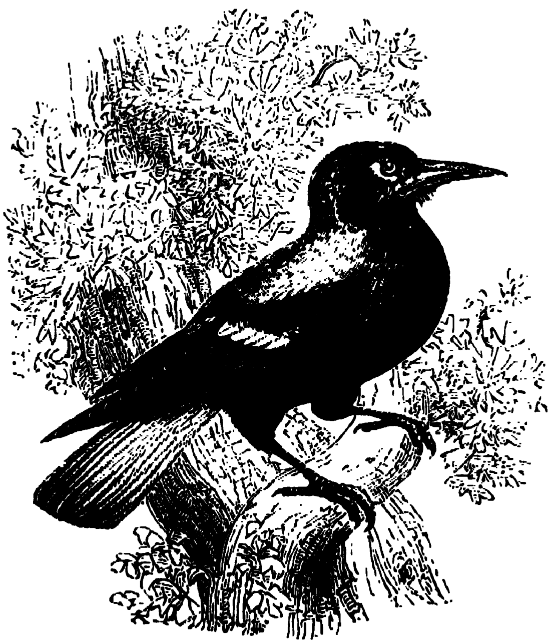
BARI'DIUS, a genus of Insects of the order *Coleoptera* and family *Curculionidæ.* These are cylindrical little beetles which feed upon aquatic plants. They are generally of a black colour, and more or less covered with a whitish down.

BARIS, a genus of Insects belonging to the order *Coleoptera* and family *Curculionidæ.* The species of this genus feed upon the dead parts of trees. One of the species, *Baris lignarius*, feeds upon the elm tree, both in the larva state and that of the perfect insect. When the little beetle is about to lay its eggs it generally selects the interior of a hollow tree for that purpose, and bores a hole with its short snout in the dead wood where it is still tolerably sound; this being accomplished it enters the hole, hinder part first, deposits its eggs, and dies: the hole being only just the size of its cylindrical body, it thus forms a protection for its young by stopping the hole so that no other insect can enter. It is not known that it ever attacks any other wood but that part where the sap has ceased to flow, and consequently the tree can receive no injury from this little weevil.

BARI'TA, the name given by Cuvier to a genus of Birds which he places among the Shrikes, but which Vigors considers to belong to the family of Crows.

The following are the characters of *Barita:* — Bill hard, long, and strong, convex above, slightly hooked at the extremity, near which both mandibles are notched; nostrils lateral, and longitudinal near the base; legs stout; outer toe joined to the middle one as far as the first joint; inner toe entirely free; hind toe elongated; claws strong and curved.

Barita Tibicen, the Piping Crow, common in New South Wales, where Quoy and Gaimard, the able naturalists attached to Freycinet's Expedition, saw numbers of them on the Blue Mountains, living gregariously in small troops, will serve as an illustration of the genus.

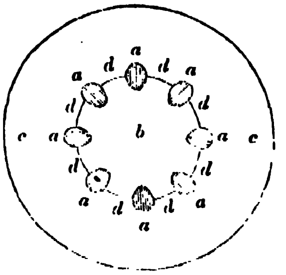


Piping Crow (*Barita Tibicen*).

The bird brought home by Freycinet reached France alive, and by its good-natured and amusing manners became a great favourite while on ship-board. It was a skilful mimic, and clucked and cackled like a hen; but its imitation of a young cock was complete. It had been trained to whistle airs at Port Jackson, and some of these it appeared to forget, but recollected them on being prompted.

BARK, in Vegetable Physiology, is the external coating of the stem and branches of plants, ensheathing the wood. In woody *Exogens* it separates spontaneously from the wood in spring and summer, and in herbaceous plants of the same class it may be easily removed with a little care; but in *Endogens* and *Acrogens* it is so continuous with the central part of the stem that it can never be divided except by violence, and by lacerating the tissue which lies immediately below it. This difference arises from the manner in which the plants of these three great natural classes respectively grow. Exogens add annually new matter to the inside of their bark and the outside of their wood, which renders it necessary that a spontaneous separation of wood and bark should take place in order to make room for the newly-generated substance; but Endogens, which grow by addition to their centre, and Acrogens, by elongation of their point, require no such separation. [EXOGENS; ENDOGENS; ACROGENS.]

Bark may be considered to originate thus:—When a plant is in the state of embryo, that part which finally develops into a stem and root, or, as botanists say, into the axis of growth, is something like two cones applied to each other by their bases, but it will simplify our ideas if we consider it as a cylinder. In a dormant state it consists of nothing but cellular substance; but in Exogens, as soon as the cotyledons, or seed-leaves, are roused into growth, woody matter is generated in the form of a number of little bundles, which are arranged in a circle (*a a*) about half way from the centre to the circumference, thus forming a sort of hollow cylinder within the first. The cylinder so commenced cuts off the cellular substance into two parts: one central (*b*), which finally becomes pith, and the other external (*c*), which becomes bark; the two maintaining their connection by means of the passages (*d d*) between the woody bundles (*a a*). These passages ultimately become the medullary processes. The direction thus given in the beginning to the several parts in the interior of an exogenous stem is never afterwards departed from, but all the additions which are subsequently made are moulded, as it were, upon this original form. The woody bundles (*a a*) increase in size by growing outwards, and consequently the medullary processes are extended; the bark continues to grow and give way to the pressure of the wood from within, till at last a year's increase has been accomplished. Up to this time no separation between the wood and the bark has taken place; but in a second year, as it is necessary for the new matter to be added to the outside of the wood and to the inside of the bark (at *d d*), a spontaneous separation of the two takes place over the whole surface of the wood, the medullary processes softening, stretching, and growing externally, in order to admit of such a separation. But Endogens and Acrogens always retain their bark in the same connection with the wood as it is in Exogens at the end of the first year, there being no necessity for a separation between the two in order to admit of subsequent growth.



In its anatomical structure bark consists of a mass of cellular tissue pierced longitudinally by woody matter, which is composed entirely of woody tubes without any trace of vessels, but which is sometimes accompanied by long fistular cavities, in which resinous, or milky, or juicy, or other secretions are lodged.

In the first year of its existence bark is a cylinder, the woody matter of which is a continuation of that of the wood itself. In Endogens and Acrogens it undergoes no material increase or alteration subsequently, unless it be that the parts are increased in quantity without shifting their position. But in Exogens, in consequence of their wood being annually augmented by external additions, as before stated, the bark undergoes annual changes. Corresponding with the annual additions to the wood are annual additions to the inside of the bark, consisting of a cellular layer overspreading the whole of the inside, and then a layer of woody matter, which answers to the spaces of wood included between the medullary processes. These annual additions, which are called the *liber* (whence books which were written upon such layers, properly prepared, were called *libri*), must therefore be exactly the same in number as the annual layers of wood, and would be arranged with equal regularity if the bark were not affected by any disturbing cause. But in consequence of the wood's perpetual increase in diameter there is an incessant lateral strain upon the liber, so that after the first year there is little trace of regularity to be discovered in the structure of the bark. It soon becomes a mere confused mass of woody tubes and cellular tissue, in which all trace of annual concentric formation has disappeared. The manner in which it was originally generated is however said to be detected in some plants by the facility with which the bark will peel into layer after layer; but it may be doubted whether this phenomenon is not more connected with the original arrangement of the tissue of which the bark is composed than with the annual formations. These layers are sometimes so numerous that as many as 150 have been separated on a single tree.

When the bark of an Exogenous tree is examined, it will be found to consist of four parts or layers, which to a greater or less extent can be made out in every tree. These layers have been technically called the *Epidermis*, the *Epiphlæum*, the *Mesophlæum*, and the *Endophlæum.*

The *Epidermis* is but a continuation of that layer of condensed cellular tissue which is found on the external surface of every part or organ of the plant. It varies in thickness as well as compactness in almost every tree. It is frequently split up by the growth of the layers which lie beneath it, and with the next layer is separated from the stem in large pieces, as is the case in the common Birch (*Betula alba*). Like the epidermis on the leaves, it possesses stomates, which in the case of plants, as the *Cactaceæ*, seem to possess the power of performing the functions of the same organs on the leaf. The epidermis is variously coloured as well as affected by the colour of the layer immediately beneath it.

The *Epiphlæum* is the outermost layer of bark; it is composed of cellular tissue, and when cut through presents under the microscope a tabular appearance indicative of pressure above and below. This layer is very variable in its development. Sometimes it grows to a very remarkable extent, as is seen in the Cork Oak (*Quercus Suber*), in which the layer of the bark used for making corks, &c., is the endophlœum. On this account it has been called the Suberous Layer. It occurs in other plants besides the *Quercus Suber*, and constitutes a very pretty variety of the common elm, in which, in consequence of the growth of the suberous layer, the stem becomes quite altered in character.

The *Mesophlœum* lies immediately beneath the epiphlœum; it consists of a layer of polyhedral cellular tissue, and in the cells of which it is composed the colouring matter of the bark is deposited. It is in these cells that chlorophyle is deposited in the stems of most young plants, which give to them their green and fresh appearance. Even when the epidermis has assumed another colour the epiphlœum often appears quite green, as is the case in the common Elder (*Sambucus nigra*).

The mesophlœum, with the epiphlœum above it, is often split by the growth of the endophlœum beneath, giving to trees the rough broken surface which they often present. The mesophlœum and epiphlœum are occasionally thrown off from the same cause as the epidermis. The under layers grow rapidly, and the union between them and the upper layers being maintained by no organic matter, the latter is thrown off. This takes place in the Plane (*Platanus*), in which large masses of the epiphlœum are constantly flaking off. New cellular layers in this case are formed below, and it is supposed that this process explains the reason of the tolerance which the planes exhibit of a London atmosphere. In other trees the function of the bark is interfered with by the particles of carbon and perhaps gases affecting the function of the bark, whilst the plane, constantly renewing the outer layers of its bark, is not liable to this interruption. Whether this explanation be the true one or not, it is certainly very remarkable, that of all trees the plane flourishes best in the squares of the metropolis.

The *Endophlœum*, or *Liber*, is the inner layer of the bark, and consists of woody fibre as well as cells, that is, of vascular as well as cellular tissue. The vascular tissue grows here in the form of bundles, as it does in the wood itself. Its fibrous character is made manifest during the growth of many trees. In the vine it is thrown off with the layers above it by the growth of the wood underneath. In the Lace-Bark Tree (*Lagetta Lintearia*), the growth of the wood beneath the bark causes such an arrangement of the fibres that they are separated from one another, but making junctions where they cross, they form a natural kind of net-work, which has been employed as a substitute for artificial net-work in the construction of ornamental clothing. The liber of the bark of plants is much less dense than the wood; hence, where pliable materials are required, it is often made use of, as in the construction of mats from the bark of a species of *Tilia*, and the use of the bark of various trees in different parts of the world as a substitute for cordage.

The bark is nourished in the same manner as the wood of the tree, by sap carried into the stem from the roots below. The cellular and vascular tissue of which it is composed, as long as they live, are capable of producing new cells, by which a new and increasing growth is ever supplied.

(Schleiden, *Principles of Scientific Botany;* Lindley, *Introduction to Botany;* Balfour, *Manual of Botany.*)

BARLE'RIA, a genus of plants belonging to the natural order *Acanthaceæ*, and characterised by the spiny processes of its bracts, the large size of the upper and lower sepals, and its funnel-shaped corolla, which is often so twisted that the upper segment becomes lowest. The species are natives of various parts of the East Indies. A few of them have been introduced to our gardens, of which *Barleria lupulina*, with its large bracts resembling hops, and *B. Prionitis*, a common swamp-plant in Java, are the most remarkable. They all require to be cultivated in a hot-house, and are propagated readily by cuttings.

BARLEY. [Hordeum.]

BAROLITE, a synonym of *Witherite*, the native carbonate of Barytes. [Barytes.]

BA'ROMETZ, a singular vegetable production, of which, under the name of Scythian Lamb, many fabulous stories are told. It was said, among other things, to be part animal, part vegetable, and to have the power of devouring all other plants in its vicinity. It is in reality nothing but the prostrate hairy stem of a fern called *Aspidium Barometz*, which, from its procumbent position and shaggy appearance, looks something like a crouching animal, just as the hairy tawny end of the *Trichomanes Canariensis* looks like a hare's foot, whence its English name of Hare's Foot Fern. [Aspidium.]

BARREN FLOWERS, in Botany, are either those which bear only stamens without a pistil, or which have neither stamens nor pistil. Flowers of the former description are very common: those of the latter kind are chiefly found in Grasses and Sedges, where they often consist of nothing more than a deformed scale.

BARRIS, a name given on the coast of Guinea to two very different animals, the Chimpanzee or African Ape (*Pithecus Troglodytes*), and the Mandrill (*Cynocephalus Mormon*), a large and formidable species of baboon. [Ape; Baboon; Chimpanzee.]

BARSOWITE, a mineral occurring in massive and in granular distinct concretions. Its colour is snow-white; fracture splintery or imperfectly foliated; hardness 5·5; lustre of the compact varieties dull; of the granular, feebly pearly; translucent on the edges. The specific gravity is 2·740. It occurs at Barsowskoj, in the Ural Mountains. It has the following composition:—

Silica	49·08
Alumina	32·76
Lime	18·16

BARTSIA (in honour of John Bartsch, M.D., a friend of Linnæus), a genus of plants belonging to the natural order *Scrophulariaceæ*. It has a bell-shaped 4-fid calyx, a tubular ringent corolla, a pointed many-seeded capsule, the seeds compressed at the hilum, with winged ribs on the back. There is but one British species, the *B. alpina*, which has ovate, opposite, bluntly-serrate, slightly-clasping leaves. It is a rare plant, and only found in alpine pastures. The *B. Odontites* of Smith's 'English Flora' is now referred to the genus *Euphrasia*, as *E. Odontites*. [Euphrasia.] *B. alpina* is found in subalpine regions throughout Europe.

B. maxima has a branched stem, opposite lower leaves, alternate superior ones, oblong, bluntly and coarsely toothed; lower lip of corolla longer than the upper one, segments of the lower lip obtuse, equal in size. It is a native of Candia, and attains a height of one and a half or two feet. *B. Trixago* is a native of the south of Europe and Asia. *B. acuminata* is found in America. *B. viscosa* of Smith is now *Trixago viscosa*. It has opposite leaves, the upper ones alternate, ovate-lanceolate, sessile, acutely serrate. The genus *Trixago* differs from *Bartsia* in its seeds being slightly angular, very minutely crenato-ribbed, with a basal hilum. Babington and Koch both adopt the genus *Trixago*, but the latter refers *B. viscosa* of Smith to the genus *Euphrasia*.

(Don, *Gardener's Dictionary;* Koch, *Flora Germanica;* Babington, *Manual.*)

BARYTES, or BARYTA, the *Oxide of Barium*. The Oxide of Barium is found in the earth in combination with acids, principally the sulphuric and carbonic.

Native *Sulphate of Barytes*, known by the name of *Heavy Spar*, also *Hepatite* and *Bologna Spar*, presents itself in various forms, as crystalline, fibrous, saccharoid, compact, and earthy. The crystals are usually tabular, in modified rhombic and rectangular prisms. Its degree of hardness is from 3 to 3·5, and the specific gravity from 4·3 to 4·7. Some varieties are fetid when rubbed. It is composed of sulphuric acid 34, and barytes 66. It decrepitates before the blowpipe, and fuses with difficulty. It is distinguished by its heavy specific gravity from *Celestine* and *Arragonite*, and from the various carbonates by not effervescing with acids. *Heavy Spar* is often associated with the ores of other metals.

This substance is much used in the arts. It is ground up and used as white paint, and also for adulterating white lead. Mixed with equal parts of white lead, it is sometimes called *Venice White;* and another variety, with twice its weight of barytes, is called *Hamburgh White;* and another, one-third white lead, is called *Dutch White*. The barytes in these mixtures seems to prevent the white lead from being tarnished by sulphuretted hydrogen, and they are therefore preferred for some kinds of painting. The variety called *Bologna Spar* is highly phosphorescent after calcination. *Allomorphite* is a synonym of *Heavy Spar*. *Cawk* is a massive variety. *Dreelite* is a sulphate of barytes and lime.

Native *Carbonate of Barytes, Witherite, Barolite*, is remarkable for its high specific gravity, being 4·3. It is prismatic, and occurs generally in 6-sided prisms, or modified rhombic prisms, very imperfectly cleavable. It is also found in globular botryoidal shapes, showing a prismatic structure. It is brittle, and decrepitates before the blowpipe, fusing easily into a transparent globule, which becomes opaque on cooling. It effervesces with nitric acid, and is composed of barytes, 77·6, and carbonic acid, 22·4. It is found chiefly at Alston Moor in Cumberland, and Anglezarke in Lancashire, and also in Styria.

Witherite is a poisonous mineral, and is used for killing rats. It is also employed in pyrotechny for making the nitrate which gives a yellow colour, and it is used as a water-colour. *Baryto-Calcite* and *Bromlite* are varieties, the former from Alston Moor in Cumberland, the latter from Bromley Hill. They consist of the carbonate of lime and baryta. *Sulphato-Carbonate of Barytes* is a variety containing the sulphate of barytes.

(Dana, *Manual of Mineralogy.*)

BARYTO-CALCITE. [Barytes.]

BARYTO-CELESTINE, a sulphate of Barytes and Strontia. [Strontia.]

BARYTO-STRONTIANITE, a carbonate of Barytes and Strontia. [Strontia.]

BASALT, a hard dark-coloured rock of igneous origin. The chemical composition is variable, as appears from different analyses, two of which, by Beudant and Phillips, are as follows:—

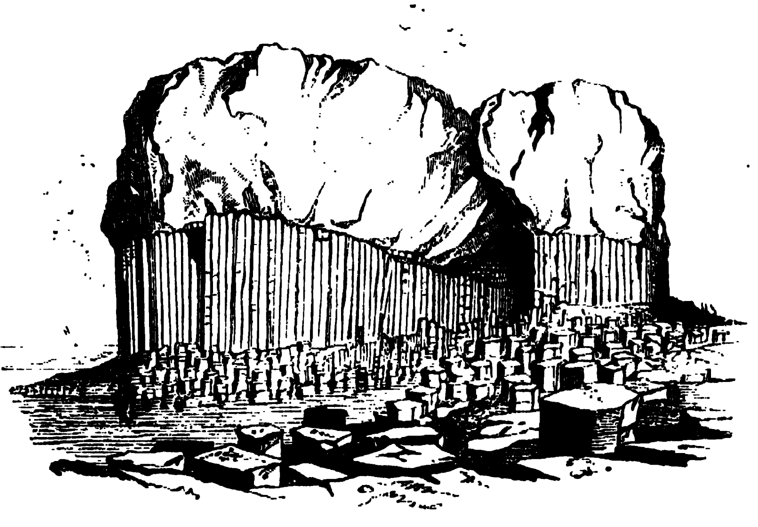
	Beudant. Beaulieu.	Phillips. Saxony.	Difference.
Silica . . .	59·5 .	44·50 .	15·00
Alumina . . .	11·5 .	16·75 .	5·25
Lime . . .	1·3 .	9·50 .	8·20
Magnesia . . .	0·0 .	2·25 .	2·25
Soda . . .	5·9 .	2·60 .	3·30
Potash . . .	1·6 .	0·00 .	1·60
Oxide of Iron . .	20·2 .	20·00 .	0·20
Oxide of Manganese	0·0 .	0·12 .	0·12

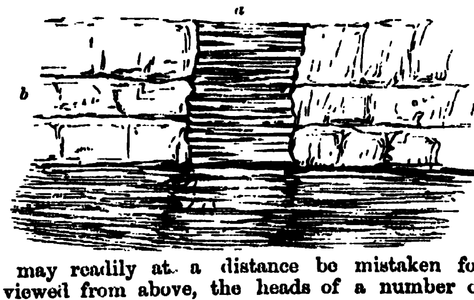
True Basalt has been regarded as composed of Augite, Felspar, and oxide of iron; but this definition is far too limited for either theoretical or practical purposes, unless the constituent minerals be considered of variable chemical compositions, as appears to be the case. Since Augite and Hornblende may, from the researches of Rose, be regarded as the same mineral, it follows that a very fine-grained Greenstone, containing a considerable per-centage of oxide of iron, can, even under this definition, be considered a true Basalt. There can indeed be little doubt that the same igneous rock has been termed Greenstone when the grains of Felspar and Hornblende were sufficiently distinct, which, when exceedingly fine-grained, has been named Basalt. Basalt can only be considered as one variety of that mass of melted rock which has been ejected at various periods from beneath the crust of the globe, and to which various names have been assigned, according to the characters which circumstances have impressed upon different portions of it.

Like others of the same class, Basalt occasionally passes into many rocks which have been in a state of fusion beneath the surface of the earth, and subsequently ejected. Dr. Hibbert notices a passage of Basalt into Granite in the Shetland Islands. (Brewster's 'Edinburgh Journal of Science,' vol. i. p. 107.) When however we view the mass of igneous rocks generally, it appears that Basalts are the products of comparatively late geological epochs. We may therefore infer that during the earlier states of our planet, conditions were not favourable to their production, or at least to their propulsion to the surface; though probably some varieties of Hornblende Rock, particularly when impregnated with much oxide of iron, do not differ materially from Basalt in their chemical contents. The mode of occurrence of these rocks and of Basalts is however very different.

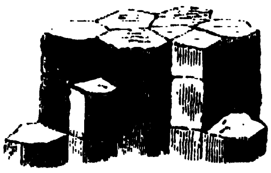
Basalt is a rock of very extensive occurrence on the surface of the earth, and is very frequently detected in the vicinity of volcanoes, both extinct and active. The greatest mass of Basalt yet observed is that noticed by Colonel Sykes in the Deccan, constituting the surface of many thousand square miles of that part of India. This immense mass of Basalt is either massive, prismatic, or globular, occurs in horizontal beds, and is traversed by dykes [DYKE] of Basalt, which sometimes cross each other. There is no trace of any crater in this basaltic region; and indeed this is the case with numerous other districts of Basalt, whence it has been inferred that such tabular masses have not been ejected from a conical vent similar to those of volcanoes, but that the Basalt of which they are formed rose through cracks and fissures while in a highly liquid state, spreading out in sheets of melted matter over the adjacent rocks.

As Basalt is frequently columnar, it is a rock which has excited much popular attention, and travellers have been sometimes induced to describe rocks as basaltic merely because they were columnar, which however is a character that this rock possesses in common with many others of igneous origin. When Basalt occurs in horizontal tabular masses, and is columnar, the columns are generally perpendicular, as in the annexed figure. When Basalt forms the substance of a perpendicular dyke, cutting through other rocks, and is columnar, the columns are usually horizontal, in the manner represented beneath, *a* being the basaltic dyke, and *b b* the rocks through which the dyke passes. Basaltic columns are sometimes also curved, and of this mode of occurrence there is a beautiful example in the island of Staffa.





When basaltic columns are jointed, and exposed to the destructive action of breakers on a coast, they often present the appearance of some great ruined work of art. Such deceptive appearances are however not confined to coasts, for in some countries, and especially in India, masses of Basalt rise suddenly from the plains, and the broken columns, shooting upwards, may readily at a distance be mistaken for buildings. When viewed from above, the heads of a number of basaltic columns, if unbroken, appear like a pavement composed of numerous polygonal pieces of stone fitted into each other, as in the following figure.



According to Mr. Gregory Watt the columnar structure of Basalt is due to the pressure of numerous spheres or spheroids on each other during the cooling of the rock, such spheres or spheroids being produced in planes of refrigeration or absorption. This author took seven cwts. of an amorphous Basalt named Rowley Rag, kept it in fusion for more than six hours, and cooled it so gradually that eight days elapsed before it was taken from the furnace. The shape of the mass was uneven, and while the thinner portion was, in consequence of more rapid cooling, vitreous, the thicker was stony, the one state passing into the other. It was observed that numerous spheroids had been formed, sometimes two inches in diameter. They were radiated with distinct fibres, the latter also forming concentric coats when circumstances were favourable to such an arrangement. When the temperature had been sufficiently continued, the centres of the spheroids became compact before they attained the diameter of half an inch. When "two spheroids came into contact no penetration ensued, but the two bodies became mutually compressed and separated by a plane, well defined, and invested with a rusty colour," and when several met they formed prisms.

The following are Mr. Gregory Watt's inferences from these facts:—"In a stratum composed of an indefinite number in superficial extent, but only one in height, of impenetrable spheroids, with nearly equidistant centres, if their peripheries should come in contact in the same plane, it seems obvious that their mutual action would form them into hexagons; and if these were resisted below, and there was no opposing cause above them, it seems equally clear that they would extend their dimensions upwards, and thus form hexagonal prisms, whose length might be indefinitely greater than their diameters. The farther the extremities of the radii were removed from the centre, the greater would be their approach to parallelism; and the structure would be finally propagated by nearly parallel fibres, still keeping within the limits of the hexagonal prism with which their incipient formation commenced; and the prisms might thus shoot to an indefinite length into the undisturbed central mass of the fluid, till their structure was deranged by the superior influence of a counteracting cause." ('Observations on Basalt, &c.;' 'Phil. Trans.,' 1804.)

According to this theory, which is certainly the best hitherto framed to account for the columnar structure of Basalt, the irregularity of the prisms would obviously depend upon the unequal distances of the centres of the spheroids, and the consequent unequal pressure; and it is further inferred that the joints sometimes observable in basaltic columns correspond with the concentric coats noticed above. Two of the most beautiful examples of columnar Basalt hitherto discovered are found in the British Islands, one forming the Giant's Causeway, on the north coast of Ireland, and the other at Staffa, among the Hebrides. The largest columns yet observed are found at Fairhead at the former place, where, according to the accurate measurement of some by the Ordnance Trigonometrical Survey of Ireland, they are 317 feet in height, the sides of these enormous prisms occasionally measuring 5 feet.

Some non-columnar Basalts present no trace of any particular arrangement of parts, while others show a globular structure, so that when the rock becomes more decomposed it has the appearance of numerous bombshells and cannon-balls cemented together by a ferruginous substance. This globular structure is sometimes also apparent when the decomposition of the rock has not been considerable, being well exhibited in the concentric arrangement of coats of Basalt round centres at variable distances from each other.

Other Basalts are amygdaloidal, containing a variety of substances, such as Agates, Onyxes, and other minerals, which have been infiltrated into cavities formed by bubbles of gas or vapour while the rock was in a state of fusion. As these bubbles have sometimes been lengthened by the flow of the rock before it finally cooled, the infiltrated contents filling such lengthened cavities have the appearance of almonds sticking in the mass of the rock, whence the name amygdaloid. When, as sometimes occurs, a great tabular mass of Basalt is composed of superimposed beds, some columnar, some amorphous, and others amygdaloidal, these characters are sufficient to authorise a conclusion that the whole mass has not been produced at one upburst of Basalt, but that there were several flows of melted matter to which different conditions gave different characters; the amygdaloidal structure particularly pointing to the absence of very considerable pressure upon the Basalt so characterised, before it became solid.

BASANITE, a variety of Jasper. [JASPER.]

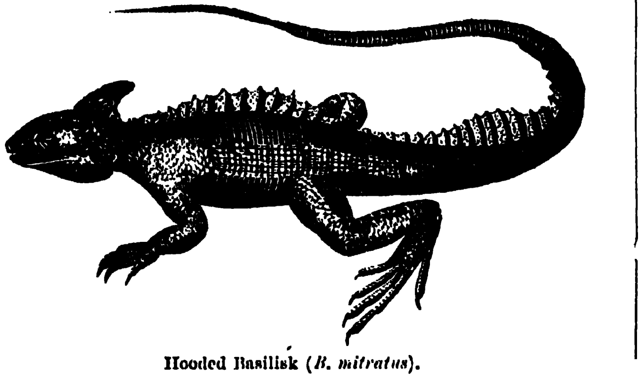
BASICERINE, a hydro-fluoride of Cerium. [CERIUM.]

BASIL. (CALAMINTHA.)

BA'SILISK (***Basiliscus***, Daudin), a genus of Saurian Reptiles, belonging to the Iguanian Family. It is to be observed that the Basilisk of modern Erpetology is a very different animal from the Basilisk (*βασιλίσκος*) or Royal Serpent of antiquity, the *Tsepha* or *Tsiphoni* of the Hebrews, which is translated *Cockatrice* in our English version of the Scriptures, and which was formerly the subject of so many fabulous narrations. [COCKATRICE.]

The Basilisks are distinguished from other genera of the Iguanian Reptiles by the absence of the lax and dilatable skin under the throat, by the want of thigh pores, and still more particularly by the elevated crest or fin which, like the dorsals of some fishes, runs along the whole length of the back and tail, and is supported by the spinous processes of the dorsal and caudal vertebræ. To the occiput is attached a membranous bag, which the Basilisk has the power of distending with air, or emptying, as its occasions require, and which appears to supply in this genus the absence of the dilatable skin on the throat, with which nature has furnished the guanas, either as a reservoir to contain a quantity of fresh air to supply their necessities while diving, or by enlarging their magnitude without adding to their weight, to assist them in the actions of swimming and in keeping the head above water, or perhaps for both these purposes. In the particular case of the Basilisks, their aquatic habits are still more powerfully increased by the vertical fin of the back, which, like that on the tail, is capable of being erected or depressed at the will of the animal, and consequently, whilst it does not impede its motions on the dry land, greatly facilitates its power of swimming and moving about in the water. In short, these animals may be said to carry about with them a portable swimming apparatus, which is of the utmost service to them as aquatic animals, without encumbering them at other times,—a beautiful provision of nature to supply the deficiency of palmated or webbed feet, which, as in the case of all other palmated animals, would have reduced the progression of the Basilisks on land to a slow and awkward gait, and rendered it altogether impossible for them to ascend trees or move securely among their branches. Yet their whole organic structure, the length of their limbs, and the division and flexibility of their toes, all announce the rapidity of movement and arboreal habits of these animals, in which are united, by the most simple means, functions and habits the most directly opposed to one another. The genus *Ophryessa* of authors exhibits much of the same structure, though perhaps not quite so strongly developed, nor is it easy to conceive any just grounds for separating these animals from the Basilisks. Two species only are usually referred to this genus.

1. *B. mitratus* (Daudin), the Hooded Basilisk, measures 7 or 8 inches from the nose to the origin of the tail, which is itself nearly twice as ong again, being 19 or 20 inches in length. This animal is easily recognised by the generic characters already described, and more especially by the bag or hood of the occiput, which may be said to be in a manner peculiar to it, since it is but slightly indicated in the other species; this bag, when distended with air, is about the size of a pullet's egg. The general colour is a mixture of vinous and sandy brown, slightly marbled on the back and sides with different shades of blue, and silvery-white on the belly. Transverse bands of a deep-brown colour, but broken and irregular, pass down the sides from the dorsal fin to the flanks; two small whitish bands pass over the eyes and from the corners of the mouth, and are prolonged upon the sides of the neck; and the tail is so remarkably attenuated towards the extremity, as to show the articulations of the vertebræ beneath. This species inhabits Guyana and the tropical parts of South America generally. Its habits have been sufficiently noticed in speaking of the general characters of the genus.



Hooded Basilisk (*B. mitratus*).

2. *B. Amboinensis* (Daudin), the Crested Basilisk, a large species, upwards of 3 feet in length, is of a green colour, marked with white lines on the head and neck, brown on the back and tail, and silvery-white on the belly, irregularly dotted with numerous white points. This species, as its scientific name imports, is an inhabitant of Amboyna and the islands of the Indian Archipelago generally. It keeps in the vicinity of rivers and fresh-water ponds, where it loves to bask on the branches of the trees which overhang the stream. On the first appearance of danger it drops into the water, and conceals itself beneath some rock or stone, whence it may be taken with the naked hand, or with a noose, for it is a stupid and timid animal. It is caught for the sake of its flesh, which is white and as tender as chicken; in taste it is said to resemble venison. The female deposits her eggs in the sand, and leaves them to be hatched by the sun, paying no attention afterwards to her young progeny.

BASILOSAURUS, the generic title proposed by Dr. Harlan for a large fossil animal, of which the remains were collected in Tertiary Strata on the river Washita in Louisiana. The animal was probably 70 feet long. Professor Owen has referred it to the Cetaceans, under the title of *Zeuglodon Cetoides.*

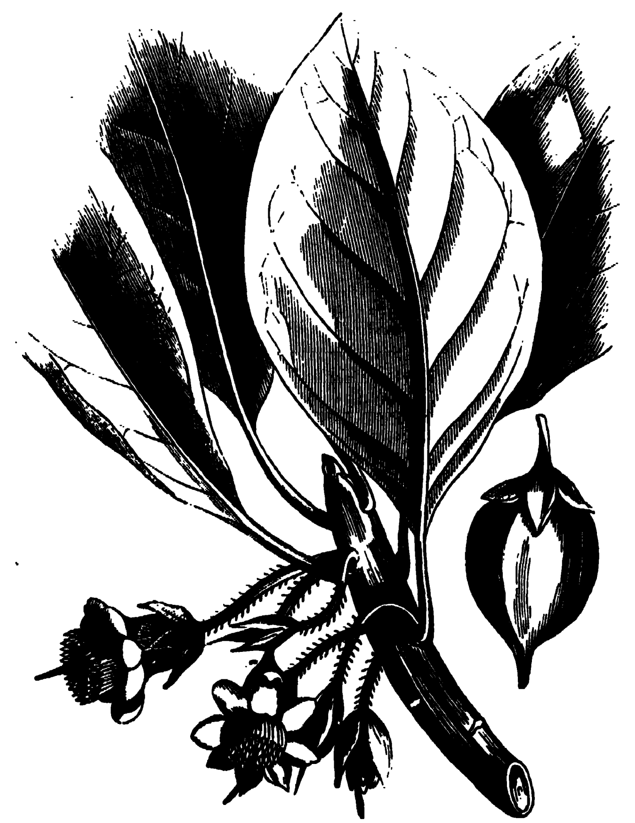
BASIN. In Geology, depressions of the strata occasioned by synclinal dips are thus designated, especially such as are on a large scale. Thus the Tertiary Basins of London, Hampshire, and Paris, resting on Chalk; the Coal-Basin of South Wales, resting on Old Red-Sandstone; and, in a larger sense, the European Basins between the Ural, the Scandinavian chains, and the Pyrenees, Alps, &c. Some of these Basins are due to the original circumstances of deposition; others have acquired their configuration from elevations and depressions of particular geographical areas.

BASSE, a Fish. [LABRAX.]

BA'SSIA, a genus of plants belonging to the natural order *Sapotaceæ*. It has a calyx of four or five leaves, a monopetalous fleshy corolla, with its border generally 8-parted, and a great number of stamens. The ovary terminates in a long taper style, and contains from six to eight 1-seeded cells. The fruit has a pulpy rind, with not more than three or four cells, the remainder being abortive.

The species are found in the East Indies and in Africa, where they are of great economical importance on account of the abundance of a sweet buttery substance which is yielded by their seeds when boiled.

B. butyracea, the Indian Butter-Tree, the Fulwa, or Phulwara-Tree, is found wild on the Almora hills in India, where it grows to a considerable size, its trunk sometimes measuring 50 feet in height, and 5 or 6 feet in circumference. It has broad, oval, long-stalked leaves, from 6 to 12 inches long, smooth on their upper surface, hairy on their under. The flowers, which are large and pale-yellow, hang down near the tips of the branches, from the axils of the leaves, and generally grow three together. They are succeeded by smooth, pulpy



Indian Butter-Tree (*Bassia butyracea*).

fruits, about as large as a pigeon's egg, usually containing two or three roundish light-brown seeds. From these is produced a fat-like substance, which is a kind of vegetable butter, concerning which we find the following information in the 'Asiatic Researches,' by Dr. Roxburgh :—"On opening the shell of the seed or nut, which is of a fine chestnut colour, smooth and brittle, the kernel appears of the size and shape of a blanched almond. The kernels are bruised on a smooth stone, to the consistency of cream, or of a fine pulpy matter, which is then put into a cloth bag, with a moderate weight laid on, and left to stand till the oil or fat is expressed, which becomes immediately of the consistency of hog's-lard, and is of a delicate white colour. Its uses are in medicine, being highly esteemed in rheumatism and contractions of the limbs. It is also much valued, and used by natives of rank as an unction, for which purpose it is generally mixed with an *utr* (aromatic oil) of some kind. Except the fruit, which is not much esteemed, no other part of the tree is used. After the oil has been expressed, the dregs are employed by the poor as food. This Phulwara Butter will keep many months in India without acquiring any bad colour, taste, or smell, and might no doubt be substituted advantageously for animal butter. The timber is of no value, being nearly as light as that of the Semul, or Cotton-Tree (*Bombax heptaphyllum*)."

B. longifolia, the Indian Oil-Tree, is a large tree, a good deal like the last, but its leaves are narrower, and its flowers much more fleshy. It is a native of the peninsula of India, and is found in plantations along the southern coast of Coromandel, where it is called the Illupie-Tree. Its fruit is yellowish, and yields by pressure a valuable oil, which is used by the poorer natives of India for their lamps, for soap, and, instead of better oil, for cookery. The flowers also are roasted and eaten by the Indian peasants, or bruised and boiled to a jelly, and made into small balls, which are sold or exchanged for fish, rice, and various sorts of small grain. The wood is as hard and durable as teak, so that this is one of the most generally useful trees found on the continent of India.

B. latifolia, the Mahwa, Madhaca, or Madhooka-Tree, has oblong leaves, and a corolla with a very protuberant tube. It is a native of the mountainous parts of the Circars and of Bengal, where it forms a middling-sized tree. Its wood is hard and strong, and proper for the naves of wheels; its flowers are eaten raw by the natives and by jackals, and they yield by distillation a strong intoxicating spirit. From their seeds a considerable quantity of greenish-yellow oil is obtained, which is found useful for the supply of lamps; it is, however, inferior to that of the last species. It is curious that this oil stains linen or woollen cloth as animal oil does, while the fatty substance of the *B. butyracea* possesses no such property, but when rubbed on cloth leaves no trace behind.

A fourth species has been named *B. Parkii* and is believed to be the Shea-Tree, or African Butter-Plant, which is so very important an article of African internal commerce; and which it would apparently be extremely desirable to introduce into the West Indies and Bengal, as a new source of internal wealth. This is the plant which is frequently spoken of by Park in his 'Travels in Africa' :—

"The people were everywhere employed in collecting the fruit of the shea-trees, from which they prepare a vegetable butter, mentioned in the former part of this work. These trees grow in great abundance all over this part of Bambarra. They are not planted by the natives, but are found growing naturally in the woods; and in clearing wood-land for cultivation, every tree is cut down but the shea. The tree itself very much resembles the American oak, and the fruit, from the kernel of which, first dried in the sun, the butter is prepared by boiling the kernel in water, has somewhat the appearance of a Spanish olive. The kernel is enveloped in a sweet pulp, under a thin green rind; and the butter produced from it, besides the advantage of its keeping the whole year without salt, is whiter, firmer, and to my palate of a richer flavour than the best butter I ever tasted made of cow's milk. The growth and preparation of this commodity seem to be amongst the first objects of African industry in this and the neighbouring states, and it constitutes a main article of their inland commerce."

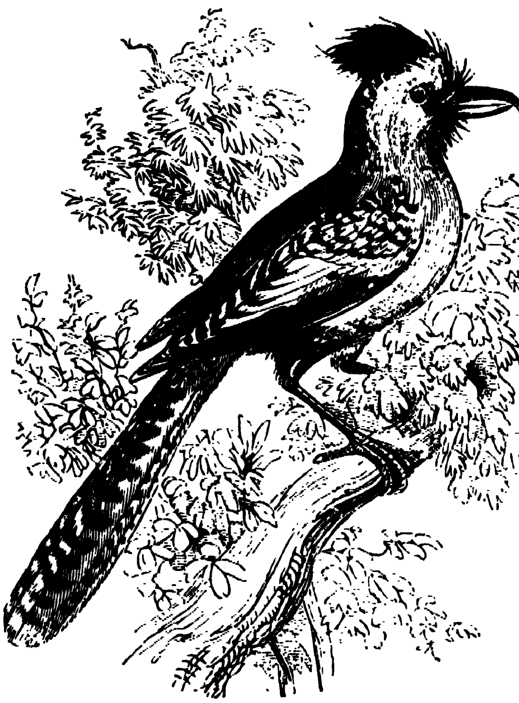
Duncan has also given an account of this tree, and expressed his conviction that it might become an important article of commerce between Europe and Africa, as it is available for all the uses for which the hard oils are used in the arts and manufactures.

BASSUS, a genus of Insects, belonging to the order *Hymenoptera*, and the family *Braconidæ*. These are four-winged flies, with long and narrow bodies. They frequent the flowers of umbelliferous plants.

BAT. [CHEIROPTERA.]

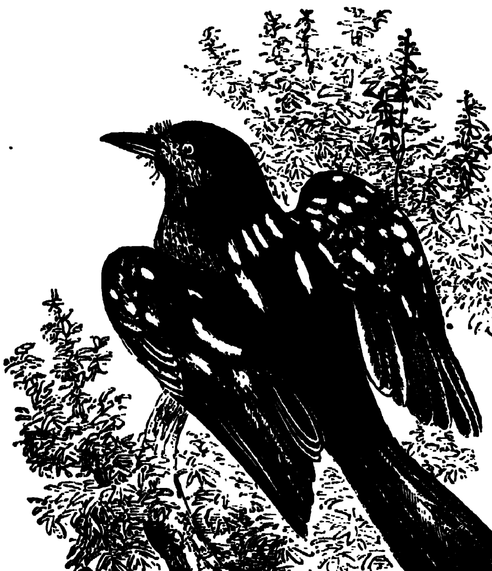
BATA'RA, D'Azara's name for the Bush-Shrikes, forming the genus *Thamnophilus* of Vieillot. Mr. Swainson considers the typical group to consist of the species with long tails; and of this division, *Thamnophilus Vigorsii* (Such), *Vanga striata* (Quoy and Gaimard), may be taken as an illustration.

Dr. Such states this to be the largest species yet known, and gives 13 inches as the length of the body. The bill is black, and very much compressed. In the male (which is the sex here figured) the back, wings, and tail are black, broadly banded with fulvous, and the under part of the body is a dirty whitish-brown. On the head is a rufous crest which is blackish at the apex. In the female the bands are whitish and the crest blackish, and the under part of the body ash-colour.



Thamnophilus Vigorsii.

Thamnophilus nævius, the Spotted Shrike of Latham, is an example of the round and comparatively short-tailed division.



Spotted Shrike (*Thamnophilus nævius*).

Leach thus describes it from a specimen in the British Museum :—"Black; back and belly ash-coloured; the former anteriorly spotted with white; quills of the wings externally, and the tips of those of the tail, white; under part of the body ash-colour, of which colour the back partakes in a considerable degree."

BATA'TAS, the Malayan name of a Convolvulaceous plant, the root much eaten in the south of Europe before the cultivation of the potato, which both became a substitute for it, and appropriated its name. It has generally been considered a species of *Convolvulus*; but Professor Choisy in his recent classification has erected it and a few others into a peculiar genus, distinguished by having an ovary with four cells, in each of which there is only one seed.

The only species of any general interest is the *Batatas edulis*, the *Convolvulus Batatas* of authors, the Sweet Potato. This plant, originally found wild in the Malayan archipelago, has been gradually dispersed over all the warmer parts of the world, where it is still an object of culture for the sake of its roots, which, when roasted or boiled, are mealy, sweet, and wholesome, but slightly laxative. It is a perennial plant, with long creeping stems, leaves variously lobed and angled, and pale purple flowers about an inch long. It is impatient of cold, and consequently unfit for cultivation in the northern parts of the world; but it is a productive agricultural plant in many warm countries. It is partially cultivated in the south of Spain and of France, whence its roots are sent to the markets of Madrid and Paris, where they are held as a delicacy. They however have the great fault of keeping badly, being very apt to become mouldy and to decay, unless extraordinary pains are taken to preserve them dry. They are sometimes raised in the hothouses of the curious in this country. *B. Jalapa* has none of the properties of the plant after which it is named. [CONVOLVULACEÆ.]

Sweet Potato (*Batătas edulis*).

BATOLI'TES, a genus of Fossil Shells established by Montfort, and placed by him among his *Coquilles Univalves Cloisonnées*. Montfort states that those shells acquire a very great length, and that they constitute masses of rock in the High Alps. [BIROSTRITES; HIPPURITES.]

BATRA'CHIA, FOSSIL. The number of Fossil Reptilia referrible to this division is gradually enlarging, though still very small. To the Anourous Batrachians we must, with Jäger and Professor Owen, refer the Labyrinthodons of the New Red-Sandstone Series of Warwickshire and Wirtemberg (which include the *Cheirotheria* whose foot-prints ornament the Red-Sandstones of England and Germany); while the tertiary fossil of Oëningen (which Scheuchzer imagined to be a human skeleton) is determined by Cuvier to be analogous to the Newt of Europe and the *Menopoma* of North America. Remains of Frogs and Salamanders occur in the Tertiary Brown Coal-Beds of the Rhine Valley. [AMPHIBIA.]

BATRACHITE, a mineral, which is a variety of *Olivine*. [OLIVINE.]

BATRACHOSPERMEÆ, a tribe of plants referred by some writers to the order *Fucaceæ*. It is regarded by Harvey as an aberrant group of *Chlorospermeæ* leading through *Ectocarpaceæ* to *Melanospermeæ*. [ALGÆ.] The species have a polysiphonous frond composed of a primary thread, surrounded by parallel accessory ones. The vesicles are terminal or lateral and clustered.

The principal genus of this family is *Batrachospermum*, which have got this name from Βάτρακος, a frog, and σπέρμα, a seed, on account of their gelatinous fronds giving them the appearance of the ova of the *Amphibia*. The species are flexible, and have a gelatinous character. The surface is covered with innumerable little hairs, looking like cilia, which give them a very beautiful appearance under the microscope. They mostly inhabit pure and running waters where the force of the stream is not considerable. On removing them from the water the hairs, which are expanded whilst immersed, collapse, and they appear like masses of jelly without any traces of organisation.

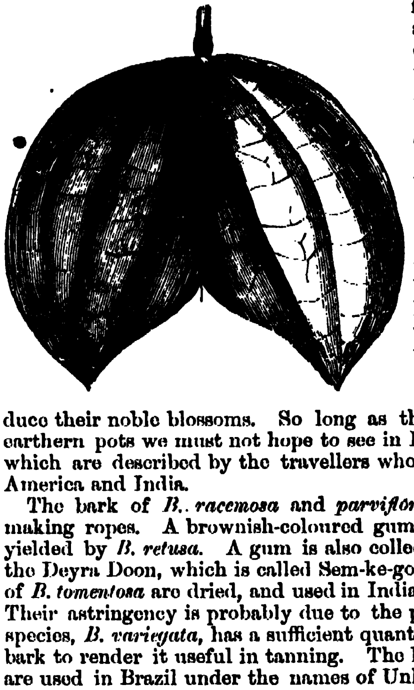
Several species of this genus have been described by Dr. Hassall as inhabiting streams in the neighbourhood of London. *B. moniliforme* is figured in Lindley's 'Vegetable Kingdom,' p. 20; and Hassall has figured some of his new species in his 'British Fresh-Water Algæ.'

BATRACHOSPERMUM. [BATRACHOSPERMEÆ.]

BATTUS, the generic title proposed by Dalman to replace the name *Agnostus* which Brongniart gave to some minute trilobate *Crustacea* which occur in the Silurian Limestones of Norway, Wales, &c.

BAUHI'NIA, a genus of plants belonging to the natural order *Leguminosæ*. Linnæus applied the name very happily to commemorate the merits of the two Bauhins, for the genus is remarkable for its leaves being generally divided into two twin lobes.

The species are usually twining plants, found in the woods of hot countries, and often stretching from tree to tree like living cables, forming with other plants an almost insurmountable obstacle to the traveller who would penetrate the recesses of a tropical forest. Some of them however are small trees, as for example *B. porrecta*, which in Jamaica is called Mountain Ebony, because its wood is sheathed with black. Their flowers are often very beautiful, for which reason they have long been cultivated in the hot-houses of Europe; but they are too impatient of the wretched treatment they usually receive in stoves to flourish and produce their noble blossoms. So long as these plants are cramped in earthern pots we must not hope to see in Europe those noble flowers which are described by the travellers who have visited the forests of America and India.



The bark of *B.. racemosa* and *parviflôra* has been employed in making ropes. A brownish-coloured gum is said by Roxburgh to be yielded by *B. retusa*. A gum is also collected from *B. emarginata* in the Deyra Doon, which is called Sem-ke-gond. The flowers and buds of *B. tomentosa* are dried, and used in India as remedies in dysentery. Their astringency is probably due to the presence of tannin, and one species, *B. variegata*, has a sufficient quantity of this substance in its bark to render it useful in tanning. The leaves of various Bauhinias are used in Brazil under the names of Unha de Boy, or Ox-Hoof, as demulcent remedies.

BDE'LLIUM, commonly called a gum, but in reality a gum-resin, the origin of which has been a subject of doubt. It would appear that there are several kinds of Bdellium, the source of two of which seems now to be ascertained; the others are matters of controversy. The Bdellium of the ancients, said by Pliny (xii. 9) to be brought from Bactria and other parts of Asia, still comes from Asia. The Bdellium of Africa is yielded by the *Balsamodendron Africanum*. Dr. Royle says that Indian Bdellium is produced by a species of *Balsamodendron*, called by Dr. Roxburgh *Amyris Commiphora* ('Fl. Ind.' ii., p. 244), *Amyris Agallocha* ('Calcutta Catalogue,' p. 28), the native name of which is Googul. (Royle, 'Illustrations of the Flora of the Himalayah,' part vi., p. 176.) The opinion of its being obtained from a palm, either the *Lontarus domestica* (Gaertn.) or the *Borassus flabelliformis*, is very improbable. This substance occurs in masses of variable size and shape, sometimes as large as a walnut, in oblong or angular pieces of a yellow, red, or brownish colour. The clearest pieces are transparent; the odour is weak and peculiar; the taste bitter, balsamic, and resembling myrrh or Venice turpentine. It is tolerably brittle at the ordinary temperature of the atmosphere, but with a slight increase of heat the finer kinds may be kneaded between the fingers. Its specific gravity is 1·371.

Resembling myrrh in appearance, it also resembles it in its effects upon the human system, and is often fraudulently substituted for it; it is however weaker, while it is more disagreeable and acrid. [BALSAMODENDRON.] It was formerly used in many compounds and plasters, such as Diachylon. It is now disused in Britain; but is to be found intermixed with gum-Arabic.

The Sicilian Bdellium is produced by the *Daucus Hispanicus* (Decand.), the *D. gummifer* of Lamarck, or perhaps the *D. gingidium* (Linn.), according to Boccone ('Museo di Piante Rare della Sicilia,' &c., tom. xx.), which grows on the islands and shores of the Mediterranean.

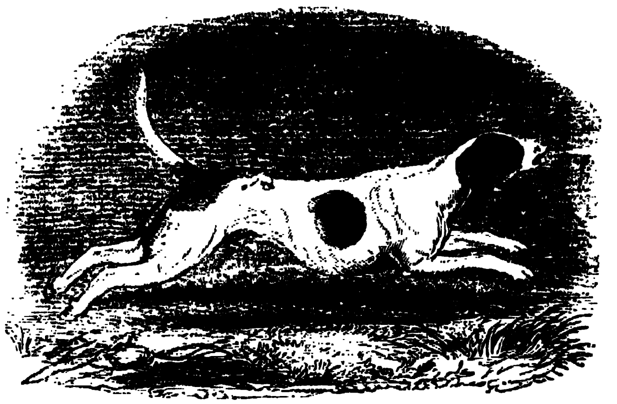
The Egyptian Bdellium is conjectured to be produced by the *Borassus flabelliformis* (Linn.), the *Chamærops humilis*, or the *Hyphæne cuciphera* (Pers.)

The Bdellium mentioned in the second chapter of Genesis is obviously a mineral, and has no reference to the substances above mentioned.

BEACHES, RAISED, a term introduced into modern Geology to characterise a very numerous class of gravelly, sandy, and shelly deposits, which have been once parts of the sea-bed, and have been raised to constitute dry land in very modern geological periods. It is scarcely possible to assign exactly the limits of these formations, even by the aid of the organic remains which they contain; for while some raised beaches contain only species now living in the adjoining sea, others include one or more extinct species, and thus conduct by insensible gradations from the almost modern shell-beds of the raised shores of the Forth and the Clyde, and the variously elevated shell-accumulations of Uddewalla and other points of Sweden, to the still richer and more ancient (though still to be called Newer Pleiocene) deposits of Sicily. The term Pleistocene (meaning 'most recent') which has come into use, meets this difficulty but feebly, and in fact only draws an arbitrary or epochal line, instead of the soft gradations of long periods which really appear in nature. Nearly all the British, Irish, and European shores furnish examples in abundance: as the shores of the Forth and Clyde, the coasts of Yorkshire and Lancashire, the coasts of Cornwall and Devon, of Wexford, Normandy, Sweden, and the Mediterranean.

BEAD-TREE. [MELIA.]

BEAGLE, a small well-proportioned hound, slow but sure, having an excellent nose and most enduring diligence, formerly much in fashion for hunting the hare, but now comparatively neglected, its place being occupied, where hare-hunting is patronised, by the Harrier. [HARRIER.]



The Beagle.

These were the little hounds so much prized by 'the good old English gentleman;' for at a trifling expense, and greatly to the delight of the neighbouring rustics who followed on foot, he could keep his ten or eleven couple, not more than so many inches high individually, and, mounted on his easy pad, would generally make certain of killing his hare, though it frequently cost him two or three hours to perform the feat. During this protracted chase he had ample leisure for enjoying the sight of his admirably-matched pack running so well together that 'they might have been covered with a sheet,' and for gratifying his ears with their tuneable cry.

The hare distanced them immeasurably at first, and in the course of the run she might be observed to sit and listen 'sad on some little eminence,' but

——— "In louder peals, the loaded winds
Brought on the gathering storm"—

and after exhausting all her speed, shifts, and doublings, she almost always fell a victim to their persevering and destructive instinct.

A well-bred beagle of the proper size, which should not exceed that above mentioned, is a very pretty and symmetrical variety. This symmetry (the term is used in relation to the purposes for which the dog is employed) was the result of much care among amateurs, who spared no efforts to bring it to what they considered the standard of perfection.

Some prided themselves on the diminutive but still effective size of their packs. Daniel and others have not forgotten to commemorate Colonel Hardy's 'cry of beagles.' They amounted to ten or eleven couple, and were always carried to and from the field in a pair of panniers upon a horse's back. Small as they were, they rarely failed, though they could never get near enough to press the hare in the early part of the run, to stick to her and worry her to death at last.

Such diminutive hounds are sometimes called Lap-Dog Beagles and Rabbit Beagles.

The fairy pack above alluded to had a little barn for their kennel, where also their panniers were kept. The door was one night broken open, and every hound, panniers and all, stolen; nor could the disconsolate owner ever discover either the thieves or their booty.

BEAM-TREE. [PYRUS.]

BEAN. [FABA; PHASEOLUS; DOLICHOS; VICIEÆ.]

BEAN-GOOSE. [GOOSE.]

BEAR, the English name for a family of ***Plantigrade Mammalia***, forming a natural group, with six incisor teeth and two canine teeth in each jaw, twelve molars in the upper and fourteen in the lower jaw; pentadactyle or five-toed feet, armed with strong claws; and a short tail. The Bears exhibit but a comparatively small carnivorous development; for notwithstanding their strength, their dentition, particularly in the form of the crowns of their molar teeth, indicates a propensity bordering on the frugivorous exclusively. Aristotle well knew this, and thus described the habits of the Bear ('Nat. Hist.,' viii. 5):—"But the bear is an omnivorous animal, and by the suppleness of its body climbs trees and eats the fruits and also legumes. It also devours honey, having first broken up the hives; crabs too and ants it eats, and also preys upon flesh." Aristotle then describes how the animal attacks the stag, the boar, and even the bull.

The ranger in the 'Tour on the Prairies' notices the honey-seeking propensity in language which, though not quite classical, is truly nomadic:—"The bear is the knowingest varmint for finding out a bee-tree in the world. They 'll gnaw for a day together at the trunk, till they make a hole big enough to get in their paws, and then they 'll haul out honey, bees, and all." And indeed it appears that although they are omnivorous, they for the most part rarely devour flesh unless pressed by necessity. Their claws too, though formidable weapons, are not retractile, and are more calculated for digging and climbing than for tearing prey. It is their general characteristic to lay themselves up in caves or hollows for the winter, which they pass in a dormant state, and without taking food. The female produces her young at this season.

European Bears.

Ursus Arctos (Linn.), the Brown Bear, *Ἄρκτος* of Aristotle, the *Ours* of the French, *Orso* of the Italians, *Bär* of the Germans, *Björn* of the Swedes. This appears to have been the only species certainly known to Linnæus; and though zoologists are not without their suspicions as to some of the species since recorded, the number of those which can no longer be considered doubtful will prove how much this department of Natural History has been enriched since his time. The Brown Bear is widely diffused. The mountainous districts of Europe, from very high latitudes (Arctic Circle) in the north, to the Alps and Pyrenees in the south; Siberia, Kamtchatka, and even Japan, to the eastward, and a portion of the northern regions of America, form the range of its geographical distribution. Africa and the Moluccas have been added; but it is far from improbable that these localities have been assigned to it by travellers who have taken some other species for it.

To the Kamtchatkans this Bear seems to give the necessaries and even the comforts of life. The skin, we are told, forms their beds and their coverlets, bonnets for their heads, gloves for their hands, and collars for their dogs; while an overall made of it, and drawn over the soles of their shoes, prevents them from slipping on the ice. The flesh and fat are their dainties. Of the intestines they make masks or covers for their faces, to protect them from the glare of the sun in the spring, and use them as a substitute for glass, by extending them over their windows. Even the shoulder-blades are said to be put in requisition for cutting grass.

The Laplanders hold it in great veneration, and, according to Leems, called it the Dog of God; for it appears that among the Norwegians there had long been a proverb, that it had the strength of ten men and the sense of twelve. They never, says the same author, presume to call it by its proper name of Guouzhja, lest it should revenge the insult on their flocks; but make mention of it as Moedda-Aigja, or the Old Man with a Fur-Cloak ('senem cum mastrucâ').

The Brown Bear is a solitary animal. Its retreat during the period of hybernation is the natural hollow of a tree, or some cavern; and if these are not to be found the animal constructs a habitation for itself, sometimes by digging, sometimes by forming a rude kind of hut or den with branches of trees, lined with moss. Here it retires when fat with the summer's food, and remains dormant, without taking any sustenance, till the ensuing spring. Cuvier makes the period of gestation about seven months, stating that they couple in June, and that the birth takes place in January; and the same number of months is assigned in the article in the old French 'Encyclopédie,' taken from observations of the bears kept at Berne. The cubs when first born are not much larger than puppies. They are long-lived, for it appears that one of the Berne bears had been confined there 31 years; and another, born there, is spoken of at the age of 47 in the menagerie at Paris. They are excellent swimmers, notwithstanding their uncouth appearance. Mr. Lloyd, in his 'Field Sports of the North of Europe,' gives a very interesting account of the habits of this species, and of his adventures in hunting it.

That the Brown Bear was at one time common in the British Islands there can be no doubt. The Caledonian bears (another name for British with the Romans) were imported to make sport for the Roman people, to whom the excitement of witnessing the suffering of man and beast in its most distressing shape seems to have been but too welcome. From the well-known lines of Martial, descriptive of the dreadful punishment of the malefactor Laureolus, it appears that they were sometimes used as instruments of torture:—

Nuda Caledonio sic pectora præbuit urso,
Non falsâ pendens in cruce Laureolus.*

Ray quotes authority for the Brown Bear having been one of the

---

* We are quite aware that some commentators are of opinion that Martial is here speaking of a mimic scene, and that the verses which follow those above

Welsh beasts of chase, and Pennant adduces the places which retained the name of Pennarth, or the Bear's Head, as evidence that it existed in that principality. In the 'History of the Gordons' it is stated that one of that family, so late as the year 1057, was directed by the king to carry three bears' heads on his banner, as a reward for his valour in slaying a fierce bear in Scotland.

For many years it has been swept away from our islands so completely that we find it imported for baiting, a sport in which our nobility, as well as the commonalty, of the olden time—nay, even royalty itself—delighted. A bear-bait was one of the recreations offered to Elizabeth at Kenilworth, and in the Earl of Northumberland's 'Household Book' we read of 20*s.* for his bear-ward :—"Item. My lorde usith and accustomyth to gyfe yerly when his lordshippe is at home to his bar-ward, when he comyth to my lorde in Cristmas with his lordshippe's beests, for makynge of his lordshippe pastime, the said xij days, xxs." In Southwark there was a regular bear-garden, that disputed popularity with the Globe and the Swan theatres on the same side of the water. Now however, so much do tastes alter (in this instance certainly for the better), such barbarous sports are banished from the metropolis. (Stat. 3 Wm. IV. cap. 19, sec. 29.)

The firm support afforded by the well-developed sole of the foot enables the Bears to rear themselves with comparative facility on their hind feet, and this has been taken advantage of to teach the animal to dance in an erect position. The discipline put in force to produce this accomplishment is said to be so severe that it is never forgotten.

Baron Cuvier, in his 'Ossemens Fossiles,' distinguished the Black Bear of Europe under the title of *Ursus niger Europæus*, observing that the frontal bone was flattened, and that the well-marked depressions and ridges of the skull, for the reception of the strong muscles of the lower jaw, were evidence of its being more decidedly carnivorous than the Brown Bear; but in the last edition of his 'Règne Animal' he confesses his doubts about the data on which he had come to this conclusion, and it is probably a variety only. The usual size of the Brown Bear is about 4 feet in length by about 2½ feet in height. The claws are 2 inches long, very much curved and nearly equal.

Common Brown Bear (*Ursus Arctos*).

F. Cuvier has figured the bear of the Pyrenees and of the Asturias, whose fur in its youth is of a yellowish white colour. The hair of the feet is an intense black. This is most probably only a variety, though perhaps a distinct one, of *Ursus Arctos*. The Barren-Ground Bear of America Sir John Richardson is inclined to believe now is a variety of this, and not of the next species, as he at one time was inclined to think.

American Bears.

U. Americanus, American Black Bear, or Musquaw.—Pallas first described this species (the Sass of the Chippewayan Indians and the Musquaw of the Crees), whose general proportions are smaller than those of *U. Arctos*. The head of the American Black Bear is narrower, the ears more distant, and the muzzle more prominent, and it wants the depression above the eyes. The fur is composed of soft smooth hairs, which are of a glossy black for the greater part of their length, instead of possessing the shaggy and woolly character of the comparatively grizzled fur of the Brown Bear, except on the muzzle, which is clothed with short thick-set hairs, brown on the upper part and paler on the side. The tail is apparently more prominent, and the sharper and more curved claws are nearly hidden in the hair.

The Black Bear inhabits every wooded district of the American continent from the Atlantic to the Pacific, and from Carolina to the shores of the Arctic Sea. It still occurs, though not very often, in the Blue Ridge, in Virginia. Its southern boundary is placed at the Isthmus of Panama. Man has however gradually driven it from its haunts to make way for his works, and has compelled it to take refuge in the mountains and the immense inland forests. In Canada it is still abundant, and it is tolerably numerous on the western coast as far as California.

Black Bear (*Ursus Americanus*).

It is smaller than the other American bears, the total length of an adult seldom exceeding five feet. Its favourite food appears to be berries of various kinds, but when these are not to be procured it preys upon roots, insects, fish, eggs, and such birds or quadrupeds as it can surprise. It does not eat animal food from choice, for when it has abundance of its favourite vegetable diet it will pass the carcass of a deer without touching it. It is rather a timid animal, and will seldom face a man unless it is wounded, or has its retreat cut off, or is urged by affection to defend its young. This bear when resident in the fur countries almost invariably hybernates, and about 1000 skins are annually procured by the Hudson's Bay Company from Black Bears destroyed in their winter retreats. It generally selects a spot for its den under a fallen tree, and, having scratched away a portion of the soil, retires to it at the commencement of a snow-storm, when the snow soon furnishes it with a close warm covering. Its breath makes a small opening in the den, and the quantity of hoar frost which occasionally gathers round the aperture serves to betray its retreat to the hunter. In more southern districts, where the timber is of a larger size, bears often shelter themselves in hollow trees. The Indians remark that a bear never retires to its den for the winter until it has acquired a thick coat of fat; and it is remarkable that when it comes abroad in the spring it is equally fat, though in a few days thereafter it becomes very lean. The period of the retreat of the bears is generally about the time when the snow begins to lie on the ground, and they do not come abroad again until the greater part of the snow is gone. At both these periods they can procure many kinds of berries in considerable abundance. In latitude 65° their winter repose lasts from the beginning of October to the first or second week of May; but on the northern shores of Lake Huron the period is from two to three months shorter. In very severe winters great numbers of bears have been observed to enter the United States from the northward. It is not however true that the Black Bears generally abandon the northern districts on the approach of winter, as has been asserted, the quantity of bear-skins procured during that season in all parts of the fur-countries being a sufficient proof to the contrary. The females bring forth about the middle of January; and it is probable that the period of their gestation is about 15 or 16 weeks, but it has not been precisely ascertained. The number of cubs varies from one to five, probably with the age of the mother, and they begin to bear long before they attain their full size.

It will be observed that the period of gestation attributed to the Brown Bear is seven months. Cuvier says that they couple in June, and produce their young in January. Sixteen weeks is the probable time allotted to the American Black Bear for the same purpose by Sir John Richardson, from whom we give the above account, and who had the best opportunities of collecting evidence on the subject. The bears kept in the fosse at Berne furnished the proof of gestation for seven months; but it is so characteristic of the family for the females to conceal themselves, that in a state of nature little evidence to be depended on for its accuracy can be obtained. "No man," according to Brickell, "either Christian or Indian, ever killed a she-bear with young;" and Sir John Richardson's numerous inquiries among the Indians of Hudson's Bay ended in the discovery of only one hunter who had killed a pregnant bear.

---

quoted are not genuine; but the expression 'non falsâ cruce' is pretty strong; and if the rest of the verses are allowed to be Martial's, there is no doubt that he here describes a real spectacle. Whichever be the truth, the horrible use to which these bears were occasionally put in the arena is but too evident.

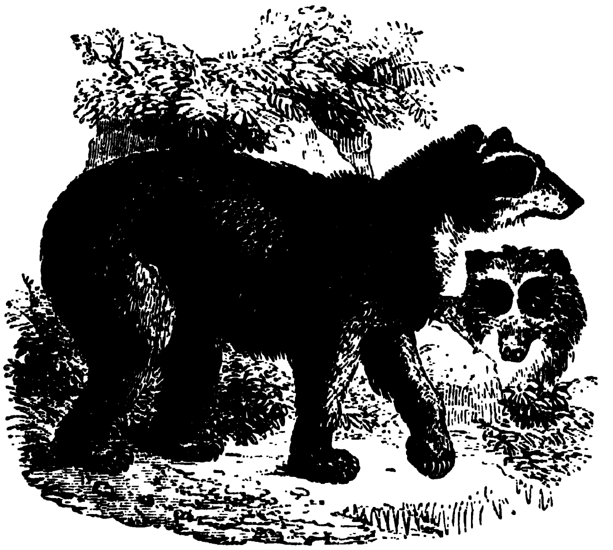
The value attached to the skin of the Black Bear—a value very much decreased, for the skin that once fetched from 20 to 40 guineas is now hardly worth more than from 20 to 60 shillings—and the high esteem in which the Indians held their flesh, caused great havoc among them. The importation into England in 1783 amounted to 10,500 skins, and ascended gradually to 25,000 in 1803, since which time there appears to have been a considerable decline, as in a table of exports and imports of skins in Great Britain, published in the Catalogue of the Great Exhibition (vol. ii., p. 529), the number of bear-skins is 9500; of these 8000 are again exported, so that the consumption in Great Britain is only 1500 annually. It is nevertheless used for military purposes in this country, as for caps, pistol-holsters, rugs, &c. It is hence called often the Army Bear.

The Black Bear is regarded with much superstition by the Indians. The following account is given by Mr. A. Henry :—"In the course of the month of January I happened to observe that the trunk of a very large pine-tree was much torn by the claws of a bear, made both in going up and down. On further examination I saw that there was a large opening in the upper part, near which the smaller branches were broken. From these marks, and from the additional circumstance that there were no tracks in the snow, there was reason to believe that a bear lay concealed in the tree. On returning to the lodge I communicated my discovery; and it was agreed that all the family should go together in the morning to assist in cutting down the tree, the girth of which was not less than three fathoms. The women at first opposed the undertaking, because our axes being only of a pound and a half weight were not well adapted to so heavy a labour; but the hope of finding a large bear, and obtaining from its fat a great quantity of oil, an article at the time much wanted, at length prevailed. Accordingly in the morning we surrounded the tree, both men and women, as many at a time as could conveniently work at it; and there we toiled like beavers till the sun went down. This day's work carried us about half-way through the trunk, and the next morning we renewed the attack, continuing it till about two o'clock in the afternoon, when the tree fell to the ground. For a few minutes everything remained quiet, and I feared that all our expectations would be disappointed; but as I advanced to the opening there came out, to the great satisfaction of all our party, a bear of extraordinary size, which I shot. The bear being dead all my assistants approached, and all, but particularly my old mother (as I was wont to call her), took the head in their hands, stroking and kissing it several times; begging a thousand pardons for taking away her life; calling her their relation and grandmother; and requesting her not to lay the fault upon them, since it was truly an Englishman that had put her to death. This ceremony was not of long duration, and if it was I that killed their grandmother they were not themselves behindhand in what remained to be performed. The skin being taken off, we found the fat in several places six inches deep. This being divided into two parts loaded two persons, and the flesh-parts were as much as four persons could carry. In all, the carcass must have exceeded five hundred-weight. As soon as we reached the lodge the bear's head was adorned with all the trinkets in the possession of the family, such as silver arm-bands, and wrist-bands, and belts of wampum, and then laid upon a scaffold set up for its reception within the lodge. Near the nose was placed a large quantity of tobacco. The next morning no sooner appeared than preparations were made for a feast to the manes. The lodge was cleaned and swept, and the head of the bear lifted up, and a new Stroud blanket which had never been used before spread under it. The pipes were now lit, and Wawatam blew tobacco-smoke into the nostrils of the bear, telling me to do the same, and thus appease the anger of the bear on account of my having killed her. I endeavoured to persuade my benefactor and friendly adviser that she no longer had any life, and assured him that I was under no apprehension from her displeasure; but the first proposition obtained no credit, and the second gave but little satisfaction. At length the feast being ready, Wawatam made a speech resembling in many respects his address to the manes of his relations and departed companions; but having this peculiarity, that he here deplored the necessity under which men laboured thus to destroy their friends. He represented however that the misfortune was unavoidable, since without doing so they could by no means subsist. The speech ended, we all ate heartily of the bear's flesh; and even the head itself, after remaining three days on the scaffold, was put into the kettle."

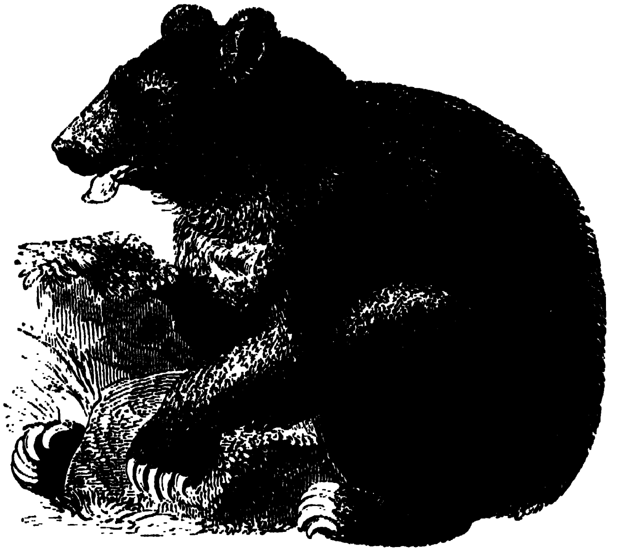
The Cinnamon Bear is a variety of this species. There is a specimen in the Zoological Gardens, Regent's Park, which was presented in 1829, so that he is now at least 24 years old. His mate died in 1849. The Yellow Bear of Carolina, and the Ours Gulaire (*Ursus gularis* of Geoffroy), with a white throat, are also varieties.

U. ornatus (F. Cuvier), the Spectacled Bear, inhabits the Cordilleras of the Andes in Chile. Its fur is smooth, shining, and black, with the following exceptions :—Its short muzzle is of a dirty yellow or buff colour, and there are two semicircular marks of the same hue, reminding the observer of a pair of spectacles, above the eyes; the under parts of the throat and neck and the upper part of the breast are whitish.

U. ferox (*Danis ferox*, Gray), the Grizzle Bear of Umfreville, Grisly Bear of Mackenzie, Grizzly Bear of Warden, *Ursus cinereus* of Desmarest, *Ursus horribilis* of Say, Meesheh Musquaw or Meechee Musquaw of the Cree Indians, and *Ursus ferox* (Lewis and Clarke, who first accurately described the animal, calling it often the White Bear), is nearly double the size of the Black Bear. Cuvier however, in spite of its size, regarded it as a variety of *U. Arctos*. Lewis and Clarke give the measurement of one as 9 feet from the nose to the tail, and state that they had seen one of larger dimensions. Eight hundred pounds is reported to be the weight to which it attains. The length of the fore foot in one of those measured by the travellers above quoted is given as exceeding 9 inches, that of the hind foot at 11¾ without the talons, and the breadth 7 inches. The claws of the fore feet, which are a good deal longer and less curved than those of the hind feet, measured in another individual more than 6 inches. This part of its organisation is well adapted for digging, but not for climbing, and the adult Grisly Bear is said not to ascend trees. The muzzle is lengthened, narrowed, and flattened, and the canine teeth are highly developed, exhibiting a great increase of size and power. The tail is very small, and so entirely lost in the hair which covers the buttocks, that it is a standing joke among the Indian hunters, as Sir John Richardson observes, when they have killed a Grisly Bear, to desire any one unacquainted with the animal to take hold of its tail. The fur, or rather hair is abundant, long, and varying through most of the intermediate gradations between grey and blackish brown, which last is prevalent and more or less grizzled. On the muzzle it is pale and short, on the legs it is darker and coarser. The eyes are small and rather sunk in the head.



Spectacled Bear (*Ursus ornatus*).



Grisly Bear (*Ursus ferox*).

Unwieldy as this animal appears, it is capable of great rapidity of motion, and its strength is overpowering. The bison contends in vain with the Grisly Bear. The conqueror drags the enormous carcass (weighing about 1000 lbs.) to a chosen place, digs a pit for its reception, and repairs to it till the exhausted store compels him to renew the chase. And yet he will be satisfied with fruits and roots; and on his diet depends the aggravated or mitigated ferocity of his disposition. This animal is very tenacious of life. The long claws are strung into necklaces, and highly prized by the Indians as trophies of their prowess.

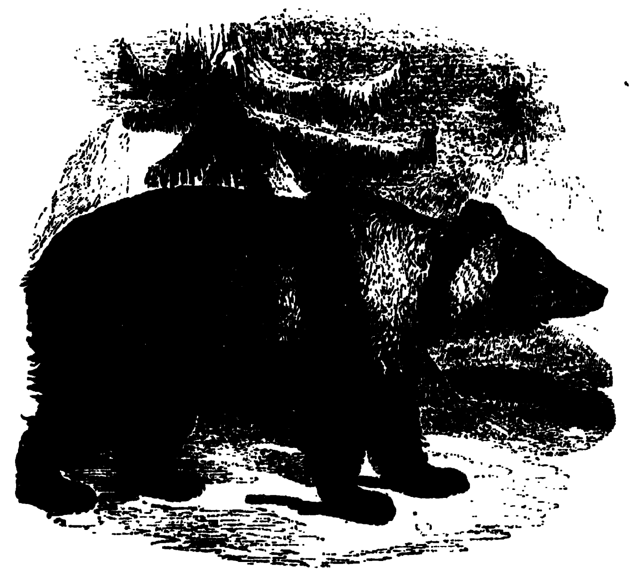
The following account of the habits of the Grisly Bear is given by Sir John Richardson:—"A party of voyagers who had been employed all day in tracking a canoe up the Saskatchewan had seated themselves in the twilight by a fire, and were busy in preparing their supper, when a large grisly bear sprang over the canoe that was tilted behind them, and seizing one of the party by the shoulder carried him off. The rest fled in terror, with the exception of a metif named Bourasso, who, grasping his gun, followed the bear as it was retreating leisurely with its prey. He called to his unfortunate comrade that he was afraid of hitting him if he fired at the bear, but the latter entreated him to fire immediately, without hesitation, as the bear was squeezing him to death. On this he took a deliberate aim, and discharged his piece into the body of the bear, who instantly dropped its prey to pursue Bourasso. He escaped with difficulty, and the bear ultimately retreated to a thicket, where it was supposed to have died; but the curiosity of the party not being a match for their fears the fact of its decease was not ascertained. The man who was rescued had his arm fractured, and was otherwise severely bitten, but finally recovered. I have seen Bourasso, and can add that the account which he gives is fully credited by the traders resident in that part of the country, who are best qualified to judge of its truth from their knowledge of the parties. I have been told that there is a man now living in the neighbourhood of Edmonton-house who was attacked by a grisly bear, which sprang out of a thicket, and with one stroke of its paw completely scalped him, laying bare the skull, and bringing the skin of the forehead down over the eyes. Assistance coming up, the bear made off without doing him further injury, but the scalp not being replaced the poor man has lost his sight, although he thinks his eyes are uninjured. Mr. Drummond, in his excursions over the Rocky Mountains, had frequent opportunities of observing the manners of the grisly bears, and it often happened that in turning the point of a rock or sharp angle of a valley he came suddenly upon one or more of them. On such occasions they reared on their hind legs, and made a loud noise like a person breathing quick, but much harsher. He kept his ground, without attempting to molest them; and they on their part, after attentively regarding him for some time, generally wheeled round and galloped off; though, from their known disposition, there is little doubt but he would have been torn in pieces had he lost his presence of mind and attempted to fly. When he discovered them from a distance he generally frightened them away by beating on a large tin-box in which he carried his specimens of plants. He never saw more than four together, and two of these he supposes to have been cubs; he more often met them singly, or in pairs. He was only once attacked, and then by a female, for the purpose of allowing her cubs to escape. His gun on this occasion missed fire, but he kept her at bay with the stock of it until some gentlemen of the Hudson's Bay Company, with whom he was travelling at the time, came up and drove her off. In the latter end of June, 1826, he observed a male caressing a female, and soon afterwards they both came towards him, but whether accidentally or for the purpose of attacking him he was uncertain. He ascended a tree, and as the female drew near fired at and mortally wounded her. She uttered a few loud screams, which threw the male into a furious rage, and he reared up against the trunk of the tree in which Mr. Drummond was seated, but never attempted to ascend it. The female in the meanwhile retiring to a short distance, lay down, and as the male was proceeding to join her Mr. Drummond shot him also. From the size of their teeth and claws he judged them to be about four years old. The cubs of a grisly bear can climb trees, but when the animal is fully grown it is unable to do so, as the Indians report, from the form of its claws."

The Rocky Mountains, and the plains to the eastward of them, particularly, according to Mr. Drummond, the districts which are interspersed with open prairies and grassy hills, are the chief haunts of the Grisly Bears. To the north they have been observed as far as 61° of latitude, and it is supposed that they are to be found still farther. To the south it is said that they extend as far as Mexico. There are three young specimens of this animal at present (1853) in the Gardens of the Zoological Society, Regent's Park.

Asiatic Bears.

Ursus collaris (F. Cuvier), the Siberian Bear, approaches closely to the Brown Bear (*Ursus Arctos*), and is at best a doubtful species. The hair in quality and colour is much the same with that of the Brown Bear, with the distinction of a large white collar which passes over the upper part of the back and the shoulders, and is completed upon the breast.

U. Thibetanus (*Helarctos Tibetanus*), the Tibet Bear.—M. Duvaucel discovered this species in the mountains of Sylhet, and Dr. Wallich found it in those of Nepaul. The Tibet Bear has the neck remarkably thick, and the head flattened, the forehead and muzzle forming almost a straight line. The ears are of a large size. Its clumsy limbs support a compact body, and the claws are comparatively weak. Its general colour is black; but the lower lip is white, and there is a large mark of the same colour, somewhat in the form of the letter Y, supposing the stem of the letter to be placed in the middle of the breast, and the forks to pass up in front of the shoulders. In bulk it is about intermediate between the Sloth Bear (*Prochilus labiatus*) and the Malayan Bear (*Ursus Malayanus*). Mr. Bennett, in his 'Tower Menagerie,' gives a figure and description of one which was brought from Sumatra, and could not be prevailed on to touch flesh either raw or cooked, bread and fruits forming his only food. In his disposition he was moderately tame, and particularly fond of play.



Siberian Bear (*Ursus collaris*).

U. Isabellinus, Isabella-coloured Bear.—Dr. Horsfield first described this species from a skin forwarded from the mountains of Nepaul. The skull had been removed, but the front teeth in both jaws and the claws remained.

Isabel Bear (*Ursus Thibetanus*).

"Our animal," says Dr. Horsfield, "is of a habit decidedly different from that of several species of *Ursus* from the same part of the world, which have been recently added to the systematic catalogues, namely, the *Ursus Thibetanus*, the *Ursus labiatus*, and the *Ursus Malayanus*. All these have a jet-black fur, a semilunar mark of a white colour on the breast, and other peculiarities affording types of sub-genera, among which *Prochilus* and *Helarctos* have been defined. Our animal, on the contrary, appears to resemble the European bears in its structure, as far at least as can be determined from the parts which have been preserved in the specimen. Among these, the claws afford the best means of comparison; they are small, obtuse, and straight, while those of the Asiatic bears above mentioned are large, strongly curved, acute, and fitted for climbing." A living specimen of this species is now to be seen in the Zoological Gardens, Regent's Park. It is a native of the whole Himalayan range, and is so light-coloured as to have led to the supposition that it was another form of the White Bear.

Ursus Syriacus, the Syrian Bear.—The she-bears which came out of the wood, "and tare forty and two" of the mockers of Elisha (2 Kings ii. 23, *et seq.*), are probably the first bears on record. These bears of Syria may be occasionally traced in subsequent history. Thus Matthew Paris, in his 'England,' relates how Godfrey (Dux Godefridus), as he was riding for recreation in a neighbouring wood during the siege of Antioch (*Antiochiam Minorem*), saw a poor stranger, who was loaded with a bundle of dry wood, flying from an enraged bear, whereupon Godfrey gallantly went to the rescue, and the bear turning upon him he was unhorsed, the horse being wounded by the bear, and fought on foot, when, after a severe struggle, in which he received a most dangerous wound ("vulnus fere letiferum"), he buried his sword up to the hilt in his savage adversary, and killed him. The historian, in continuation, relates the great joy of the army at Godfrey's recovery. ('Hist. of England,' tom. ii. p. 34, folio, London, 1640.)

Syrian Bear (*Ursus Syriacus*).

The Syrian Bear frequently preys on animals, but for the most part feeds on vegetables. The fields of *Cicer arietinus* (a kind of chick-pea), and other crops near the snowy region, are often laid waste by it.

The skin is sometimes fulvous brown, and, as has been stated, sometimes fulvous white, varied with fulvous spots. These changes are supposed to have been occasioned by the abrasion of the long hair, whereby the woolly fur beneath and that of the head become exposed. Two very fine specimens of this species, a male and female, are living in the Zoological Gardens, Regent's Park.

U. labiatus (*Melursus Lybius*, Meyer), Labiated Bear or Sloth Bear. This uncouth animal, on its arrival in Europe about sixty years ago, was taken for a Sloth and obtained the name of *Bradypus pentadactylus* and *Ursinus*, Five-Fingered Sloth, Sloth Bear, or Ursine Sloth. By the two last names it was formerly shown in menageries; and Bewick gave an excellent portrait of it in his 'Quadrupeds,' as "an animal which has hitherto escaped the attention of naturalists." Meyer called it a *Melursus*; and Fischer a *Chondrorhynchus*. It is the *Bradypus ursinus* of Shaw (though it bears no relation to the true sloths either in structure or habits); the *Ursus labiatus* of De Blainville; and the *Ursus longirostris* of Tiedemann; the Ours Paresseux and Ours Jongleur of the French. The short limbs, the depressed air of the head, surmounted by the hillock of a back, and the whole contour of the apparently unwieldy mass, give the idea of deformity, and make it a favourite with the Indian mountebanks or jugglers, who rely much on the attraction of its ugliness.

Sloth Bear (*Ursus labiatus*).

The cartilage of the nose is capable of extension, and the lips of considerable protrusion, as may be seen if the spectator hold a morsel of fruit or biscuit at a proper distance for exciting the animal to exert this faculty. The muzzle is elongated, and, with the ends of the feet, is whitish or yellowish. The forehead rises almost abruptly from the muzzle. The fur, with the exceptions above noticed and that next mentioned, is deep black, with here and there some brown spots, and is rather long, particularly round the head in old individuals. Upon the under side of the neck and breast is a white mark resembling the letters V or Y. In bulk it is about the size of the Brown Bear.

The food of this species in a state of nature is said to consist of fruits, honey, and the white ants, which are so destructive. It inhabits the mountainous parts of India, where its retreat is stated to be in some cavern. Major (now Colonel) Sykes noticed it in Dukhun (Deccan).

In captivity it appears to be mild, but melancholy. A pair were kept for some time in the garden of the Zoological Society. They lived very sociably, and often lay huddled together, uttering a kind of rattling but low whine, or purring, which was continuous and monotonous, but not entirely unmusical: indeed, by more than one who heard it, it was termed their song. The paw was generally at the mouth when they made this noise. A living specimen is still to be seen [illegible] the Zoological Gardens.

U. Malayanus, Raffles (*Helarctos Malayanus*, Horsfield), the Malay[illegible] Bear, the Bruang of the Malays, is jet-black, with the muzzle [illegible] a yellowish tint, and has a semilunar white mark upon the breast. Dr. Horsfield observes, that the largest prepared specimen which he had examined measured 4 feet 6 inches along the back.

Malayan Sun-Bear (*Ursus—Helarctus—Malayanus*).

The sagacity of the Malayan Bear is said to be great, and its liking for delicacies extreme. The honey of the indigenous bees of its native forests is supposed to be a favourite food; and certainly the extreme length of the tongue is well adapted for feeding on it. Vegetables form the chief diet of this bear, and it is said to be attracted to the vicinity of man by its fondness for the young shoots of the cocoa-nut trees, to which it is very injurious; indeed Sir Stamford Raffles found those of the deserted villages in the Passumah district of Sumatra destroyed by it. It has not unfrequently been taken and domesticated.

In confinement it is mild and sagacious. Sir Stamford Raffles thus describes the manners of one which appears to have been deservedly a great favourite:—

"When taken young," he says, "they become very tame. One lived for two years in my possession. He was brought up in the nursery with the children; and, when admitted to my table, as was frequently the case, gave a proof of his taste by refusing to eat any fruit but mangosteens, or to drink any wine but champagne. The only time I ever knew him to be out of humour was on an occasion when no champagne was forthcoming. It was naturally of an affectionate disposition, and it was never found necessary to chain or chastise him. It was usual for this bear, the cat, the dog, and a small blue mountain bird or lory of New Holland, to mess together, and eat out of the same dish. His favourite playfellow was the dog, whose teasing and worrying was always borne and returned with the utmost good humour and playfulness. As he grew up he became a very powerful animal, and in his rambles in the garden he would lay hold of the largest plantains, the stems of which he could scarcely embrace, nd tear them up by the roots."

There are several specimens in the gardens of the Zoological Society, Regent's Park.

U. Euryspilus (*Helarctos Euryspilus* of Horsfield), the Bornean Bear, differs from the Malayan Bear principally in having a large orange-coloured patch, deeply notched at its upper part, upon the chest. In size it is supposed to be rather less than the last. The individual which was exhibited in the Tower of London, and from which Dr. Horsfield wrote his description, measured along the back from muzzle to tail 3 feet 9 inches. It was obtained in Borneo when very young, and during the voyage was the constant associate of a monkey and other animals. In confinement its manners greatly resembled those of the Malayan Bear. Its habits in a state of nature do not appear to be known, but are most probably similar to those of the Malayan species. Dr. Horsfield, speaking of its habits in captivity, says—"The *Helarctos* readily distinguishes the keeper, and evinces an attachment to him. On his approach it employs all its efforts to obtain food, seconding them by emitting a coarse but not unpleasant whining sound. This it continues while it consumes its food, alternately with a low grunting noise; but if teased at this time, it suddenly raises its voice and emits at intervals harsh and grating sounds. Our animal is excessively voracious, and appears to be disposed to eat almost without cessation. When in a good humour, it often amuses the spectators in a different manner. Calmly seated in its apartment, it expands the jaws, and protrudes its long and slender tongue as above described. It displays on many occasions not only much gentleness of disposition, but likewise a considerable degree of sagacity. It appears conscious of the kind treatment it receives from its keeper. On seeing him it often places itself in a variety of attitudes to court his attention and caresses, extending its nose and anterior feet, or suddenly turning round exposing the back, and waiting for several minutes in this attitude with the head placed on the ground. It delights in being patted and rubbed, and even allows strangers to do so; but it violently resents abuse and ill treatment, and having been irritated, refuses to be courted while the offending person remains in sight."

Bornean Bear (*Ursus—Helarctos—Euryspilus*).

The individual whose manners are here described fell a victim to its voracity. During the hot weather of the summer of 1828 it overgorged itself one morning, and died within ten minutes after the meal. Its skin is preserved in the Museum of the Zoological Society.

African Bears.

The existence of bears in Africa has been more than doubted. Even Cuvier, who saw the weak points of the negative evidence on this subject, says, "the existence of bears in Africa is not so indisputable."

Pliny (viii. 36) observes, that it was recorded in the Annals that Domitius Ænobarbus, the curule Ædile, in the consulship of M. Piso and M. Messala (B.C. 62) exhibited a hundred Numidian Bears, and as many Æthiopian hunters in the circus, and adds his wonder that the bears should have been called Numidian, as it was evident that no bears were produced in Africa. In the 57th chapter of the same book he makes the broad assertion that in Africa there are neither boars, nor stags, nor goats, nor bears.

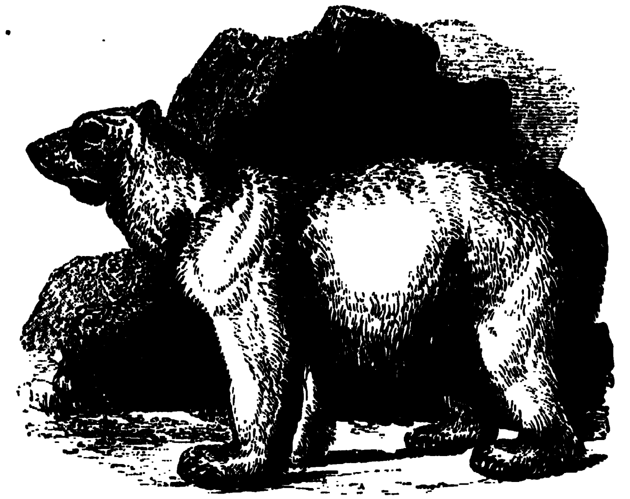
"Prosper Alpinus," says Cuvier, "attributes bears to Egypt, but which were assuredly no bears at all, for he states that they are of the size of a sheep, and of a white colour. Never did one of the naturalists of our expedition see there any true bears." Bruce says positively, that there is no bear in any part of Africa.

The inclination of Cuvier's mind, seems to have been against the existence of bears in Africa; and yet the record of the annalist quoted by Pliny, and the numerous passages concerning Lybian Bears in Herodotus, Virgil, Juvenal, Martial, and others, make a strong case for their existence.

It was reserved for Ehrenberg to solve these doubts in great measure. Writing on this subject, he says—"Moreover, we ourselves have seen in the mountains of Abyssinia, and therefore in Africa itself, an animal most like to a bear (nay, why had I not said—a bear?) and hunted it repeatedly, but in vain. It is called by the natives *Karrai*." He then goes on to state, that he can give to those who are interested in the geographical distribution of the bear, true tidings of a blackish plantigrade wild beast most like unto a bear, in the mountains of Abyssinia, though neither Bruce nor Salt make mention of it; and that, according to the description of the inhabitants, the mountains of Arabia Felix are inhabited by a similar or the same blackish bear, said to be remarkable for its lengthened muzzle. He adds, "Forskal moreover has brought tidings of an indigenous Arabian bear."

Marine Bear.

U. maritimus, Linn. (*Thalarctos maritimus*, Gray), the Polar Bear, or Ice Bear.—Martens was one of the first who distinguished this species from actual observation. The Brown Bear, as has been stated, appears to have been the only species known to Linnæus. It is not indeed till his 10th edition that he shows any suspicion that the Polar Bear was distinct; and in his last he only ventures to say, in a notice appended to the description of *Ursus Arctos*, "Ursus *maritimus* albus major arcticus. Martens. *Spitzb.* 73. t. o. f. c. forte distincta species est, nobis non visa, capite longiore, collo angustiore."



Polar Bear (*Ursus—Thalarctos—maritimus*).

The habits, and many parts of its organisation adapted to those habits, of the Polar or Sea Bear, l'Ours Polaire of the French, *Ursus maritimus* of Erxleben, *Ursus marinus* of Pallas, *Ursus albus* of Brisson, *Thalarctos maritimus* of Gray, according to the testimony of all zoologists, have confirmed the accuracy of Martens.

An inhabitant of the dreary regions which surround the North Pole with eternal frost, and of those coasts which are rarely free from ice, the Polar Bear is almost entirely carnivorous, in a state of nature. Animals of the land and of the sea, birds and their eggs, the dead and the living, are alike devoured. An admirable swimmer and diver, and of great strength, he chases the seal with success, and is said to attack the walrus itself. Cartwright relates an anecdote in proof of his agility in the water. He saw a Polar Bear dive after a salmon, and the bear dived with success, for he killed his fish. Captain Lyon gives the following account of its hunting the seal:—"The bear on seeing his intended prey, gets quietly into the water, and swims until to leeward of him, from whence, by frequent short dives he silently makes his approaches, and so arranges his distance, that at the last dive he comes to the spot where the seal is lying. If the poor animal attempts to escape by rolling into the water, he falls into the bear's clutches; if on the contrary he lies still, his destroyer makes a powerful spring, kills him on the ice, and devours him at leisure." The same author informs us that this bear not only swims with rapidity, but is capable of making long springs in the water. Sabine states that he saw one about midway between the north and south shores of Barrow's Straits, which are 40 miles apart, though there was no ice in sight to which he could resort for rest.

The floating carcasses of whales and other marine animals form a considerable part of its food, and the smell of the burning kreng often brings it to the whale ships. Sir John Richardson says, that it does not disdain, in the absence of other food, to seek the shore in quest of berries and roots. The Polar Bear moves faster on firm ground than might be supposed from his appearance. Captain Lyon describes its pace when at full speed, as "a kind of shuffle, as quick as the sharp gallop of a horse."

This species is of a more lengthened form than that of the others, the head is very much elongated and flattened, the ears and mouth comparatively small, the neck very long and thick, and the sole of the foot very large. The fur is silvery-white tinged with yellow, close short and even on the head, neck, and upper part of the back; long fine and inclined to be woolly on the hinder parts, legs, and belly. The sole of the foot exhibits a beautiful instance of adaptation of means to an end, for it is almost entirely covered with long hair, affording the animal a firm footing on the ice. The claws are black, not much curved, thick and short. Captain Lyon's crew found none of the terrible effects (skin peeling off, &c., &c.) from eating the flesh, ascribed to it by some of the earlier voyagers.

The accounts given of the size, strength, and ferocity of this animal by the early navigators are appalling; but the accuracy of modern investigation has dissipated a good deal of the awe with which it was regarded, and has gone far to prove, that the excited imagination of some of the narrators has led them beyond the truth.

The gallant adventurers who conducted the modern northern expeditions penetrated far beyond the points formerly reached, and had opportunities of observing numbers of Polar Bears. The greatest length from nose to tail, recorded by Captain Phipps, is 7 feet 1 inch, the weight of the beast being 610 pounds. Sir John Ross records the measurement of 7 feet 10 inches, and the weight of 1160 pounds; and Captain Lyon states, that one which was unusually large measured 8 feet 7¼ inches, and weighed 1600 pounds. The greater number of full grown individuals are spoken of as far inferior to these in dimensions and weight.

Two very fine specimens are at present living in the gardens of the Zoological Society, Regent's Park.

Pennant states that Polar Bears are frequent on all the Asiatic coasts of the Frozen Ocean, from the mouth of the Obi eastward, and that they abound in Nova Zembla, Cherry Island, Spitzbergen, Greenland, Labrador, and the coasts of Baffin's and Hudson's bays, but that they are unknown on the shores of the White Sea. Sir Edward Parry saw them within Barrow's Straits as far as Melville Island; and, during his daring boat-voyage, beyond 82° N. lat. Sir John Richardson says, that the limit of their incursions southward on the shores of Hudson's Bay and of Labrador, may be stated to be about the 55th parallel. Sir John Franklin learnt from the Esquimaux to the westward of Mackenzie River, that they occasionally, though rarely, visited that coast. Captain Beechey did not meet with any in his voyage to Icy Cape.

As the Polar Bear resides principally on the fields of ice, he is frequently drifted far from the land. "In this way," says Sir John Richardson, "they are often carried from the coast of Greenland to Iceland, where they commit such ravages on the flocks that the inhabitants rise in a body to destroy them."

The Esquimaux account of the hybernation of this species is thus related by Captain Lyon:—

"At the commencement of winter the pregnant she-bears are very fat, and always solitary. When a heavy fall of snow sets in, the animal seeks some hollow place in which she can lie down, and then remains quiet while the snow covers her. Sometimes she will wait until a quantity of snow has fallen, and then digs herself a cave: at all events, it seems necessary that she should be covered by and lie amongst snow. She now goes to sleep, and does not wake until the spring sun is pretty high, when she brings forth her two cubs. The cave, by this time, has become much larger, by the effect of the animal's warmth and breath, so that the cubs have room enough to move, and they acquire considerable strength by continually sucking. The dam at length becomes so thin and weak, that it is with great difficulty she extricates herself, when the sun is powerful enough to throw a strong glare through the snow which roofs the den. The Esquimaux affirm, that during this long confinement the bear has no evacuations, and is herself the means of preventing them by stopping all the natural passages with moss, grass, or earth. The natives find and kill the bears during their confinement by means of dogs, which scent them through the snow, and begin scratching and howling very eagerly. As it would be unsafe to make a large opening, a long trench is cut, of sufficient width to enable a man to look down, and see where the bear's head lies, and he then selects a mortal part into which he thrusts his spear. The old one being killed, the hole is broken open, and the young cubs may be taken out by hand, as, having tasted no blood, and never having been at liberty, they are then very harmless and quiet. Females which are not pregnant roam throughout the whole winter in the same manner as the males. The coupling time is in May."

That part of these accounts which relates to the non-hybernation of some of these bears is corroborated by Sir Edward Parry, who saw them roaming in the course of the two winters which he passed on the coast of Melville Peninsula.

That the Polar Bear will subsist on vegetable diet was proved in the case of two which lived and throve for years in the French menagerie without being allowed to touch animal food. The individual kept in the Tower in the reign of Henry III. seems to have been indulged in diet and recreation more congenial to its habits, for there are two of the king's writs extant in choice Latin, directing the sheriffs of London to furnish four-pence a day for "our white bear in our Tower of London, and his keeper," and to provide a muzzle and iron-chain to hold him when out of the water, and a long and strong rope to hold him when he is fishing in the Thames. (Madox, 'Exchequer Writs.')

Fossil Bears.

The fossil remains of these animals, when first found, ministered, as might have been expected from the spirit of the age, to the speculations of the lovers of the marvellous, and figured in the medical prescriptions of the time. The caverns of the neighbourhood of the Harz were ransacked for them; and their supposed virtue as medicines, under the title of fossil Unicorns' Bones, procured a ready sale. In the 'Protogæa' of Leibnitz, there is a figure of one of these fossil unicorns, the product of an imagination sufficiently lively.

But it was not till the year 1672, as Cuvier observes, that any notice, truly osteological, appeared on the subject, when Hayn gave some representations of their bones brought from a cave of the Carpathians, as those of dragons; and, by way of helping the evidence, informed his readers that there were still to be found in Transylvania dragons alive and flying.

These were the remains of the extinct Bear of the Caves (*Ursus spelæus*), an animal which must have been the largest species of the genus. Rosenmüller, in 1794 and 1795, gave the figure of a cranium from Gailenreuth; and John Hunter, in the 'Philosophical Transactions' (1794), described the bones found there; and the Margrave of Anspach the caves.

Blumenbach distinguished the skulls found in the caverns as those of two distinct species, and gave them severally the names of *Ursus spelæus* and *Ursus arctoideus*, which Cuvier adopted, expressing however his opinion that they were only varieties of the same species. Goldfuss described a species as *U. priscus* from the same remains.

The principal caverns in which these remains have been found are those of Scharzfeld and Baumann, the latter of which owes its name (Baumann's Höhle) to a wretched miner, who in 1670 lured by the hope of finding ore sought its recesses. There he wandered, alone and in darkness, three days and three nights. At length he found his way out, but in so exhausted a condition, that he only returned to the light of day to die.

The caverns of the Carpathians supplied the dragons' bones above mentioned.

In Franconia, near Muggendorf, the caves are numerous, and abound in bones. Here are the caverns of Gailenreuth, Rabenstein, Kühloch, &c.

The south-west border of the Thuringerwald has those of Glücksbrunn and Leibenstein, near Meinungen, and Westphalia those of Klüterhöhle and Sundwick.

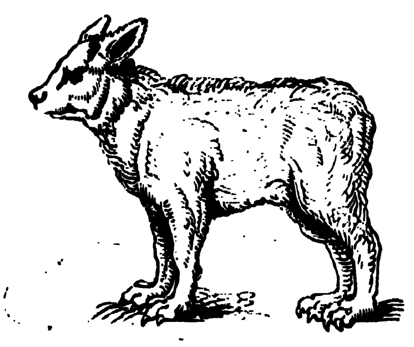
In England the remains of Bears have been found in the largest numbers in Kent's Hole, near Torquay. They have also been found in Tertiary deposits at Grays in Essex, Bacton in Norfolk, in the valley of the Severn near Tewkesbury, the Manea Fen in Cambridgeshire, at Newbourn in Suffolk, and in other places. Professor Owen, in his 'History of British Fossil Mammals,' refers these remains to *U. Arctos*, *U. priscus*, and *U. spelæus*. He doubts the existence of the fossil species *U. arctoideus* and *U. planus*. Dr. Buckland ('Reliquiæ Diluvianæ') thus describes the scene in the cavern of Kühloch:—"It is literally true, that in this single cavern (the size and proportions of which are nearly equal to those of the interior of a large church) there are hundreds of cart-loads of black animal dust, entirely covering the whole floor, to a depth which, if we multiply this depth by the length and breadth of the cavern, will be found to exceed 5000 cubic feet. The whole of this mass has been again and again dug over in search of teeth and bones, which it still contains abundantly, though in broken fragments. The state of these is very different from that of the bones we find in any of the other caverns, being of a black, or, more properly speaking, dark umber-colour throughout, and many of them readily crumbling under the finger into a soft dark powder, resembling mummy powder, and being of the same nature with the black earth in which they are imbedded. The quantity of animal matter accumulated on this floor is the most surprising and the only thing of the kind I ever witnessed; and many hundred, I may say thousand, individuals must have contributed their remains to make up this appalling mass of the dust of death. It seems, in great part, to be derived from comminuted and pulverised bone; for the fleshy parts of animal bodies produce, by their decomposition, so small a quantity of permanent earthy residuum, that we must seek for the origin of this mass principally in decayed bones. The cave is so dry, that the black earth lies in the state of loose powder, and rises in dust under the feet: it also retains so large a proportion of its original animal matter, that it is occasionally used by the peasants as an enriching manure for the adjacent meadows." The following is added by Dr. Buckland in a note:—"I have stated, that the total quantity of animal matter that lies within this cavern cannot be computed at less than 5000 cubic feet. Now, allowing two cubic feet of dust and bones for each individual animal, we shall have in this single vault the remains of at least 2500 bears, a number which may have been supplied in the space of 1000 years, by a mortality at the rate of 2½ per annum."

The remains of *Ursus spelæus* have been found near Steyer, in Upper Austria. Necker de Saussure found them also in the clefts of the rocks containing iron ore at Kropp, in Carniola.

The remains of bears have been detected generally in the ossiferous caverns of the south of France. The bones found in the largest proportion at the Grotte d'Echenoz, on the south of Vesoul, by M. Thirria, and examined by Cuvier, were those of *Ursus spelæus*. Bones of bears have been also found in the osseous breccia at Pisa, Nice, &c.

Ursus spelæus (Blumenbach), Great Cavern Bear. The skull of this extinct species is considerably raised above the root of the nose, so that the forehead, which presents two convex elevations, is a good deal curved. Its size is about one-fifth larger than the largest of those of the Brown Bear (*Ursus Arctos*), or of the Polar Bear.

U. priscus (Goldfuss), has a smaller skull, and differs less from the crania of living bears than that of the preceding species.



We ought not perhaps to conclude this article without referring to those hybrids which were supposed to be the offspring engendered between a dog and a bear. Even at the present day there is an inclination to believe in the existence of such animals, but we need hardly observe that it is extremely improbable, to use no stronger term, that two animals differing so widely in their dentition and general structure, in the periods of gestation and in their habits, should produce a mule. An account of such a creature is given in the 'Histoires Prodigieuses extraictes de plusieurs Fameux Auteurs, Grecs et Latins, sacrez et prophanes, divisées en Cinq Tomes, le Premier par P. Boaistuau, Tome Premier, Paris, 1582.' A drawing of the animal is also given, of which we present a copy.

This animal the author states he saw in England in the reign of Elizabeth, but the probability is that the author was deceived by the English bear-wards and dog-fighters of Elizabeth's time, and that some dog, selected for its bear-like appearance in certain points, an appearance aided by cropping the ears and tail, and other skilful artifices, was palmed upon him and upon others as a hybrid engendered between a dog and a bear.

BEAR-BERRY. [ARCTOSTAPHYLOS.]

BEAR'S FOOT. [HELLEBORUS.]

BEARDIE. [COBITIS.]

BEAUMONTITE, a mineral, a hydrous crenato-silicate of Copper, containing 15·8 per cent. of crenic acid. It is of a bluish-green to greenish-white colour, and pulverulent when dry. It is found at Chessy, dep. of Rhône, in France. (Dana, *Manual of Mineralogy*.)

BEAVER, the English name for the genus *Castor* (Cuvier), one of the order of rodent or gnawing animals (*Rodentia*, Cuvier, *Glires*, Linnæus), with 2 incisors, or cutting teeth, and 8 molars in each jaw, 20 in all; and particularly distinguished from all the rest of that order by a broad horizontally-flattened tail, which is nearly oval, and covered with scales. There are five toes on each of the feet, but those of the hinder ones only are webbed, the webs extending beyond the roots of the nails. The second toe of these last is furnished with a double nail, or rather with two, one like those of the other toes, and another beneath it, situated obliquely with a sharp edge directed downwards. There is also, as Sir John Richardson observes, a less perfect double nail on the inner toe of the hind feet.

The incisor teeth of the Beaver are broad, flattened, and protected anteriorly by a coat of very hard orange-coloured enamel, the rest of the tooth being of a comparatively soft substance, whereby a cutting chisel-like edge is obtained; and indeed, no edge tool, with all its combinations of hard and soft metal, could answer the purpose better. In fact, the beaver's incisor tooth is fashioned much upon the same principle as that followed by the tool-maker, who forms a cutting instrument by a skilful adaptation of hard and soft materials till he produces a good edge.

But the natural instrument has one great advantage over the artificial tool; for the former is so organised that as fast as it is worn away by use a reproduction and protrusion from the base takes place, and thus the two pairs of chisel-teeth working opposite to each other are always kept in good repair, with their edges at the proper cutting angle. When injury or disease destroys one of these incisors, its antagonist, meeting with no check to resist the protrusion from behind, is pushed forward into a monstrous elongation. So hard is the enamel, and so good a cutting instrument is the incisor tooth of the Beaver, that when fixed in a wooden handle, it was, according to Sir John Richardson, used by the Northern Indians to cut bone, and fashion their horn-tipped spears, &c., till it was superseded by the introduction of iron, when the beaver-tooth was supplanted by the English file.

The power of these natural tools is well described by Lewis and Clarke, who saw their effects on the banks of the Missouri. "The ravages of the beaver," say they, "are very apparent; in one place the timber was entirely penetrated for a space of three acres in front on the river, and one in depth, and great part of it removed, although the trees were in large quantities, and some of them as thick as the body of a man."

Sir John Richardson thus speaks of this part of their operations:—"When the beaver cuts down a tree it gnaws it all round, cutting it however somewhat higher on the one side than the other, by which the direction of its fall is determined. The stump is conical, and of such a height as a beaver sitting on his hind quarters could make. The largest tree I observed cut down by them, was about the thickness of a man's thigh (that is 6 or 7 inches in diameter), but Mr. Graham says that he has seen them cut down a tree which was 10 inches in diameter." Beavers have no canine teeth.

Castor Fiber of Linnæus (*Castor Americanus* of F. Cuvier), the American Beaver, is the animal of whose sagacity, and even social polity, such wonderful tales have been told. The best account of this animal is that given by Hearne:—

American Beaver (*Castor Fiber*).

"The beaver," he says, "being so plentiful, the attention of my companions was chiefly engaged on them, as they not only furnished delicious food, but their skins proved a valuable acquisition, being a principal article of trade, as well as a serviceable one for clothing. The situation of the beaver-houses is various. Where the beavers are numerous they are found to inhabit lakes, ponds, and rivers, as well as those narrow creeks which connect the numerous lakes with which this country abounds; but the two latter are generally chosen by them when the depth of water and other circumstances are suitable, as they have then the advantage of a current to convey wood and other necessaries to their habitations, and because, in general, they are more difficult to be taken than those that are built in standing water. They always choose those parts that have such a depth of water as will resist the frost in winter, and prevent it from freezing to the bottom. The beavers that build their houses in small rivers or creeks, in which water is liable to be drained off when the back supplies are dried up by the frost, are wonderfully taught by instinct to provide against that evil by making a dam quite across the river, at a convenient distance from their houses. The beaver-dams differ in shape according to the nature of the place in which they are built. If the water in the river or creek have but little motion the dam is almost straight; but when the current is more rapid it is always made with a considerable curve, convex towards the stream. The materials made use of are drift-wood, green willows, birch, and poplars, if they can be got; also mud and stones intermixed in such a manner as must evidently contribute to the strength of the dam; but there is no other order or method observed in the dams, except that of the work being carried on with a regular sweep, and all the parts being made of equal strength. In places which have been long frequented by beavers undisturbed, their dams, by frequent repairing, become a solid bank, capable of resisting a great force both of water and ice; and as the willow, poplar, and birch generally take root and shoot up, they by degrees form a kind of regular planted hedge, which I have seen in some places so tall that birds have built their nests among the branches.

"The beaver-houses are built of the same materials as their dams, and are always proportioned in size to the number of inhabitants, which seldom exceeds four old and six or eight young ones; though by chance I have seen above double the number. Instead of order or regulation being observed in rearing their houses, they are of a much ruder structure than their dams; for, notwithstanding the sagacity of these animals, it has never been observed that they aim at any other convenience in their houses than to have a dry place to lie on; and there they usually eat their victuals, which they occasionally take out of the water. It frequently happens that some of the large houses are found to have one or more partitions, if they deserve that appellation, but it is no more than a part of the main building left by the sagacity of the beaver to support the roof. On such occasions it is common for those different apartments, as some are pleased to call them, to have no communication with each other but by water; so that in fact, they may be called double or treble houses, rather than different apartments of the same house. I have seen a large beaver-house built in a small island that had near a dozen apartments under one roof; and, two or three of these only excepted, none of them had any communication with each other but by water. As there were beavers enough to inhabit each apartment, it is more than probable that each family knew their own, and always entered at their own doors, without any further connection with their neighbours than a friendly intercourse, and to join their united labours in erecting their separate habitations, and building their dams where required. Travellers who assert that the beavers have two doors to their houses, one on the land side and the other next the water, seem to be less acquainted with these animals than others who assign them an elegant suite of apartments. Such a construction would render their houses of no use, either to protect them from their enemies, or guard them against the extreme cold of winter.

"So far are the beavers from driving stakes into the ground when building their houses, that they lay most of the wood crosswise, and nearly horizontal, and without any other order than that of leaving a hollow or cavity in the middle. When any unnecessary branches project inward they cut them off with their teeth, and throw them in among the rest, to prevent the mud from falling through the roof. It is a mistaken notion that the wood-work is first completed and then plastered; for the whole of their houses, as well as their dams, are, from the foundation, one mass of mud and wood mixed with stones, if they can be procured. The mud is always taken from the edge of the bank, or the bottom of the creek or pond near the door of the house; and though their fore paws are so small, yet it is held close up between them under their throat: thus they carry both mud and stones, while they always drag the wood with their teeth. All their work is executed in the night, and they are so expeditious that in the course of one night I have known them to have collected as much as amounted to some thousands of their little handsful. It is a great piece of policy in these animals to cover the outside of their houses every fall with fresh mud, and as late as possible in the autumn, even when the frost becomes pretty severe, as by this means it soon freezes as hard as a stone, and prevents their common enemy, the wolverene, from disturbing them during the winter; and as they are frequently seen to walk over their work, and sometimes to give a flap with their tail, particularly when plunging into the water, this has without doubt given rise to the vulgar opinion that they use their tails as a trowel, with which they plaster their houses; whereas that flapping of the tail is no more than a custom which they always preserve, even when they become tame and domestic, and more particularly so when they are startled.

"Their food consists of a large root, something resembling a cabbage-stalk, which grows at the bottom of the lakes and rivers. [*Nuphar lutea*, according to Sir J. Richardson, the common yellow water-lily.] They also eat the bark of trees, particularly those of the poplar, birch, and willow; but the ice preventing them from getting to the land in the winter, they have not any barks to feed on in that season, except that of such sticks as they cut down in summer, and throw into the water opposite the doors of their houses; and as they generally eat a great deal, the roots above mentioned constitute a principal part of their food during the winter. In summer they vary their diet by eating various kinds of herbage, and such berries as grow near their haunts during that season. When the ice breaks up in the spring the beavers always leave their houses, and rove about until a little before the fall of the leaf, when they return again to their old habitations, and lay in their winter-stock of wood. They seldom begin to repair their houses till the frost commences, and never finish the outer coat till the cold is pretty severe, as hath been already mentioned. When they erect a new habitation they begin felling the wood early in the summer, but seldom begin to build until the middle or latter end of August, and never complete it till the cold weather be set in.

"Persons who attempt to take beaver in winter should be thoroughly acquainted with their manner of life, otherwise they will have endless trouble to effect their purpose, because they have always a number of holes in the banks, which serve them as places of retreat when any injury is offered to their houses, and in general it is in those holes that they are taken. When the beavers which are situated in a small river or creek are to be taken, the Indians sometimes find it necessary to stake the river across, to prevent them from passing; after which they endeavour to find out all their holes or places of retreat in the banks. This requires much practice and experience to accomplish, and is performed in the following manner:—Every man being furnished with an ice-chisel, lashes it to the end of a small staff about four or five feet long; he then walks along the edge of the banks, and keeps knocking his chisel against the ice. Those who are acquainted with that kind of work well know by the sound of the ice when they are opposite to any of the beavers' holes or vaults. As soon as they suspect any, they cut a hole through the ice big enought to admit an old beaver, and in this manner proceed till they have found out all their places of retreat, or at least as many of them as possible. While the principal men are thus employed, some of the understrappers and the women are busy in breaking open the house, which at times is no easy task, for I have frequently known these houses to be 5 or 6 feet thick, and one in particular was more than 8 feet thick in the crown. When the beavers find that their habitations are invaded, they fly to their holes in the banks for shelter; and on being perceived by the Indians, which is easily done by attending to the motion of the water, they block up the entrance with stakes of wood, and then haul the beaver out of its hole, either by hand, if they can reach it, or with a large hook made for that purpose, which is fastened to the end of a long stick. In this kind of hunting, every man has the sole right to all the beavers caught by him in the holes or vaults; and as this is a constant rule, each person takes care to mark such as he discovers by sticking up a branch of a tree, by which he may know them. All that are caught in the house are the property of the person who finds it. The beaver is an animal which cannot keep under water long at a time, so that when their houses are broken open, and all their places of retreat discovered, they have but one choice left, as it may be called, either to be taken in their house or their vaults; in general they prefer the latter, for where there is one beaver caught in the house, many thousands are taken in the vaults in the banks. Sometimes they are caught in nets, and in summer very frequently in traps.

"In respect to the beavers dunging in their houses, as some persons assert, it is quite wrong, as they always plunge into water to do it. I am the better enabled to make this assertion from having kept several of them till they became so domesticated as to answer to their name, and follow those to whom they were accustomed in the same manner as a dog would do, and they were as much pleased at being fondled as any animal I ever saw. In cold weather they were kept in my own sitting-room, where they were the constant companions of the Indian women and children, and were so fond of their company that when the Indians were absent for any considerable time, the beaver discovered great signs of uneasiness, and on their return showed equal marks of pleasure by fondling on them, crawling into their laps, lying on their backs, sitting erect like a squirrel, and behaving like children who see their parents but seldom. In general during the winter they lived on the same food as the women did, and were remarkably fond of rice and plum-pudding; they would eat patridges and fresh venison very freely, but I never tried them with fish, though I have heard they will at times prey on them. In fact there are few graminivorous animals that may not be brought to be carnivorous."

Mr. Broderip, in his 'Note-Book of a Naturalist,' p. 1, gives an interesting account of the manners and habits of a pet Beaver during its captivity. It manifested the same instincts, though exercised upon very different materials, as those described so graphically in the above passage from Hearne.

Little need be said of the value of the fur of the Beaver in commerce, a value greatly heightened by the proclamation of Charles I. in 1638, expressly prohibiting the use of any materials except beaver-stuff or beaver-wool in the manufacture of hats, and forbidding the making of the hats called 'demi-castors,' unless for exportation. This proclamation was an almost exterminating death-warrant to the poor beavers. They were speedily swept away from the more southern colonies, and the traffic became for the most part confined to Canada and Hudson's Bay. The havoc made amongst them, even at that period, may be imagined by an inspection of the imports of 1743. In that year the Hudson's Bay Company offered for sale 26,750 beaver-skins, and in the same year 127,080 were imported into Rochelle. These, it will be remembered, are only the legal returns, making no allowance for smuggling. In 1788 upwards of 170,000 were exported from Canada, and in 1808 126,927 were sent from Quebec alone to this country. The value of those last has been estimated at 118,994*l.* 1*s.* 3*d.* sterling, at an average of 18*s.* 9*d.* for each skin. Those numbers, as might be expected, could not be kept up without almost total extermination; and we find, accordingly, that in 1827 the importation into London from a fur country of more than four times the extent of that which was occupied in 1743 was but little beyond 50,000. At the present time (1853) about 60,000 beaver-skins are annually imported into this country, of which 12,000 are again exported. Many other materials are now employed for making hats.

The Beaver, although some have considered it another species, is an inhabitant of Europe. The earliest notice of the European Beaver (*κάστωρ*) is in Herodotus (book iv. c. 109), who describes it as inhabiting a large lake in the country of the Budini, a nation whom he places on the east side of the Upper Don (iv. 21). He says that the skin was used for clothing. Aristotle (book viii. c. 5) mentions the European

Beaver under the name of *κάστωρ*, but only mentions it; while Pliny (viii. 30, and xxxii. 3, &c.) well describes it, and is diffuse on the subject of the celebrated Castoreum, so much valued as a medicine among the ancients, and which long held a high place in the Materia Medica of the moderns, causing the persecution of this unfortunate animal before its fur became an object of traffic. Pliny points out the frauds of dealers, but shows that he did not know what the castoreum really was. "Castorea testes eorum," writes Pliny (book xxxii. c. 3), and the ancients inform us that the animal used to bite off the part when hunted, well knowing that with the possession of the desired castorea the persecution would cease. This however is untrue, as it would be utterly impossible for the animal to do so if it wished. Cuvier gives the following account of the organs which secrete this substance:—"De grosses poches glanduleuses qui aboutissent à leur prépuce produisent une pommade d'une odeur forte, employée en médicine sous le nom de castoreum." Sir John Richardson thus speaks of this substance: "I have not had an opportunity of dissecting a beaver, but I was informed by the hunters that both males and females are furnished with one pair of little bags containing castoreum, and also with a second pair of smaller ones betwixt the former and the anus, which are filled with a white fatty matter, of the consistence of butter and exhaling a strong odour. This latter substance is not an article of trade; but the Indians occasionally eat it, and also mingle a little with their tobacco when they smoke. I did not learn the purpose that this secretion is destined to serve in the economy of the animal; but from the circumstance of small ponds when inhabited by beavers being tainted with its peculiar odour, it seems probable that it affords a dressing to the fur of these aquatic animals. The castoreum in its recent state has an orange-colour, which deepens as it dries into bright reddish-brown. During the drying, which is allowed to go on in the shade, a gummy matter exudes through the sack, which the Indians delight in eating. The male and female castoreum is of the same value, ten pairs of bags of either kind being reckoned to an Indian as equal to one beaver-skin. The castoreum is never adulterated in the Fur Countries."

The same traveller says that the call of the beaver in the pairing season is a kind of groan, and gives the following as the dimensions of a full-grown beaver killed at Great Slave Lake, and now in the museum of the Zoological Society:—

	Inches.	Lines.
Length of head and body	40	0
„ head alone	7	3
„ tail, scaly part	11	6
Distance from tip of nose to anterior part of eye	2	10
Distance from the posterior part of the orbit to anterior part of the ear	2	5

He also gives the following account of the flesh, which, as much has been said of its delicacy as food, is interesting:—"The flesh of the beaver is much prized by the Indians and Canadian Voyageurs, especially when it is roasted in the skin, after the hair has been singed off. In some districts it requires all the influence of the fur trader to restrain the hunters from sacrificing a considerable quantity of beaver fur every year to secure the enjoyment of this luxury; and Indians of note have generally one or two feasts in the season, wherein a roasted beaver is the prime dish. It resembles pork in its flavour, but the lean is dark-coloured, the fat oily, and it requires a strong stomach to sustain a full meal of it. The tail, which is considered a great luxury, consists of a gristly kind of fat, as rich but not so nauseating as the fat of the body."

Pennant says that the geographical range of the American Beaver commences in latitude 60° or about the River of Seals, in Hudson's Bay, and terminates in latitude 30° in Louisiana; but Say places their limit at the confluence of the Ohio and Mississippi, about seven degrees farther to the northward of Pennant's southern boundary. Richardson observes that their most northern point is probably on the banks of the Mackenzie (the largest American river that falls into the Polar Sea, and the best wooded, owing to the quantity of alluvial soil by which it is bordered), as high as 67½° or 68° N. lat.; and that they extend east and west from one side of the continent to the other, with the exception of the barren districts. He further states that they are pretty numerous to the northward of Fort Franklin, and that, from the swampy and impracticable nature of the country, they are not likely to be soon eradicated there.

The following varieties of the American Beaver have been noticed:—

Var. α. *C. F. nigra*, the Black Beaver.

Var. β. *C. F. varia*, the Spotted Beaver. They have a large white spot on their breasts.

Var. γ. *C. F. alba*, the White Beaver. This variety is an albino.

The Little Beaver is the *Castor Zibethicus* of Linnæus, *Fiber Zibethicus* of Cuvier, *Ondatra* of Lacépède, the Musk-Rat of Canada, and Musquash of the Cree Indians. [MUSQUASH.]

F. Cuvier has pointed out some slight differences in the skulls of the European and American beavers which he had examined for the purpose of showing that they are distinct. Baron Cuvier, in the last edition of his 'Règne Animal,' expresses his uncertainty, notwithstanding scrupulous comparison, whether the beavers which live in burrows along the banks of the Rhône, the Danube, the Weser, and other rivers, are especially different from those of America, or whether their vicinity to man is the cause that hinders them from building. He does not appear to have been aware of the colony described by M. de Meyerinck in the 'Transactions of the Berlin Natural History Society' for 1829, as having been settled for more than a century on the small river Nuthe, a short distance above its confluence with the Elbe in a lonely canton of the Magdeburg district. This little association, it appears, amounted in 1822 to 15 or 20 individuals only; but they were co-operative and industrious beyond what might have been expected from their numbers. Burrows of thirty or forty paces in length on a level with the river, having one opening beneath the surface and another on land; huts eight or ten feet high, formed of branches and trunks of trees laid irregularly and covered with earth; and a dyke of the same materials, so well wrought that it raised the water more than a foot, were the results of the persevering and ingenious labours of the little band.

The American Beaver near the settlements at the present day is sad and solitary like the European Beaver; his works have been swept away, his associations broken up, and he burrows in the same manner. Such beavers are called Terriers. Pennant indeed mentions them as a variety which wants either the sagacity or the industry of others; but he is much nearer the truth when he says, in the same paragraph, "Beavers which escape the destruction of a community are supposed often to become Terriers." They are also called Old Bachelors.

The following anecdote, related by Geoffroy St. Hilaire in the 12th volume of the 'Mémoires du Muséum d'Histoire Naturelle,' shows that the European Beaver has the same sagacity as its transatlantic brethren. One of these beavers from the Rhône was confined in the Paris menagerie. Fresh branches were regularly put into his cage, together with his food, consisting of legumes, fruits, &c., to amuse him during the night, and minister to his gnawing propensity. He had only litter to shield him from the frost, and the door of his cage closed badly. One bitter winter-night it snowed, and the snow had collected in one corner. These were all his materials, and the poor beaver disposed of them to secure himself from the nipping air. The branches he interwove between the bars of his cage, precisely as a basket-maker would have done. In the intervals he placed his litter, his carrots, his apples, his all, fashioning each with his teeth so as to fit them to the spaces to be filled. To stop the interstices he covered the whole with snow, which froze in the night, and in the morning it was found that he had thus built a wall which occupied two-thirds of the doorway.

That the Beaver was formerly an inhabitant of the British Islands there is no doubt. Giraldus Cambrensis gives a short account of their manners in Wales; but, even in his time (he travelled there in 1188), they were only found on the river Teify. "Two or three waters in that principality," says Pennant, "still bear the name of Llyn yr Afange, or the Beaver Lake. * * * I have seen two of their supposed haunts; one in the stream that runs through Nant Francon, the other in the river Conwy, a few miles above Llanrwst; and both places, in all probability, had formerly been crossed by beaver-dams. But we imagine they must have been very scarce even in earlier times. By the laws of Howelda the price of a beaver's skin was fixed at 120 pence—a great sum in those days."

The Beaver also appears to have existed in Scotland. Boethius enumerates the Beavers, 'fibri,' among the animals which abounded in and about Loch Ness, and whose furs were in request for exportation towards the end of the 15th century. Dr. Walker, in his 'Mammalia Scotica,' states, on the authority of Giraldus, that Beavers formerly existed in Scotland. Tradition refers the name and arms of the town of Beverley in Yorkshire to the fact of Beavers having abounded in the neighbouring river Hull. (Owen, 'British Fossil Mammals.')

Fossil Beavers.

M. Gothelf de Fischer was the first to announce the existence of the remains of an extinct animal allied to the Beaver. These remains, consisting of a fossil cranium, were discovered on the sandy borders of the Sea of Azof. Cuvier admitted the specific distinctness of this animal, and adopted the name *Castor trogontherium*. Professor Owen, in his history of 'British Fossil Mammals,' describes the structure of the teeth in this animal from a specimen in the collection of John Hunter in the Royal College of Surgeons of England, which was found in Walker's Cliff, Norfolk, and from a specimen in the possession of Sir Charles Lyell found in the Norwich Crag at Cromer. From an examination of these specimens Professor Owen was enabled to add considerably to the details of our knowledge of the structure of this animal. On this ground he proposes to constitute for this species a new subgenus, and to call it *Trogontherium Cuvieri*. From the character of the remains of the *Trogontherium*, Professor Owen concludes that it must have been much larger than the European Beaver. That the European Beaver is distinct, and not the degenerate descendant of the great *Trogontherium*, is proved by the fact that the remains of beavers in no respect differing either in size or in anatomical characters from the *Castor Fiber* of the present day co-existed with the *Trogontherium*.

Remains of the Common Beaver have been discovered by Mr. Green, in company with the extinct Mammoth, in the lacustrine formations at

Bacton. Remains of the Beaver have also been found in the cliffs at Mundesley, and in the oyster-bed at Happisburg in Norfolk; also in the fluvio-marine crag at Thorpe in Suffolk, and from a formation earlier still in the fluvio-marine crag at Sizewell Gap near Southwold, Suffolk. M. Fischer also received the remains of another Beaver with those of *Trogontherium* from near the lake of Rostoff, in the department of Jarosslow, and which he called *Trogontherium Werneri*, but which Cuvier recognised as the remains of the Common Beaver.

BECCAFI'CO, the Italian name for *Beccafigo*, or Fig-Eater; *Becfigue* of the French; *Ficedula* of the Romans; and Συκαλὶς of the Greeks. Prince Bonaparte, in his 'Specchio Comparativo,' observes that this name is applied to different birds of the genus *Sylvia* (Sylvan Warblers), whenever they are fat, and in a good state for the table. They are generally fruit-eaters in the season; but the true *Beccafico*, with its 'carne squisita,' is, according to the Prince, the *Sylvia hortensis* of Bechstein. [SYLVIA.]

BECHERA, a genus of Fossil Plants proposed by Count Sternberg. *Bechera Charæformis* occurs in the strata of Coalbrookdale. In this genus Sternberg included the *Gyrogonites*, or fossil *Charæ* of the Tertiary Strata of the Isle of Wight.

BECKER, or *Braize*, a Fish. [PAGRUS.]

BEDSTRAW. [GALIUM.]

BEE, the name common to all the species of a very numerous tribe of Insects of the order *Hymenoptera*.

In England alone about 250 species have been discovered. Kirby, in his beautiful monograph, 'Apum Angliæ,' divides them into two great groups—*Apis* and *Melitta*, which differ principally in the proboscis. In *Apis* the tongue (*fig.* 3, *c*), or central part of the proboscis, is generally long, and the proboscis itself has two joints, one near the base, and another about the middle; that at the base directing it outwards, and that in the middle directing it inwards: when folded, the apex of the tongue points backwards. In *Melitta* the tongue (*fig.* 1, *a*) is short, and the proboscis has but one fold, which is near the base; and when folded the apex of the tongue points forwards. These two groups are also subdivided by Kirby, and the character of each subdivision is given in detail; but he did not think proper to give names to these smaller groups. It has however since been thought necessary to consider the smaller groups as genera; and hence they have all been named, the greater portion of them by Latreille. When the smaller groups were considered genera, the greater ones became families, and are named *Apidæ* and *Andrænidæ* by Dr. Leach.

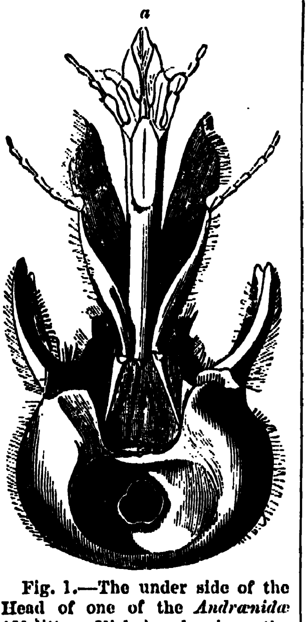


Fig. 1.—The under side of the Head of one of the *Andrænidæ* (*Melitta*, Kirby), showing the proboscis. *a*, the tongue.

The species of *Andrænidæ*, which are very abundant during the spring months, frequent grassy banks; the males are generally seen flying about hedges. The females usually construct their nests underground; for which purpose they generally select a bank in a southern aspect: some species choose sandy situations, while others prefer a heavier soil. The female having fixed upon a convenient spot, excavates a cylindrical hole, from five or six inches to a foot in depth, and only just large enough to allow her to enter; at the bottom it is slightly increased in width, and rendered smooth by being lined with a glutinous substance. The labour of forming these cells is considerable, for the soil is removed grain by grain, and deposited round the entrance of the hole, so that a little hillock is formed. The cell being completed, her next object is to furnish it with pollen; this is collected from flowers, and carried on the tibiæ of the hinder legs, which are thickly furnished with tolerably long hair, among which the pollen is carried until she arrives at the cell. When a sufficient quantity of pollen is collected, and made into a kind of paste by the addition of a portion of honey, it is formed into a little ball, in which an egg is deposited; the mouth of the cell is then carefully closed, to prevent the entrance of other insects. The egg soon hatches, and becomes a larva, which feeds upon the pollen until it is all consumed; the larva then turns to a pupa, and the pupa to the perfect insect. It is remarkable that the *Andrænidæ* seldom make their appearance after the spring months and early part of the summer, although the eggs laid at that time have undergone all their metamorphoses (in many instances) by the autumn. The newly-disclosed insect remains all the intermediate time in a torpid state. We believe that the [illegible] done by a sp[illegible]

The habits of the species of *Apidæ* are more variable: many excavate their cells in wood; some, like the cuckoo, make use of the nests of other species; others again do not excavate cells, but make use of any hole already formed, or of some other situation convenient for that purpose. Of this last description a species of the genus *Anthidium* has afforded a remarkable instance. This bee is nearly the size of the Hive-Bee, but is broader in proportion, and is easily distinguished from all the hitherto-discovered British species, by having a series of bright yellow spots on each side of the abdomen. A female of this species has been known to build her nest in the lock of a garden gate. The nest consists of a number of cells formed of down collected from the *Anemone sylvestris*, and probably from other woolly-leaved plants, scraped off by the bee with its jaws.

The flight of this insect is exceedingly swift; but when it has discovered a flower on which it intends to settle (generally that of the blind nettle), it stops suddenly, poises itself in the air for a few seconds, and then darts upon the flower, dislodging any bee which may have settled upon it before.

Sometimes it appears more anxious to dislodge other bees, and to prevent their gathering honey, than to collect for itself, for it flies about from flower to flower, and pounces upon all it meets with.

Anthophora retusa is another bee, which in its flight very much resembles the one just described. This bee is considerably larger than the Hive-Bee: the male is brown, sometimes inclining to an ochre colour, and is remarkable for the three long tufts of hair which are attached to the middle leg, two of them to the tip of the tibiæ (that on the posterior part being very long), and another to the tip of the tarsus. The female of this species is so much unlike the male, that it has been thought by many to be a distinct species. It is entirely black, except the outer side of the hinder tibiæ, which is covered with red hairs: it is without the tufts on the intermediate leg. This species constructs its cells in the sides of banks, generally choosing those which are perpendicular.

It is to this same family that the Hive-Bee belongs, to the history and economy of which we shall confine ourselves.

The *Apis mellifica*, Hive-Bee, or Honey-Bee, has for many ages justly claimed the attention and study of naturalists. Among the earliest of its observers may be enumerated Aristotle and Virgil; also Aristomachus of Soli in Cilicia, and Philiscus the Thasian. Aristomachus, we are told by Pliny, attended solely to bees for fifty-eight years; and Philiscus, it is said, spent the whole of his time in forests, investigating their habits. (Plin. xi. 9.) Both these observers wrote on the Bee. In modern times the labours of Swammerdam, Réaumur, Bonnet, Schirach, Thorley, Hunter, Huber, and others, have added greatly to our knowledge of this interesting species.

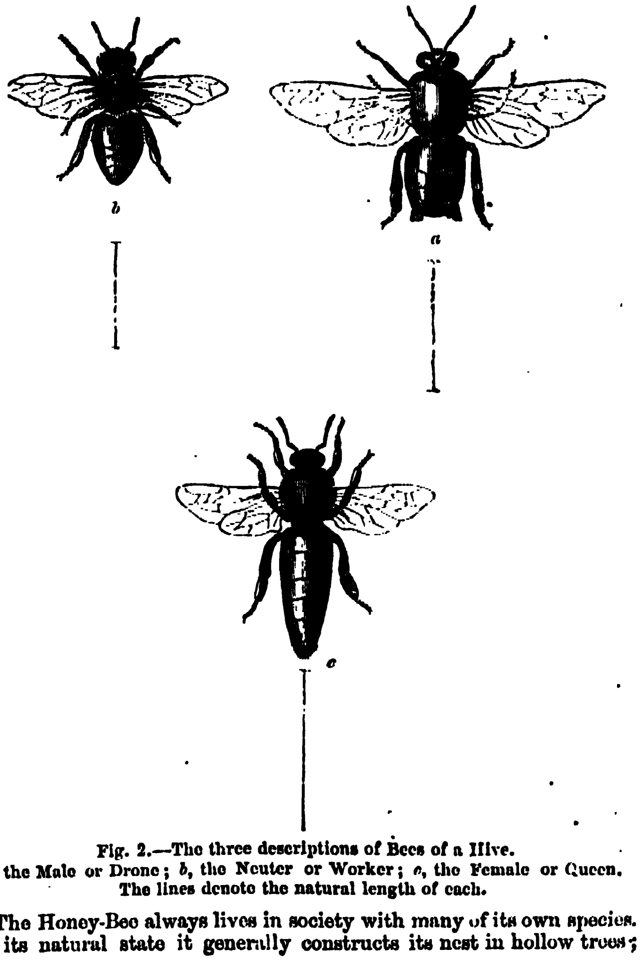

Fig. 2.—The three descriptions of Bees of a Hive.
a, the Male or Drone; *b*, the Neuter or Worker; *c*, the Female or Queen.
The lines denote the natural length of each.

The Honey-Bee always lives in society with many of its own species. In its natural state it generally constructs its nest in hollow trees;

but throughout Europe it is now rather a rare occurrence to find it otherwise than domesticated.

Each society or swarm is composed of three descriptions of Bees—the Male, or Drone; the Neuter, or Worker; and the Female, or Queen.

The *Drone*, or *Male Bee*, in general form, is almost cylindrical, the separation between the thorax and abdomen being much less distinct than in the females or neuters. The head is large, rather narrower than the thorax: the eyes are very large, and meet at the vertex of the head, but divide as they approach the forehead; close to the point of separation there are three stemmata. The antennæ are 13-jointed. The thorax is thickly covered above and beneath with short pale brown hairs resembling velvet. The length of the abdomen is scarcely greater than is its breadth, and it is terminated obtusely: it has only four segments visible from the upper side, the anal segments being hidden beneath the others. The basal and apical segments are each thickly covered with pale hairs. The colour of the abdomen is black above, having the edge of each segment of a light brown colour; the underside of the body is also pale. The legs are black; the inner side of the hinder legs is covered with pale down. All the claws are divided, the inner part being nearly equal in length to the outer part. The wings are large, and rather longer than the body; the anterior wings are rather acute at the apex.

The Drone may be readily distinguished from the queen and workers by its greater breadth, large eyes (which meet at the top of the head), and the abdomen having only four segments visible from the upper side. The wings are much longer in proportion than those of the worker or the queen, for in this sex they reach beyond the extremity of the abdomen.

The number of drones in a hive is remarkably irregular, varying from 600 or 700 to 2000; but the proportion is nôt regulated by the number of bees contained in the hive, for a small swarm will sometimes possess as many drones as a large one.

The time required to complete the metamorphosis of the drone is as follows. In three days after the deposition of the egg the larva makes its appearance: about the middle of the seventh day from this time, the larva, having then arrived at its full growth, spins its cocoon, a silken substance with which it lines the interior of its cell: this is accomplished in about a day and a half. It then turns to the pupa, and ultimately to the perfect insect, having been about 24 days from the laying of the egg to the coming forth in the winged state.

The *Neuter*, or *Worker*, is of a dark-brown colour, approaching to black; the head and thorax resemble those of the female, but the head has black hair on the vertex. The abdomen is conical, and composed of six distinct segments: the basal one is thickly covered with hair, the other segments are sparingly clothed. The legs are black: the plantæ of the hinder legs are transversely striated on the inner side. The wings when closed nearly reach to the apex of the abdomen.

In about four days after the egg of the Worker has been deposited the larva is hatched, and in five or six days more (according to the weather) it is full grown; it is then sealed up in its cell by the nurse bees with a covering of farina mixed with wax. As soon as the larva is inclosed it spins its cocoon, which operation requires about 36 hours: it then turns to the pupa, and in about eight days more to the perfect insect; having been 21 days in existence, that is, from the time the egg was laid until the insect has attained its perfect state. The numbers of workers in a well-stocked hive is about 15,000 or 20,000. The occupation of these bees is to collect honey, pollen, and propolis; to build the combs, and to attend upon the young.

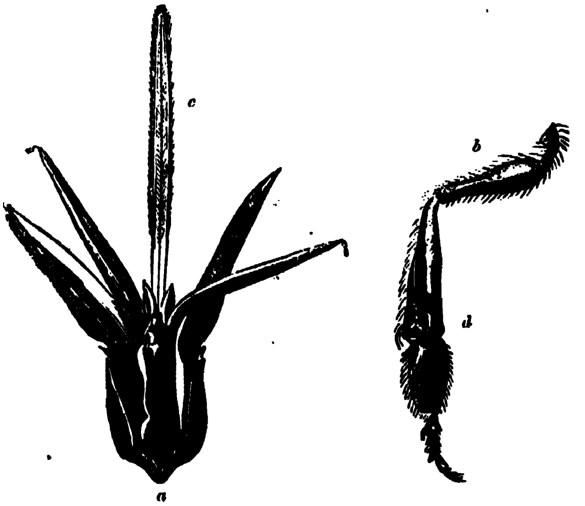

Fig. 3.—*a*, the proboscis of the Hive-Bee; *c*, the tongue; *b*, the hinder leg of the Worker-Bee; *d*, the part on which the pollen is carried.

Honey is collected by means of the proboscis. To a common observer this instrument appears to be a single tube, through which it is thought the honey is conveyed to the stomach by suction; but if we examine the proboscis through a lens of very moderate power, we find that it is composed of five very distinct parts, a central stalk and four lateral ones, two on each side. The central part is that which is principally used in collecting honey: this part is not perforated, but is a flat cartilaginous substance, and is used as a tongue in lapping up the honey, which is then conveyed to the pharynx, and is afterwards disgorged into the cells of the comb, part being used for the purpose of feeding the young, and the remainder stored up for the winter's consumption.

Pollen is collected from the anthers of flowers, and is carried on the outer surface of the tibiæ, or middle joint of the hinder leg: this part of the leg is very broad; on one side it is concave, and furnished with a series of strong curved hairs on its margins, forming a natural basket admirably adapted to the purpose for which it is used. This substance mixed with honey forms the food of the larvæ, for which purpose alone it is collected.

In many instances it is only by the bees travelling from flower to flower that the pollen or farina is carried from the male to the female flowers, without which they would not fructify. One species of bee would not be sufficient to fructify all the various sorts of flowers, were the bees of that species ever so numerous, for it requires species of different sizes and different constructions. "M. Sprengel found, that not only are insects indispensable in fructifying different species of *Iris*, but that some of them, as *I. Xiphium*, require the agency of the larger humble bees, which alone are strong enough to force their way beneath the stile flag; and hence, as these insects are not so common as many others, this *Iris* is often barren, or bears imperfect seeds."

Propolis is a resinous unctuous substance, of a reddish colour, and is collected from the buds of trees: it is not only used in lining the cells of a new comb, but it is sometimes kneaded with wax and used in rebuilding weak parts. It is also used in stopping all the crevices in the interior of a hive. The workers which arrive laden with this substance are relieved of their burden by others; these in their turn distribute it among many, who employ it for the purposes above mentioned.

Nature has provided checks to prevent the too rapid increase of the various species of insects. Among those of the Hive-Bee, the hornet and wasp, and two or three species of moths, commit great devastation. Wasps frequently take possession of a hive, and after destroying, or causing their weaker neighbours to desert the hive, consume all the honey it contains, and sometimes even construct their own nests in the hive. *Acherontia atropos*, the Sphinx, or the Death's-Head Hawk-Moth, which is almost as large as our common bat, sometimes makes its way into hives, and consumes much of the bees' stores. This insect has the power of emitting a peculiar sound, not unlike that of the queen-bee: this sound is supposed to have the same effect (that of rendering the workers motionless) as that emitted by the queen.

Two other moths commit great devastation in hives: these are small species (*Galleria alvearia*, and *G. melonella*—the Honey-Moth, and the Honeycomb-Moth, which, in spite of the guards constantly kept at the entrance of hives, gain admittance, and deposit their eggs in the combs. The larvæ hatched from these eggs form passages through the comb in all directions, spinning a silken tube as they proceed, which it appears is too strong for the bees to destroy, and of course they cannot sting the larvæ. These larvæ generally oblige the bees to desert the hive after a short time.

In attending upon the young the labour of the workers appears to be divided: a certain number always remain brooding over the cells and feeding them, while others are employed in collecting honey. It is these last that are the principal secreters of wax, and are called Wax-Workers: the former are called Nurse-Bees.

The *Queen-Bee* is of a dark-brown colour: the head is thickly furnished with yellow hairs, except on the forehead, where the hair is nearly black; on the vertex there are three small convex simple eyes, or stemmata. The antennæ are yellow beneath and brown above, and composed of twelve joints, the basil joint is more than one-third of the whole length, the remaining joints are bent forwards, and at an angle with the first. The thorax is covered with pale-brown hairs. The abdomen is the shape of an elongated cone, and nearly smooth, exhibiting six distinct segments above: the under side of the body and the base of each segment above are of a paler colour than the remaining parts. The legs are of a brownish yellow: the femora and tibiæ of the anterior legs and the base of the femora of the posterior legs are brown. All the claws of the tarsi are divided, the inner division being much shorter than the outer one. The wings are short and small in proportion, scarcely reaching more than half the length of the abdomen.

This sex is furnished with a bent sting; in the neuter the sting is straight; the male has no sting. The Queen-Bee resembles the worker in the shape of the head and thorax; but the great length of the abdomen and the paler colour of the legs and antennæ are its chief distinguishing characteristics. There is but one queen in a hive, who is treated with the greatest attention by all the other bees. It might be wondered how they can distinguish the queen from any other bee, the interior of the hive being quite dark: in this the antennæ are their sole guide, for if the workers be prevented touching her occasionally with the antennæ they proceed as if she were lost. This has been satisfactorily proved by some ingenious experiments by Huber. If by accident the Queen be killed, or if she die, her dead body is still treated with attention, and for a time even preferred to any other queen.

The Queen being accidentally or intentionally removed from a hive, her absence is soon discovered and great disorder follows; but this is only temporary, for in a few hours preparation is made to replace her loss. The larvæ of neuters from two to three days old are selected for this purpose: the cells containing them are each enlarged by sacrificing three adjoining cells, and in this space the workers build a cylindrical tube which surrounds the young larvæ, which are then supplied with the same food as that given to the ordinary royal larvæ, and which is more pungent than that given to common larvæ. In about three days' time a perpendicular tube is constructed and joined to the mouth of the cell just described; into this the larva gradually makes its way, moving in a spiral direction. It then remains two days in a perpendicular position, the head being downwards, after which it turns to the pupa and then to a queen. As several hatch nearly at the same time, the strongest stings the others to death, and becomes ruler of the hive. From this it is evident that the worker-bees are imperfect females, requiring only a slight difference of treatment in the larva state to become queens or fertile females.

If the Queen be removed from a hive, and a stranger be immediately introduced, she is surrounded and kept prisoner until she dies of hunger; for the workers never sting a Queen. If, however, 18 hours have elapsed since the loss of the former queen, the stranger is better received, for although she is at first surrounded, she is ultimately set at liberty, and treated with all the usual attention; but if 24 hours have elasped before the strange queen be introduced, she is at once admitted to the sovereignty of the hive.

While the Queen remains in a hive, the introduction of a strange queen will occasion a disturbance, somewhat similar to that which takes place when two or three young queens escape from their cells at the same time: both the stranger and the reigning queen are surrounded by the workers, and the escape of either being thus prevented, they are soon brought into contact. A battle ensues, which ends in the death of one of them, and the other then becomes ruler of the hive.

The sole occupation of the Queen is to lay eggs in the various cells prepared by the workers for that purpose, for she takes no care of the young herself. Until she is about eleven months old, the eggs laid are nearly all such as will turn to workers, but at the completion of that period, which most frequently happens in the spring time, the queen commences the great laying of the eggs of males; at this time the queen will lay from 2000 to 3000 eggs, sometimes from 40 to 50 a day being laid during the months of March and April. There is also another laying of the eggs of males in the autumn, but this is not so considerable. In the interval, the eggs of workers are almost exclusively laid.

There seems to be a relation between the laying of the eggs of males and the construction of royal cells, for the workers always commence the construction of the latter at the time that the female is laying the eggs that are to turn to drones.

The royal cells are very different from those of the male or worker, and are generally suspended from the edges or sides of the comb: their number varies from two or three to twenty, though the latter is a very unusual number. In form they are very much like a pear, having the thickest end joined to the comb, the other end, at which part the mouth or entrance of the cell is situated, hanging downwards.

In these cells the queen deposits the eggs of future queens, at intervals of at least a day, and always during the period of laying the eggs of males. When the Queen is about to lay, she thrusts her head into a cell to ascertain its fitness; she then inserts her abdomen, and in a few seconds withdraws it, leaving an egg at the bottom of the cell fixed in an upright position by a glutinous substance at one of its ends.

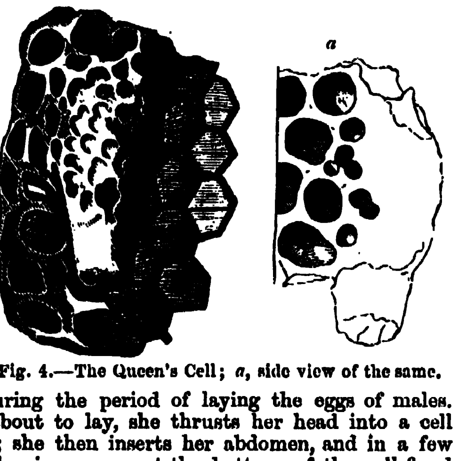

Fig. 4.—The Queen's Cell; *a*, side view of the same.

The egg is about one-twelfth of an inch long, and of a cylindrical form, with rounded ends. When the larva emerges from the egg, it is immediately supplied with food by the nurse-bees. This larva may be seen lying in a curved position at the bottom of the cell, where it continues to grow until it has completely filled up the space; when it is full grown it lies horizontally with its head towards the entrance. The food given to the larva is a mixture of farina, honey, and water, which is converted into a whitish jelly by elaboration in the stomachs of the nurse-bees: the proportions of farina and honey vary according to the age of the young, and we believe that the food is not given directly to the larva, but disgorged into the cell, so that the insect is surrounded with it. But when the larva is nearly full grown, its food is sweeter (probably containing a greater proportion of honey), and is applied by the nurse-bees directly to its mouth, somewhat in the manner of a bird feeding its young.

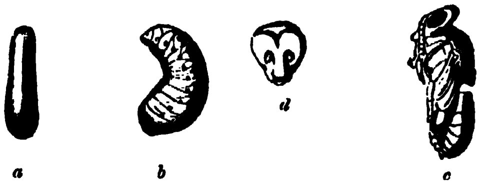

Fig. 5.—*a*, the Egg; *b*, the Larva; *c*, the Pupa of the Worker-Bee; and *d*, the head of the Larva magnified.

The drone and worker-bees are of a grayish colour when they first leave their cells, and several days elapse before they are strong enough to fly; but the queen is kept prisoner in her cell for some time after she has assumed the imago state. The reasons for this imprisonment we shall presently show.

When the larvæ in the queens' cells are about to change into pupæ the old queen begins to exhibit signs of agitation—running carelessly over the cells, occasionally thrusting her abdomen into some of them as if about to lay, but withdrawing without having done so, or perhaps laying them on the side of the cell instead of at the bottom. She is no longer surrounded by her usual circle of attendants, and her agitation being communicated to all she passes, at length a general confusion is created, till at last the greater portion of the bees rush out of the hive with that queen at their head. It is thus that the first swarm quits the hive, and it is invariably conducted by the old queen.

At any other time the queen would have been unable to fly, the great number of eggs contained in her abdomen rendering her too heavy; this however is sufficiently reduced after the great laying just described to enable her to fly with ease.

An unerring instinct obliges the Queen to leave the hive at this time, for two sovereigns never can co-exist in the same community; and had she not left it the young queens (now just about to quit their cells) would inevitably have been killed by her. Let us now observe what is going on in the hive which has just been deserted by its queen. It would seem as if it were too much reduced by the departure of the swarm, but it must be borne in mind that this event never occurs except in the middle of the day and during very fine sunny weather, when a large portion of the bees are abroad gathering honey and pollen; and if the hive contain a numerous colony, these on their return, together with those which have not been disturbed during the general confusion, and a considerable number of young brood continually hatching, form a sufficient stock, and perhaps even enough to send off another swarm.

In two or three days' time from the leaving of the first swarm perfect order is restored in the hive, and the nurse-bees continue to attend upon the young, carefully watching the queens' cells, and working at the outsides by removing the wax from the surface. It is said that the wax is removed in order to facilitate the exit of the young queen; but although the removal of it may thus be of service, we are not inclined to think it is done for that purpose.

The eggs are laid in the royal cells at intervals of at least a day, and it consequently follows that the completion and closing of these cells must take place at different times: we say completion, for at the time the queen lays the eggs the cells are only half formed, and resemble the cup of an acorn. When the cells have been closed about seven days the young queen cuts away with her jaws the part of the silken covering at the mouth of the cell, and if permitted would make her escape; but the bees guarding the cells solder the covering with some particles of wax, and keep her prisoner about two days, in which time she obtains sufficient strength to be able to fly immediately on quitting her prison. It is difficult to imagine by what means the bees guarding the royal cells can judge of the fitness of the inclosed female for liberation. The most probable conjecture is, that they judge by the quality of the sound emitted by the prisoner at this time. This sound consists of a number of monotonous notes so rapidly repeated as almost to appear one continuous sound. The sound is produced by the vibration of the wings, and probably becomes sharper and more audible as the bee acquires strength.

The young queen upon being liberated immediately approaches the remaining royal cells, and would destroy their contents by tearing them open and mortally wounding her rivals with her sting; but this is not permitted, for so long as there is a sufficient number of guards they bite and drive her away. She has the power however of arresting this ill-treatment for awhile by emitting a peculiar sound, which has such an effect on the sentinels that they remain motionless; and she sometimes takes advantage of this to make an attack upon the royal cells. But as the sound ceases when she moves the charm is dissolved, her guards recover their power, and she is again driven back.

After a time the young queen, owing to her strong desire to attack the royal cells and the constant repulses she meets with, becomes extremely agitated, and by running quickly over the cells and groups of workers communicates her disorder to a great portion of the bees, so that a large number quit the hive and cluster about the outside, and after a short time the young queen leaves the hive with a swarm. Thus it is that the second swarm is thrown off. It seldom happens that a hive sends off more than two or three swarms; after which, unless the hive be an extremely populous one, there are so few bees left that there is not a sufficient number to keep proper guard over the royal cells. The young queens consequently make their escape, two or three at a time, in which case a contest takes place between them, and the strongest remains queen of the hive, after destroying all the royal larvæ and pupæ that remain.

But if the hive be an unusually populous one there may be four or five swarms sent off, all accompanied by the same circumstances as those just related. In case a hive is poorly stocked at the time of the great laying of male eggs no royal cells are built, and consequently no swarms leave. After the swarming a general massacre of the drones takes place: these defenceless individuals (for the male has no sting) are stung to death by the neuters.

When a swarm quits a hive it usually clusters on a tree or bush in the neighbourhood, and if it be not hived it will shortly leave this situation, and take possession of an old tree or part of an old building. It is said that bees send out scouts before leaving the hive to search for a convenient situation for their new abode, and that they may be seen going backwards and forwards to the spot fixed upon some little time before the swarm departs. The clustering of the swarm probably proceeds from a desire in the bees to be congregated together prior to their last flight. As soon as the bees have taken possession of a new abode, or have been hived, they commence building the comb.

It has been stated that the first swarm is always conducted by an old queen, and the following swarms by the young queens as they are successively hatched. The latter are in a virgin state, but not so the former, nor do these require farther intercourse with the male. About two or three days after quitting her cell, and the fifth day of her existence in the winged state, the young queen quits the hive, and after reconnoitring its exterior and making herself acquainted with its situation by flying from it and returning several times, she then soars high in the air, forming spiral circles as she ascends. This ascent is generally preceded by a flight of drones, and it is at this time (whilst on the wing) that the sexual intercourse takes place. The queen is never observed to quit the hive but at this time, and hence it is supposed that this one intercourse is sufficient to fertilise all the eggs she may ever lay. Huber decidedly ascertained that it was sufficient for two years. We think it very improbable that a queen would live much beyond that time. In about 46 hours after the intercourse with the male has taken place, at which time a part of the comb would be constructed in the new hive, the queen commences laying her eggs; those first deposited being such as will turn to workers, as before described.

The Construction of the Comb.—In the 'Introduction to British Entomology' by Kirby and Spence, after referring to the various accounts of ancient and modern writers on this subject, it is observed, "Still the construction of the comb of the bee-hive is a miracle which overwhelms our faculties." John Hunter, who was the first to discover the true origin of wax, imagined that the waxen scales (which we shall hereafter mention) bore some proportion to the different parts of the cells in the formation of which they were used, and thus furnished a guide to their construction. Some naturalists have conjectured that the antennæ, mandibles, and other parts of the body were used to measure the work, and from this they have endeavoured to account for the accuracy of their proceedings. The latter conjecture appears incompatible with instinct, while the well-authenticated mode of proceeding in the construction of the comb throws great doubt on the former.

Upon examination of various combs, the partitions between all the ordinary cells (both at the sides and bottoms) are found to be exactly the same in thickness, and the cells hexagonal with angular bottoms. Exceptions to this general rule are occasionally found, and it is by observing these exceptions with attention—by observing the various modifications of the work under extraordinary circumstances, that some idea of the principles which guide the bee in its operations may be formed. The royal cell is a remarkable exception; its form we have already described. In the original construction of this cell, a profusion of material is always disposed of, particularly at the junction of the cell with the comb. The extra quantity of wax in this part, and on the surface of the cell (which is also unusually thick) is, however, soon reduced by numerous circular excavations, the depth of which varies according to that of the wax, and in the mass nearest the comb they actually become cells, though in most instances unfit for use. These cells are invariably cylindrical, with concave bottoms, except they come in contact with others, in which case the wax is always removed from the interstices thus formed, either at the sides or at the bottoms; and the partitions are thus reduced to the same thickness as those between the cells constructed in the ordinary way. Hence we frequently find, in these parts, cells with one side circular and the other angular; the situation of the angles being invariably determined by the position of those cells with which they are in contact.

To work in circles or segments of circles appears most compatible with animal mechanism acted upon by instinct, for we observe that the works of almost all insects (perhaps we may say almost all animals) proceed in circles or segments of circles. The cells of almost all the various species of bees are of this construction, and we find that, under peculiar circumstances, those of the hive-bee are so likewise, as in the case of the queen's cell, and in some of those cells close to it, and sometimes in other parts of the comb, in cases where an accident has been repaired.

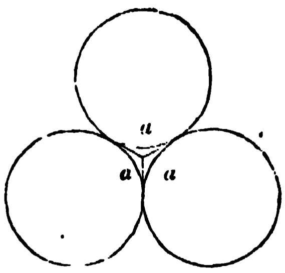

Fig. 6.

If some hive-bees could be made to work in a large solid mass of wax, the first cell formed would most probably be cylindrical, with a hollow circular bottom; this would also be the form of the following cells unless they came in contact with each other; and, in this case, supposing the circumferences of three cylinders were to touch, the bees working in each of these cylinders would cut away the wax at *a*, *a*, *a*, (*fig.* 6). But supposing the wax block were excavated on one of its sides, into the greatest number of equal-sized cylinders that it would admit of, it would then follow that each cylinder would be surrounded by six others, this being the only number of equal-sized circles which may be placed round one of the same magnitude; by the same rule of removing the wax from the interstices, each of these cylinders would become hexagons. Again, supposing this block to be a flat mass of equal thickness in all parts (the ordinary thickness of a comb), this block being cut into cylinders of equal diameter on both sides, and the base of each cylinder being exactly over parts of three opposing ones (as represented in *fig.* 7), when the wax is cut away at the interstices, as at the sides, it follows that the bottoms of the cells will be each composed of three equal rhombus-shaped pieces. Hence we have cells exactly like those of the hive-bee, but not constructed in the ordinary way, though upon such principles as analogy points out (a circular form being the basis of the work), and in such a way as we have observed, they do occasionally proceed. If we allow that the basis of the work of the hive-bee be circular, the royal cell forms no exception to the general rule, so far as the principle of its construction is concerned.

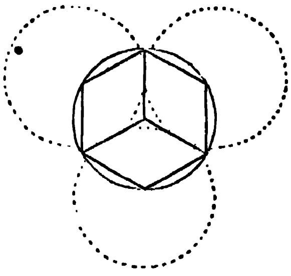

Fig. 7.

Let us now examine the construction of the comb in its usual way of proceeding:—

The first operation is the formation of wax; this is not, as many have supposed, the farina collected from flowers, but is secreted by the insect at the time of building the combs. For this purpose the wax-workers suspend themselves in festoons from the top of the hive. Those which first reach the top fix themselves by the claws of the fore legs to the roof, and are followed by others which attach themselves to them, until an inverted cone or festoon of bees is formed, each end of which is attached to the roof of the hive. Before the commencement of the new comb, the interior of a hive presents a series of festoons of this description, intersecting each other in all directions, the bees remaining in perfect repose.

At this time the wax is secreted and makes its appearance in little scales which exude between the segments on the under side of the abdomen, eight scales being visible in each bee. The wax being secreted, one of the bees commences the comb; having detached itself from the festoon, it makes its way to the roof of the hive, and after clearing a space by driving away the other bees, it detaches one of the scales from the abdomen by means of its hinder legs: this is then conveyed by the fore legs to the mouth, where it is masticated, and impregnated with a frothy liquid by the tongue, in which process it obtains a whiteness and opacity which it did not before possess. The particles of wax are then applied to the roof of the hive. Another scale undergoes the same process, and is attached to the first. The bee thus continues labouring until all its scales are disposed of; it then quits its situation and is followed by another bee, which proceeds with its scales in the work already begun, depositing the wax in a straight line with the former deposition. The same operation is performed by many other bees, until a considerable block is deposited. This block is generally about five or six lines long (a line is equal to one-twelfth of an inch), the height two lines, and the thickness half a line; and it is upon this that the formation of the cells commences.

We have seen that the foundation of the block is the work of one bee, so likewise is the commencement of the cells;—the former is the work of what is called the wax-workers, which, we are informed by Huber, do not possess the power of sculpturing the cells:—the cells are made by the sculpturer-bees, who are smaller than the wax-workers. No sooner is the block large enough to admit a sculpturer-bee between the wax-workers, than the excavation commences. There seems to be an instinctive desire to perform the work of excavation wherever there is room, even though there may not be sufficient to form a perfect cell; for we never observe a solid piece of wax in any part of a comb. On the contrary, if by any accident there has been space unoccupied by cells, we find that the wax has been excavated at that part as much as was practicable.

The bee, impelled by instinct to deposit wax and to excavate, and also guided by an acute sense of feeling in the antennæ (probably through the elasticity of the wax) as to the degree to which the excavation should proceed, forms the comb; and in so doing it seems to act, not from choice, but from a necessity imposed upon it by two antagonist principles,—one causing it to deposit and excavate wax, and the other acting through the antennæ, and limiting the degree of excavation.

It is to this desire for performing the work of excavation that we attribute the small excavations about the royal cells, which are said to be for the purpose of facilitating the exit of the young queen. If the wax were removed for that purpose, we do not see why the operation should not be confined to that part through which she makes her escape. On the other hand, if from the wax of the royal cells being thicker than it is in other parts of the comb, the workers are induced to make excavations, and desist only upon the thickness being reduced to that of the ordinary partitions, it follows that it will at last become uniformly thin, as described by Huber; the reason here given differing from Huber's, but we think more in accordance with the habits and economy of the animal.

In forming the cells, a hollow is first excavated on one side of the wax-blocks; this excavation is rather less than the width of a cell, and is immediately followed by two of a similar description on the opposite side of the block. The particles of wax removed in excavation are kneaded by the jaws of the bee and deposited on the edges of the intended cells; the two latter excavations (*b*, *b*, *fig.* 12) are necessarily on each side of the first (*a*, *fig.* 12), though close to it. In placing the two last-mentioned cells, the bees avoid the opposite part on account of the thinness of the wax, and the size of the wax-block will not admit of their being remote from the first.

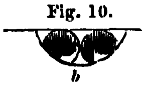
Fig. 10.



Back view.

The front, side, and back views of the block on which the first excavations for the cells are made.

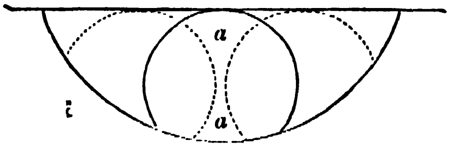


Fig. 11.

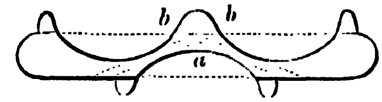

Fig. 12.

Fig. 11, Front view magnified. Fig. 12, Transverse section through the same.

The above are representations of the block and its excavations at this period. Supposing the parts at which the circles nearly come in contact with each other to be of the thickness proper for the partitions of the cells, the parts marked *a* in the front view and section (*figs.* 11 and 12) being more than the necessary thickness, the bees will (according to the instinctive principle before mentioned) naturally remove what there is superfluous, thus forming an angle, determined by two intersecting vertical planes at the bottom of the cell, inasmuch as at the same time the parts marked *b*, in the back view and section (*figs.* 10 and 12), will also be removed. The partition between these two last-mentioned cells thus becomes perpendicular and of equal thickness, and is exactly opposed to the angle at the bottom of the first cell.

By this time the necessary secretion of wax has taken place in all the bees composing the festoons, and they are all anxious to dispose of their scales of wax. The sculpturer-bees are also active, consequently more wax is added to the margins of the original block, and more excavations are formed. Supposing the block to have increased to double its original length and width, there would then be room for parts of four more excavations, on the side on which the first was made (*fig.* 13).

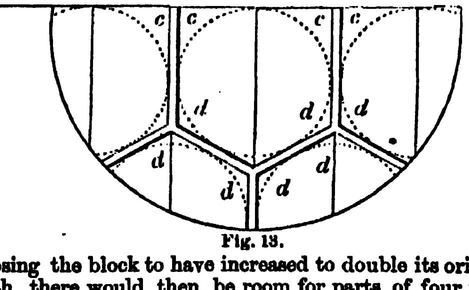

Fig. 13.

The same operation of reducing the wax in the thick parts marked *c* having taken place, the sides of the first cell also become straight and perpendicular, and by reducing the wax at the parts *d* to the proper thickness in all the cells, the bottom of the first cell, and upper parts of the two cells beneath, in the diagram, become two-sided. The work on the opposite side of the comb being in the same state of forwardness (for after the commencement it proceeds equally at all parts), will appear thus—

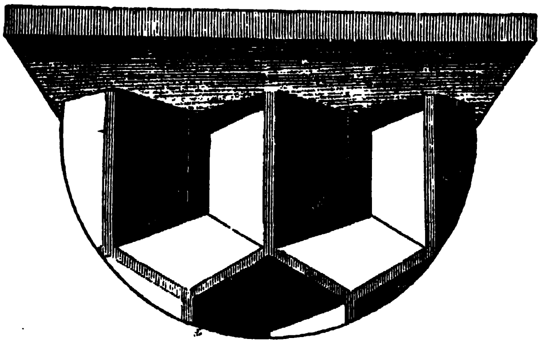

Fig. 14.

In the above figure the angles at the bases of the cells are cut into the partitions of the opposing cells, and hence it is clearly seen that, from the position of those cells, the perpendicular partitions of the cells on this side must be longer than those of the other, and that the cells themselves must have three quadrilateral plates for their bases.

In carrying up the sides of the cell, the form is regulated by the intersection of the surrounding circles, as represented in *fig.* 15. But the circles described in *fig.* 15, parts of which are shown in most of the other figures, represent those which are inclosed by the hexagons; whereas we believe the natural circumference of each cell (supposing it to be cylindrical) is that by which the hexagon is inclosed; hence it will be necessary to imagine the circles partly intersecting each other.

It has now been demonstrated that the cells of the first tiers on each side are pentagonal; that the bases of those on one side are each composed of two plates, while those of the other side are each composed of three plates; and that, according to the laws laid down, they could not have been otherwise: now as this accords with all the accounts given of the proceedings in the construction of the comb, it seems to prove that the laws which we have laid down, as guiding their formation, are correct.

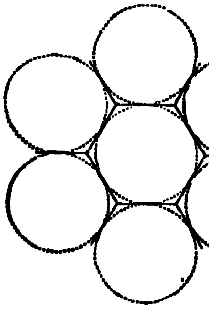

Fig. 15.

We have now followed the progress of the work until the commencement of the second tiers of cells: it is unnecessary to describe the formation of these and the following tiers. It is shown that, according to certain laws, the first tiers of each side of the comb become pentagonal, and according to the same laws it is clear that the second and following tiers must become hexagonal; for the two sides forming the lower boundary of each cell of the first tier, also form the upper boundaries (or partitions) of two cells of the second tiers. As the upper part of the first tier is determined by the roof of the hive (represented by the horizontal line in diagram 13), so is the upper portion of the cells of the second tier determined by the lower portion of those of the first tier; thus, the upper portion of each cell of the second tiers being composed of two planes meeting at an angle, and the work continuing, as in the progress of the first tier, four more planes will be constructed to form the lower portion, and complete the hexagon. It is thus that all the ordinary cells of a comb are hexagonal, and we believe it is clearly shown that they could not be otherwise, according to the mode of proceeding in their construction. Their form depends entirely upon the commencement of the work, which necessarily throws the cells in such a position that each cell must be surrounded by six others, and consequently have six sides, each side being the common partition of two cells; and so long as the cells are of equal diameter they must each be opposed to parts of three other cells on the opposite side of the comb, in such a way that supposing the external surface of the bottom of each cell were hemispherical (which would be the case were the wax not removed from the interstices), each hemisphere would touch three others; but the wax being removed from the interstices and reduced to an equal thickness at all parts, and the bases of the sides of a cell not being all in the same plane, the bottom of each cell is thus formed into three equal rhomboidal pieces in three different planes, the three angles at their junction being respectively the lowest parts or the farthest removed from the mouth of the cell.

In working the cells, the wax is always found a little thicker on the edges, thus giving additional strength to them. It has been asserted that this extra thickness is added upon the completion of the cells; but as we have never observed a cell, even though in a state of progress, without it, we think the more probable conjecture is, that the bees, in working the sides of the cells, desist upon arriving near the top, and thus leave that part thick, as it is found to be.

The ordinary cells of a comb are of two sizes; those designed for the male larvæ being rather larger than those of the ordinary size in which the neuter larvæ are reared. The width of the former cells is about 3⅓ lines, and that of the latter 2⅖. A comb is always commenced with the small-sized cells. Hence, when the larger cells are constructed, instead of being opposed to three others they encroach upon a fourth, and their bases are consequently composed of four plates instead of three: at first a minute lozenge-shaped piece is visible at the top of the basal part (*fig.* 16, *a*); this gradually increases in size as the one on the opposite side decreases (*fig.* 16, *b*).

When the full size of the cell is attained, the top and bottom pieces (*fig.* 16, *c, c*) are equal; but as soon as a sufficient number of the larger cells is formed, the lower lozenge gradually decreases, while the upper one (*fig.* 16, *e, e*) increases in size until there are but three plates again visible (*fig.* 16, *d, d*).

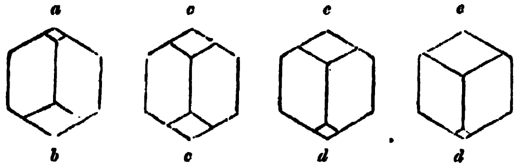

Fig. 16.

It is almost always found that the excavations for cells, formed by different insects, in whatever situations they may be, are exactly proportioned to their size. Hence it is extremely difficult to account for the enlargement of the cells of the bees, as just described. We will however venture an opinion, in hopes of calling attention to the subject.

In the former part of this account it has been stated that no sooner is a portion of the comb finished than the queen deposits eggs in the various cells, and that the cells first formed are always those of the smaller size, which are excavated by what are termed the sculpturer-bees, or nurses, which are less than the wax-workers.

We imagine that when the eggs hatch, the small bees, or nurses, are more particularly engaged in attending upon the young; and that the large-sized workers then commence the excavation of the cells themselves, and thus make cells of a larger diameter than those made by the nurses.

Huber states that the description of bees called wax-workers have not the power of sculpturing the cells; but at the same time he owns that he was unable to follow the proceedings in the construction of a comb for any considerable time after the commencement. During the time of his observations, however, he invariably found that the smaller bees were the sculpturers.

The interior of a hive consists of a number of combs arranged perpendicularly; these are fixed to the roof of the hive, and are parallel to each other, the space between them being about half an inch. When the first comb has advanced in size, so as to consist of two or three rows of cells, two other combs are commenced, one on each side of it, the work proceeding as in the first; these again are followed in their turn by two others. As the comb advances in size it assumes a form nearly circular, and is still joined to the roof of the hive only; the work proceeds by adding wax to the margin of the comb exactly at the junction of the opposing cells, and this is no sooner deposited than it is cut away and worked into cells. These cells are not equally deep throughout the comb, but their depth gradually decreases as they approach the margin: a comb in its progress has the form of a double convex lens.

The form of the comb, as above described, is that of a new one; but in the honey-storing season the sides of the comb are joined to those of the hive, to give strength to hold the additional weight; the cells are also lengthened, so that the surface of the comb then becomes even. The cells are not quite horizontal, the orifice being generally a little higher than the base, most commonly four or five degrees, but sometimes considerably more. When a comb is first completed, it is of a dull white colour and of a weak substance; it is however soon strengthened by adding propolis to the margin of the cells, and lining their interior with threads of the same material.

The cells of a comb are used for the purposes of storing up honey for the winter, and in them the larvæ are reared. Pollen, or bee-bread, is also stored up in some of the cells. Many larvæ may be reared in the same cell, and as each spins a cocoon or web on its sides which is never cleared out, it thus becomes at last too contracted to contain larvæ; it is then used for one or both of the other purposes above mentioned. When a hive is well stored with combs having empty cells, the workers disgorge the honey into these receptacles; but in case cells are wanted they retain the honey, and wax is secreted for the purpose of building more combs.

Honey is never consumed but in cases of the greatest necessity; but as soon as a cell is filled it is sealed up with a waxen covering.

During the progress of a comb in building, the slightest interruption is likely to alter its form; and as the space between each is always kept exactly the same, it frequently happens that the whole of the combs are affected by any accident happening to one. *Fig.* 17 illustrates an instance of this sort, which we have seen—

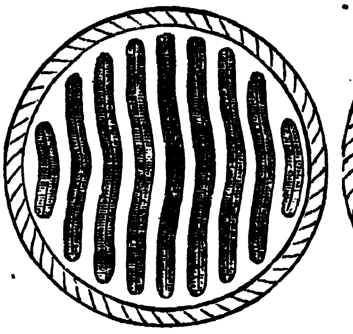

Fig. 17.

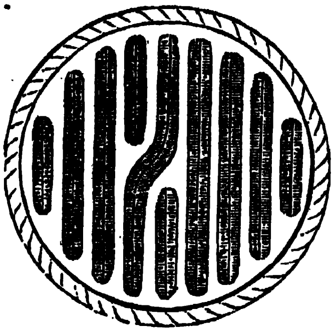

Fig. 18.

but it also frequently happens that an interruption in one comb is corrected in those that follow. A curious instance of this nature we have also observed (*fig.* 18).

In both these instances the form of the comb was affected by a stick being placed across the middle of the hive, to enable the owner (as we believe) to remove the hive with less danger of the combs giving way.

The latter case is so ingenious that at first it appears more like an operation of reason than instinct: it is nevertheless to be accounted for upon the instinctive principles with which these animals work. The course of the first comb being altered, the two adjoining ones would naturally follow its line; but if those next beyond them on each side were in a state of forwardness, the workers would be obliged to discontinue the two former, as shown in the figure, to avoid coming in contact with the two latter; for it appears to be a law in the construction of new combs that a certain space should be always left at the margins as well as between them.

In addition to the construction of the comb, the bees when in danger of attacks from their enemies barricade themselves. Sometimes the entrance of the hive is nearly blocked up with wax and propolis, and at others a wall of that substance is constructed just behind that part; this wall is perforated with holes only just large enough to admit of the egress and ingress of the bees themselves. The fortifications are occasionally much more ingenious and complicated. Weak hives are sometimes exposed to the attacks of strange bees, and in such cases fortifications would be constructed; but it is more particularly to prevent the ravages of the *Acherontia atropos* that this care is taken. As this moth only makes its appearance in the autumn, these fortifications are removed in the spring, a time when they would be of the greatest inconvenience, as the hive is then extremely populous. Huber states that "the entrances formed in 1804 were destroyed in the spring of 1805. The Sphinx (*Acherontia atropos*) did not appear that year; but it returned in great numbers in the autumn of 1807. By speedily barricading themselves, the bees prevented their threatened ravages; but before the departure of swarms in May, 1808, they demolished the fortifications, whose narrow passage prohibited free egress to the multitude."

The principal authors who have written upon the habits of bees are as follows:—Aristotle, *History of Animals*, book v.; Pliny, *Natural History*, book xi.; Swammerdam; a translation into English, from the Dutch and Latin original edition of his work, has been made by Thomas Floyd, entitled, *The Book of Nature, or the History of Insects;* Réaumur, in the fifth volume of his *Mémoires pour servir à l'Histoire des Insectes*, 1734–42; Schirach, *Histoire Naturelle de la Reine des Abeilles*, 1771; Riem, *Contemplation de la Nature;* Bonnet, tom. v., 4to ed., and tom. x., 8vo.; John Hunter, *Philosophical Transactions for* 1792; Thorley, *Female Monarchy: being an Inquiry into the Nature, Order, and Government of Bees;* Wildman, *A Complete Guide for the Management of Bees*, 1819; Huber, *Nouvelles Observations sur les Abeilles:* a translation into English of this work was published in the year 1821, entitled, *New Observations on the Natural History of Bees;* Edward Bevan, M.D., *The Honey-Bee, its Natural History, Physiology, and Management*, 1827; Kirby and Spence, *Introduction to Entomology;* T. Rymer Jones, *Natural History of Animals*, vol. ii.; *Insect Architecture*, in *Library of Entertaining Knowledge*.

BEE-EATER, the vernacular name for a species of bird belonging to the genus *Merops*, Linn., one of the family *Meropidæ*, and of the Syndactylous Tribe, which have the external toe nearly as long as the middle one, and both joined together up to the penultimate articulation.

The birds of this genus take their prey, consisting of wasps, bees, &c., like the swallows, while on the wing; and, as Cuvier observes, it is remarkable that they are not stung by them. The species are numerous, and many are figured by Levaillant. Their nests are formed in the banks of rivers, where they dig deep holes; and their geographical distribution is over the warmer regions of the old continent, Java, &c., and Australia (Paramatta), none of the genus having been found in America, where their place appears to be supplied by the Motmots (*Prionites*, Illiger). Their brilliant plumes, of colours which change according to exposure to light, the prevalent hues being azures and greens, remind the observer of the kingfisher's gorgeous dress. A familiar example of the genus occurs in the bird whose English name is at the head of this article—the Guòpier vulgaire of the French, the Mangia-Api and Lupo d'Api of the Italians, the *Μέροψ* of the Greeks, and *Merops Apiaster* of Linnæus.

Bee-Eater (*Merops Apiaster*).

In the south of Europe it is frequent in the summer. Sicily, Sardinia, Italy, the south of France, and Germany possess it, and on the southern border of Russia it is numerous. It is found in Turkey and in the Grecian Islands, and in autumn migrates towards Egypt. It breeds in holes in the banks of the Don and the Volga, laying from five to seven white eggs in a nest composed of moss, &c. Hasselquist says that it is found in the plains of Galilee, and that it is called Varuar by the Arabs; and Temminck, that the individuals found at the Cape of Good Hope differ in nothing from those killed in Europe. Ray, in his edition of Willughby, observes, "It is not unfrequent in the Campagn of Rome: for that we saw it there to be sold in the market more than once. It is not found in England that we know of. Bellonius writes that it is so common in Candy that it is seen everywhere in that island. Aristotle tells us that it feeds upon bees, whom all other writers of the history of animals do therein follow. But it feeds not only upon bees, but also upon *Cicadæ*, beetles, and other insects. Yea, as Bellonius relates, upon the seeds of the nipplewort, bastard parsley, turnip, &c., not abstaining from wheat and other grain. From its exact agreement in the shape and make of its body, bill, and feet with the kingfisher, we suspect that it likewise preys upon fish.

"Bellonius, in the first book of his observations, writes thus concerning the *Merops*. Flying in the air it catches and preys upon bees, as swallows do upon flies. It flies not singly but in flocks, and especially by the side of those mountains where the true thyme grows. Its voice is heard afar off, almost like the whistling of a man. Its singular elegance invites the Candy boys to hunt for it with *Cicadæ*, as they do also for those greater swallows called Swifts, after this manner:—Bending a pin like a hook, and tying it by the head to the end of a thread, they thrust it through a *Cicada* (as boys bait a hook with a fly), holding the other end of the thread in their hand. The *Cicada* so fastened flies, nevertheless, in the air, which the *Merops* spying, flies after it with all her force, and catching it, swallows pin and all, wherewith she is caught."

The passage in Aristotle, mentioning the *Merops* as one of the enemies most destructive to bees, is in the 40th chapter of the 9th book of his 'History of Animals;' and there are others in the 1st chapter of his 6th book, and in the 13th chapter of his 9th, wherein he notices the peculiarity of its making its nest in holes in the earth.

The species, although not common, may be considered as an occasional visitant to this country. The first record of its appearance is in the third volume of the 'Transactions of the Linnæan Society,' from which it appears that on "July 2, 1794, the president communicated an account of *Merops Apiaster*, the Bee-Eater, having been shot (for the first time in Great Britain) near Mattishall, in the county of Norfolk, by the Rev. Mr. George Smith. The identical specimen was exhibited by permission of Mr. Thomas Talbot, of Wymondham. A flight of about twenty was seen in June, and the same flight probably (much diminished in number) was observed passing over the same spot in October following." Since then four or five specimens have been recorded to have been shot in the counties of Suffolk and Norfolk, one in Dorsetshire, three in Devonshire, one in Cornwall and one in Ireland. (Yarrell, *British Birds*.)

BEECH. [FAGUS.]

BEESHA, a genus of Grasses nearly allied to *Bambusa*, with which it is actually combined by some botanists, but from which it differs, according to the concurrent testimony of all authors, in the otherwise incredible circumstance of its seeds being inclosed in a fleshy pericarp.

Two species are known, both of which have the aspect of the spineless bamboos. Of these *Beesha baccifera* is found on the mountains of Chittagong in India, where it is called Pagu Tulla, growing in dry places on the sides of hills, where the upper stratum of soil is sandy. According to Roxburgh's 'Flora Indica,' the circumference of the stems near the base is 12 or 13 inches, and their height from 50 to 70 feet—"beautifully erect, and without the least flexure or inequality of surface; bare of branches, except near the extremity. It perishes after yielding its fruit. It yields more or less Tabasheer, of a silicious crystallisation; sometimes it is said the cavity between the joints is nearly filled with this, which the people call Choona, or Lime." ('Flora Indica,' ii. 197.)

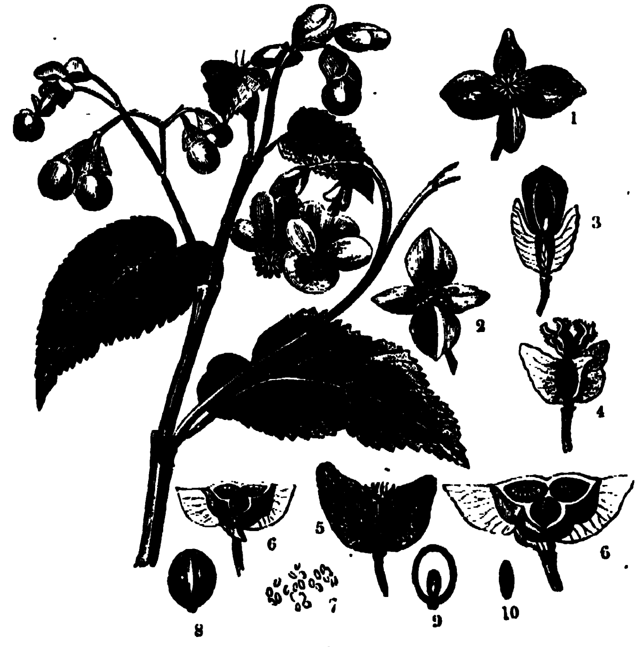
Beesha Fax is a smaller species, not above 18 feet high. It is found in Amboyna and other parts of the Malayan Archipelago, where it is applied to many useful purposes. It is the *Arundarbor cratium* of Rumphius's 'Herbarium of Amboyna.'

BEET. [BETA.]

BEETLE. This term has frequently been used as the name common to the species of the family *Scarabæidæ*, but it is more commonly and properly used to designate those insects which are covered by a strong horny substance, the abdominal part of the body being protected by two sheaths under which the wings are folded. Hence the term is synonymous with *Coleoptera*. [COLEOPTERA.]

BEGONIA. [BEGONIACEÆ.]

BEGONIA'CEÆ, *Begoniads*, a natural order of Exogens, consisting of three genera, *Begoina*, *Eupetalum*, and *Diploclinium*. The species are 159, and are found exclusively in the dampest parts of the tropics in both the New and Old World, particularly in Asia and America. They have perfectly unisexual flowers, with a superior calyx, generally coloured pink, consisting in the sterile flowers of from 2 to 4 pieces, and in the fertile flowers of from 5 to 8 pieces. The stamens are numerous; the style simple; the stigmas three, often forked, and having a wavy or twisted appearance. These latter originate from a 3-cornered 3-celled ovary containing a multitude of little seeds, which changes to a thin-sided capsule with 3 extremely unequal wings. The leaves are always



Begoniaceæ.

1, A sterile flower; 2, a fertile one; 3, the same in bud; 4, the half-grown ovary and stigmas; 5, fruit; 6, the same cut through horizontally; 7, seeds the natural size; 8, one seed magnified; 9, the same cut through to show the embryo in its natural position in the albumen; 10, an embryo separate.

more or less unequal-sided, and have highly-developed membranous stipules at their base.

It is very difficult to say with what other natural order this has most affinity. By Link it has been stationed near *Umbelliferæ*, a most unintelligible association. Jussieu, attracted by its highly-developed stipules, and apparently apetalous flowers, together with the acid flavour which is so prevalent in the order, suspected its near alliance with *Polygonaceæ;* while Lindley, with a greater degree of probability, now makes it constitute a member of the Cucurbital alliance of his Epigynous subclass of Exogens with polypetalous flowers.

All the species of the genus, *Begonia*, of which the order principally consists have irregular fleshy leaves, often richly coloured with crimson, succulent stems, and neat-looking pink flowers growing in few-flowered panicles. Most of the species at present described may be procured in a living state in the gardens of Europe.

The roots of the various species of *Begonia* are astringent and slightly bitter. *B. Malabarica* and *B. tuberosa*, with others, are used as potherbs in the countries where they grow. Endlicher says that some of the Mexican species are drastic purgatives.

BELEMNITE'LLA. The group of *Belemnites* which occurs in the Chalk Formation, and which is marked on the anterior and ventral face by a long narrow fissure, is thus named generically by D'Orbigny. To this group belong *B. mucronatus*, *B. granulatus*, *B. mammillatus*, &c., in Europe, and *B. Americanus* in the United States, if this last be really distinct from *B. mucronatus*.

BELEMNITES (from the Greek *βέλεμνον*, a dart or arrow), Pfeilstein and Donnerstein of the Germans, Pierre de Foudre of the French, a genus of extinct *Cephalopodous Mollusca*, whose conical remains were for a long time utterly misunderstood. Before the geological history of this extinct marine animal was well made out, few natural productions ministered more largely to the superstitious feelings of man. The ancients, it was said, had a legend that they came from the lynx, and called them Lapides Lyncis and Lyncuria. They were also, from being found on Mount Ida, and from their supposed resemblance to those organs, called Idæi Dactyli, or Petrified Fingers. This idea was too much in unison with the gloomy imagination of the northern nations to be lost: we accordingly find the term Devil's Fingers bestowed on them, and not unfrequently that of Spectre-Candles.

Afterwards came the age of Thunder-Stones and Picks, when this fossil was alleged to be the produce of electricity, and was called by the learned *Lapis fulminans*. They were also called Arrow-Heads.

Subsequently, and at the period when organic remains were almost universally regarded as *lusus naturæ*, formed by the plastic power of the earth, the Belemnite was considered, even by those who had adopted more correct opinions upon the subject of many fossil shells, to be strictly mineral,—to be a stalactite or a crystal; and by some who found it in the sandy parts of Prussia, where amber also occurs, it was supposed to be that substance petrified.

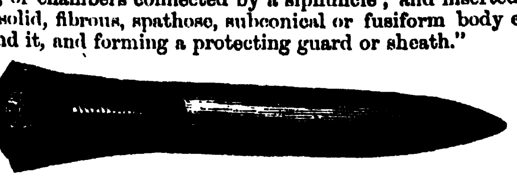
At length it began to be granted that the Belemnite was of organic animal origin, and the conical cavity at its broader end caused it to be looked upon as the tooth of some unknown creature; while some pronounced it to be a spine, like those of an *Echinus*, and others gave way to various conjectures not worth recording. Then arrived the dawn of Von Tressau, Klein, Breynius, Da Costa, Brander, and Plott, who allowed the fossil to be of testaceous origin, but knew nothing of its relative position. At last, the increasing light of science placed the Belemnite in a comparatively clear point of view.

A substance with which fable had been so busy was not likely to have been overlooked in the old Materia Medica: we accordingly find that it was administered in a powdered state as a remedy for the night-mare, and for the stone. Dr. Woodward states, that in Gloucestershire the powder was blown into the eyes of horses affected with watery humours; and in Prussia it is said to have been used when pulverised in dressing wounds.

The true place of the Belemnite is among the *Cephalopoda*. Cuvier and Lamarck had arrived at this conclusion, and they also believed that it was an internal shell. It forms the first genus of the first family (*Orthocerata*) of Lamarck's first division of the *Cephalopoda*, namely, the Polythalamous, or Many-Chambered, division.

Miller, in a paper in the 'Transactions of the Geological Society,' gives the following as the generic character:—

"A cephalopodous (?) molluscous animal, provided with a fibrous spathose conical shell, divided by transverse concave septa into separate cells, or chambers connected by a siphuncle; and inserted into a laminar, solid, fibrous, spathose, subconical or fusiform body extending beyond it, and forming a protecting guard or sheath."



Belemnites canaliculatus.

Since Miller's paper was written many important facts have been added to our knowledge of the structure of Belemnites.

In addition to the circumstances attending the discovery at Solenhofen of some traces of the general form of the animal, of which the remains ordinarily found are a part, and of the ink-bag and horny laminæ at Lyme and Whitby, an almost complete restoration of the Belemnite animal was made from specimens laid open in the cutting of the Great Western Railway, near Chippenham in Wiltshire. The Oxford Clay here excavated afforded to Mr. Pratt and the late Marquis of Northampton admirable specimens of the phragmacones and laminar plates, outlines of some of the soft parts of the body and arms, and the form and arrangement of the hooked appendages of the arms. Indeed one of Mr. Pratt's specimens reveals the place and size of the eyes, the funnel or breathing-tube, the tendinous parts of the mantle, and the lateral fins, the ink-bladder, and ink-duct. (Owen, 'Hunterian Lectures,' 1843.) Professor Owen, to whom the finest specimens of these discoveries were submitted, has found a strong resemblance between the fossil animal and the group of recent Sepioid Animals called *Onychoteuthis*, on whose arms are not the usual cusps, but slender horny hooks. The arms, eight in number, were equal, slender, and furnished with hooks through all their length, alternating in a double row. The fins appear round, and a little behind the middle of the body, as in *Sepiola;* the caudal extremity pointed, inclosing the fibrous guard, the anterior extremity of the laminar plate, under which the ink-bag is placed, nearly transverse, and not arched so as from analogy with the sepiosteum might have been expected. The Belemnitic Animal—a dibranchiate eight-armed Cuttle—must in some instances, to judge from specimens of the fibrous conical extremity, have reached (arms included) four or more feet in length, and its figure appears favourable for swift motion. In the Lias deposits whole shoals of some of the species appear to have perished together, and there are found about the cones many indications of the presence of animal substances.

The geological distribution of the Belemnites has been largely examined. In 1835 Professor Phillips presented to the British Association at Dublin a full account of the structures and mode of occurrence of the British species: assigning names and characters to the principal groups which occur in the Cretaceous, Upper Oolitic, Lower Oolitic, and Liassic Strata. M. d'Orbigny also published results perfectly accordant, derived from a full investigation, especially of the species occuring in France. It thus appears that in the first place *Belemnites* are confined as a group to the Mesozoic Strata; that many species allied to the *B. compressus* of Voltz, *B. penecillatus* of De Blainville, and *B. paxillosus* of Schlottheim, belong to the Lias; that others, allied to *B. ellipticus* of Miller, *B. quinquesulcatus* of De Blainville, *B. Aalensis* of Voltz, belong to the Lower Oolite series; that others allied to *B. sulcatus* of Miller, *B. Altdorfensis* of Schlottheim, abound in the period of the Oxford Clay; while *B. mucronatus*, *B. quadratus*, *B. Listeri*, *B. attenuatus*, and others now ranked as *Belemnitella* by D'Orbigny, characterise the Cretaceous Strata. The investigations entered into on this subject are yet incompletely published; but the reader may refer with advantage to the Treatises of De Blainville and Voltz, to Buckland's *Bridgewater Treatise*, D'Orbigny's *Palæontologie Française*, and to Owen's *Hunterian Lectures*. Figures illustrating several points will be found in Mantell's *Medals of Creation*, vol. ii.

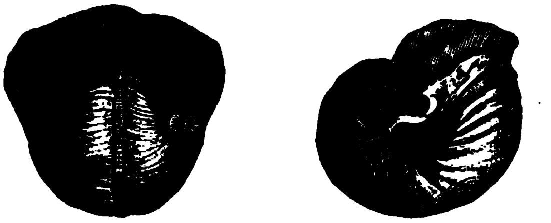
BELL-FLOWER. [CAMPANULA; SPECULARIA; WAHLENBERGIA.]

BELLADO'NNA, the Deadly Nightshade, a violently poisonous wild plant. [ATROPA.]

BELLADO'NNA LILY (literally *Fair-Lady Lily*), a species of *Amaryllis*, so called on account of its beauty and delicate blushing flowers. It is found wild at the Cape of Good Hope, has become naturalised in the ditches of Madeira, and is not uncommon in the gardens of England, where it lives for many years without shelter, if planted on a sunny border well protected from wet in winter. Its stems are about 18 inches high, of a rich purplish green, with a dense violet bloom spread over them. The flowers grow in a cluster at the top of the stem, are of a funnel shape, with six divisions curving backwards at the points, and not less than three inches long; their colour is a rich but not deep rose, which varies in intensity in different varieties. They appear in August and September, without their leaves, and give an extremely rich and very exotic appearance to the borders in which they appear. The bulbs may be procured in any quantity from Madeira.

BELLE DE NUIT, a name given by the French to various kinds of Bind-Weeds. In tropical countries these plants occur in great abundance, expanding their large fragrant and delicate flowers of white, or blue, or lilac, in such magnificence that they may well be called the 'glory of the night.' The species to which the name is more particularly applied is what botanists call *Ipomæa*, or *Calonyction Bona Nox*, whose white flowers have a diameter of five or six inches, and open at sunset in the woods of the East and West Indies, drooping at daylight.

BELLE'ROPHON, a Fossil Shell, the animal of which is unknown. Denys de Montfort established the genus, but he placed it among the Polythalamous, or Chambered, Shells. De France cut in half the very specimen which belonged to De Montfort, and thus proved that it was unilocular, like *Argonauta*. It is rich in species, which occur exclusively in the Palæozoic Formations, as the Silurian Strata, Devonian Rocks, and Mountain Limestone. It has been generally referred to the *Cephalopoda*, and considered analogous to *Argonauta*. D'Orbigny has however given reasons for ranking it with the *Heteropodous Mollusca*, and compares it with *Carinaria*.



Bellerophon hiulcus.

BELLIS (from *bellus*, pretty), a genus of plants belonging to the natural order *Compositæ*, and to De Candolle's suborder *Corymbiferæ*, tribe *Asteroideæ*, subtribe *Asterineæ*, division *Astereæ*, and subdivision *Bellideæ*. It has a receptacle without scales, flowers of the ray ligulate, pistilliferous in one row, those of the disk hermaphrodite tubular, the involucre composed of two rows of equal obtuse scales, the receptacle conical, the fruit compressed without pappus. De Candolle enumerates five species belonging to this genus. One of them, the *B. perennis*, is the Common Daisy, and is a native of Great Britain and throughout Europe. It has obovate-spathulate single-ribbed crenate-dentate leaves. It is an exceedingly common plant on banks and in pastures in Europe. It blossoms nearly all the year round, and is constantly found with opened flowers from March to October. It is subject in its wild state to varieties; sometimes all the florets are found ligulate, more rarely they are all tubular. There are several varieties of the Common Daisy cultivated in gardens. There is a double variety called Large-Double, another Double-Quilled, and a proliferous variety known by the name of Hen-and-Chickens. These varieties assume various colours from deep red to pink and white. They are easily cultivated, and form pretty plants for edges and borders, and continue in blossom a long time.

B. sylvestris and *B. annua* are natives of Europe, but are not cultivated.

The genus *Bellium* closely resembles *Bellis*; it differs however in possessing a pappus surrounding its fruits. The species are found in the south of Europe, and appear like small species of *Bellis*.

(Babington, *Manual*; Loudon, *Cyclopædia of Plants*.)

BELLIUM. [BELLIS.]

BELLOWS-FISH. [CENTRISCUS.]

BELO'NE, a genus of Fishes belonging to the family *Esocidæ* of the *Abdominal Malacopterygii*. It has a head and body greatly elongated, the latter covered with minute scales; both jaws very much produced, straight, narrow, and pointed, and armed with numerous small teeth; the dorsal fin placed over the anal fin. The species are remarkable for the green colour of their bones.

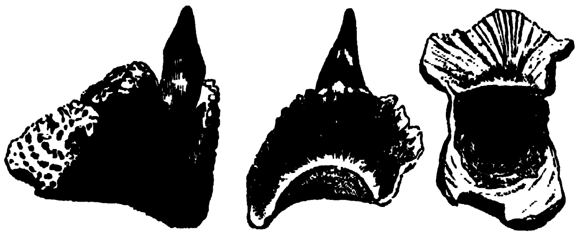
One species, the *Belone vulgaris*, is common on the British coast. It is known by various names, but more especially that of Gar-Fish. It was placed by Linnæus in the genus *Esox*, and being an inhabitant of the sea, it got the name of Sea-Pike. From the fact of its leaving the deep water in spring to deposit its ova near the shore in the months of April and May, and thus preceding the mackerel in their annual visit to shallow water for the same purpose, it has received the name of Mackerel-Guide. Its other English names according to Yarrell are Greenbone, Horn-Fish, Long-Nose, Gorebill, and Sea-Needle. The usual length of this fish is about 24 inches. It has elongated jaws, beset with numerous minute teeth. The eye is large. The body is uniform in depth to the anal fin, thence tapering to the tail. The dorsal and anal fins begin and end nearly on the same plane. The ventral fins are small. The tail is forked; the external long rays are nearly as long again as those of the centre. The upper part of the head and back is of a dark greenish blue; the sides and belly are silvery white; the pectoral, ventral, and anal fins white. This fish is taken off the coast of Berwick during the Mackerel season, and Dr. Johnston says it is not unfrequently called a Sword-Fish. It is taken also on the Devonshire and Cornish coasts. The fish are brought into the London markets in the spring, and eaten in considerable quantities. The flesh has the flavour of mackerel, but it is drier. Great numbers are said to be caught off the coast of Holland, but they are only used there as bait. Mr. Couch says of the Gar-Fish, that it "swims near the surface at all distances from land, and is seen not unfrequently to spring out of its element; its vivacity being such that it will for a long time play about a floating straw, and leap over it many times in succession. When it has taken the hook it mounts to the surface, often before the fisherman has felt the bite; and then with its slender body half out of the water, it struggles with the most violent contortions to wrench the hook from its jaws. It emits a strong smell when newly taken." In the Ionian Islands, according to Mr. Tonna, it is caught by attaching several lines with floats to a raft. In this way a large number are taken in a very short time. Specimens of this fish have been exhibited in the Aquavivarium of the Zoological Society, in the Gardens, Regent's Park.

There are several other species, some of which are said to attain a length of 8 feet, and to bite very severely. Their flesh generally is wholesome. (Yarrell, *British Fishes*; Cuvier, *Règne Animal*.)

BELONO'STOMUS, a genus of Fossil Fishes established by Agassiz. The British species occur in the Lias, Oolite, and Chalk; the foreign in the Oolite of Pappenheim.

BELO'PTERA, a genus of Fossil *Mollusca*, established by Deshayes and described by De Blainville as an animal entirely unknown, containing in the back part of its muscular envelope a symmetrical calcareous or bony shell formed of a thick solid summit very much loaded behind, and a front tube more or less complete, the cavity of which is conical and annular, the shell or bone having wing-shaped appendages without any anterior shield-like prolongation.

De Blainville divides the genus into two sections. The first consists of species whose wing-shaped appendages are united below the summit, and whose cavity is somewhat in the shape of a scuttle (*hotte*). Of this section *Beloptera sepioidea* is given as an example.



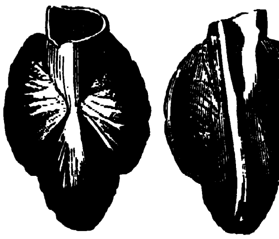
Side view. End view. Internal cavity.

Beloptera sepioidea.

The second includes species whose wing-shaped appendages are distinct, and whose cavity is completely conical with traces of chambers and of a siphon. Of this division *Beloptera belemnoidea* is given as an illustration.

De Blainville observes that this genus ought to be placed at the end of the *Sepiadæ*, or Cuttles; and that the first of the species is evidently very much allied to the bones of those animals, while the second approaches the *Belemnites*.

After all, the probability is, that these bodies are only portions of the bones of some of the Cuttle-Fishes; and this appears to have been the opinion of Cuvier.



Beloptera belemnoidea.

If a perfect bone of the common species of our coasts be closely examined, a structure very analogous to the conical circularly-grooved cavity of *Beloptera*, although in a more expanded form, will be observed. These fossils have been found in the London Clay, and other beds above the Chalk.

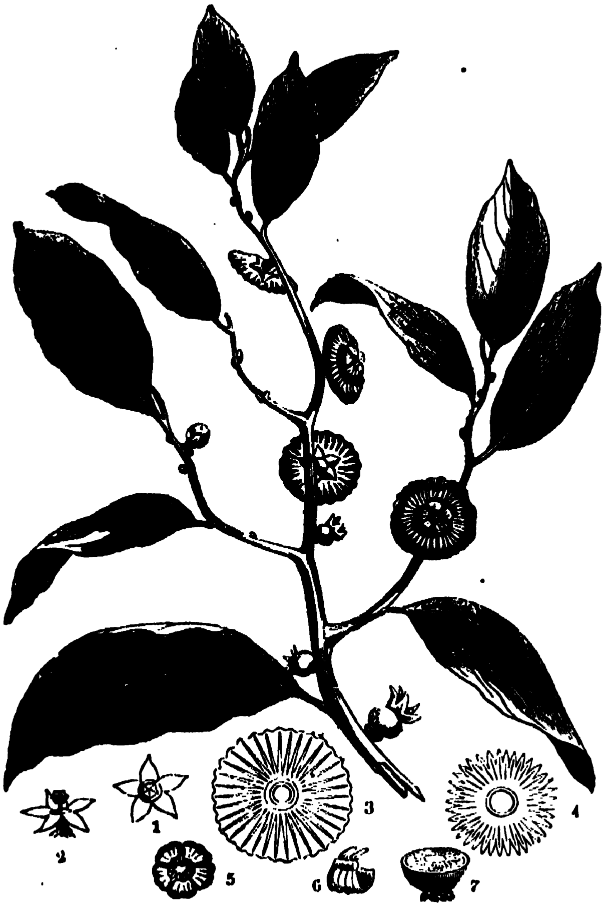
Voltz, in his Memoir on Belemnites, makes *Beloptera sepioidea* a distinct genus under the name of *Belosepia*.

BELO'PTERA (De Blainville), the shelly portion of a Fossil Cephalopod, intermediate between *Belemnites* and *Sepia*. It occurs in the French Tertiary Strata, and includes *B. Cuvieri*, *B. compressa*, and *B. Belemnitoidea* (De Blainv.). Mr. Morris adds *B. anomala* and *B. longirostrum*, from the English Tertiaries.

BELOSE'PIA (Voltz). In this genus M. Voltz ranks two of the species (*B. Cuvieri* and *B. compressa*) which form part of the *Beloptera* of De Blainville.

BELVISIA'CEÆ, *Napoleon-Worts*, a small natural order of plants, comprehending only two genera. One of these was discovered in the kingdom of Oware, by Palisot de Beauvois, who called it *Napoleona* in honour of Napoleon I. It was subsequently named *Belvisia* after its discoverer. It has been figured under the name of *Napoleona imperialis* in the 'Flora of Oware and Benin,' where we find the only account of it. It was discovered in the neighbourhood of the town of Oware, growing to the height of seven or eight feet, and loaded with large broad bright-blue flowers, sitting close upon the branches. They are remarkable for having a superior calyx of five pieces, together with a double monopetalous corolla, of which the outer forms a flat crenellated disk, and the interior is divided into a great number of regular narrow segments. The stamens are only five, or rather perhaps ten, united by pairs into five parcels, resembling so many petals. The stigma is peltate with five angles, and covers over the anthers. The fruit is said to be a berry, with a single cell, containing a parcel of seeds lying in pulp. From such an account it will be evident to the botanical reader that this must be one of the greatest curiosities in the vegetable kingdom.

Palisot de Beauvois, its discoverer, considered it the type of a new natural order allied to the Gourds; Brown, we believe, suspects its relation to the Passion-Flowers; Lindley originally stationed it near *Styraceæ*; in his 'Nixus,' he placed it near the Campanulas, but in his 'Vegetable Kingdom' places it between *Myrtaceæ* and *Rhizophoraceæ*. The other genus belonging to this order is *Asteranthos*, which is said by Desfontaines to be a Brazilian genus, but this is doubtful. This order has only four species.



Belvisia cærulea.

1, Calyx viewed from above; 2, the same in profile; 3, the outer corolla; 4, the inner corolla; 5, the stamens seen from above; 6, one of the stamens separate; 7, an ovary cut through.

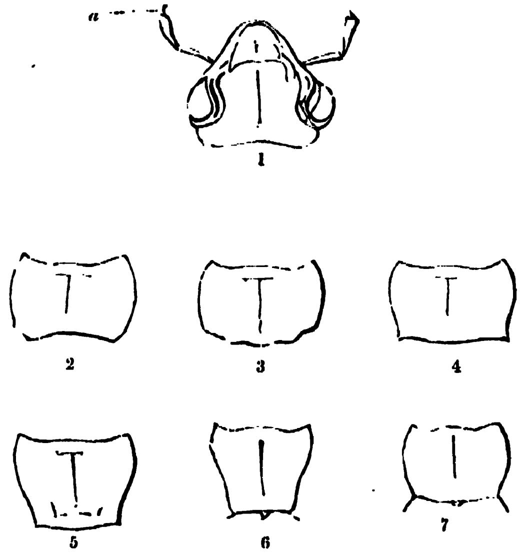
BE'LYTA, a genus of Insects belonging to the order *Hymenoptera*, and family *Proctotrupidæ*. The species of this genus are minute four-winged flies, having the antennæ 14- or 15-jointed, filiform in the males, and thickened towards their extremity in the females. They frequent sandy situations.

BE'MBEX, a genus of Hymenopterous Insects, forming the type of the family *Bembicidæ* of Leach. The chief generic characters are as follows:—Palpi very short; maxillary palpi 4-jointed; labial 2-jointed; mandibles with a single tooth internally; the anterior wings have three submarginal cells (the third extending to the apex of the marginal), and two recurrent nervures both springing from the second submarginal; labium and mandibles prolonged into a rostrum, or beak; body smooth, nearly conical, but rather flat beneath—in the male frequently furnished with two or more spines at the apex. Legs, in the female spinose, anterior tarsi strongly ciliated. This genus connects *Monedula* with *Philanthus*. The species are peculiar to hot climates, and, in some instances, very much resemble wasps, both in size and colour. The female forms oblique cylindrical burrows in sandy banks, with a cell at the end of each. Her next object is to collect flies, such as the species of *Syrphidæ* and *Muscidæ*, as food for her young. In the excursions made for this purpose, she is exceedingly rapid in her motions, and produces a loud buzz in flying. Having furnished a cell with five or six flies, she deposits a single egg in it, and after having carefully closed its mouth, proceeds in the same manner with another cell. When hatched from the egg, the larva devours these flies, and changes into the pupa state, and shortly after to the perfect insect. Although these insects are not strictly social, as the bees and wasps, yet generally the burrows of many of the same species are formed in the immediate neighbourhood of each other.

Upon leaving her burrow, the female takes great precaution to secure its entrance from her enemies, by stopping the mouth with sand. No precaution, however, is sufficient to protect it from the intrusion of its parasites. Among others, the beautiful *Panorpes carnea* is enabled, by the spined structure of its legs, to make its way through the sand-protected entrance—which it takes the opportunity of doing during the absence of the female *Bembex*. Entering with the tail foremost, it deposits an egg, which hatches in the following spring. The larva of the *Bembex* then becomes food for that of the *Panorpes*.

BEMBIDI'IDÆ, a family of Coleopterous Insects belonging to the division *Geodephaga* of M'Leay. They are minute carnivorous Beetles, which generally frequent damp situations, such as the margins of rivers, ponds, and ditches. They are usually of a bright blue or green metallic colour, having two or four pale yellow spots on the elytra. It is doubtful whether this family can hold the same rank in the *Geodephaga* as those of the *Carabidæ*, *Harpalidæ*, &c.: the species, however, may be easily distinguished by the minute terminal joint to the palpi. The characters of the several genera contained in this group are as follows:—

A. Body depressed and linear.	
a. Antennæ with the third and fourth joints equal	*Lymnæum.*
b. Antennæ with the fourth joint longer than the third	*Cillenum.*
B. Body rather ovate.	
a. Thorax transverse, not truncate, heart-shaped:	
a. Posteriorly rounded:	
1. Whole	*Tachys.*
2. Emarginate	*Philocthus.*
b. Posteriorly acute	*Ocys.*
b. Thorax truncated, heart-shaped:	
a. The posterior angles very acute and prominent:	
1. Antennæ with the third, fourth, and fifth joints long	*Peryphus.*
2. Antennæ with the third, fourth, and fifth joints short	*Notaphus.*
b. The posterior angles slightly acute-deflexed:	
1. Eyes moderate:	
*Thorax rather remote from the abdomen at the base	*Lopha.*
**Thorax closely united to the abdomen .	*Tachypus.*
2. Eyes large	*Bembidium.*



1, Head of one of the *Bembidiidæ*, showing the form of the Palpi—*a*, the terminal joint; 2, Thorax of *Tachys*; 3, Thorax of *Philocthus*; 4, Thorax of *Ocys*; 5, Thorax of *Peryphus*; 6, Thorax of *Lopha*; 7, Thorax of *Tachypus*.

BEN-NUTS, the fruit of *Moringa pterygosperma*, from which Ben-Oil, much used in perfumery, is obtained. [MORINGA.]

BENCAO DE DEOS. [ABUTILON.]

BENINCASA, a genus of plants named by Savi, in honour of Count Benincasa, an Italian nobleman. It belongs to the order *Cucurbitaceæ*, and has but one species, *B. cerifera*. The fruit is described as covered with hairs and a glaucous bloom. It grows in the East Indies. Lindley, in the 'Vegetable Kingdom,' calls it the White Gourd, and says it is identical with *Cucurbita pepo*. Ainslie says that in the East it is presented at every native marriage feast, and is supposed to ensure prosperity to the married pair.

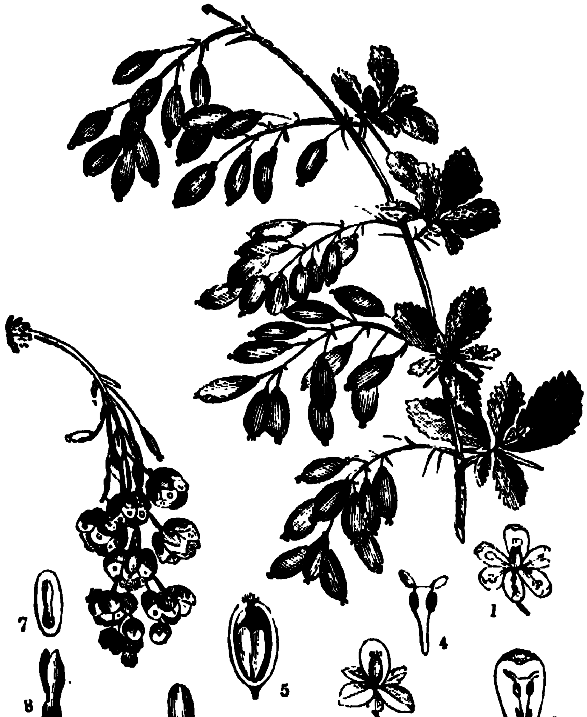
BENT GRASS. The species of *Agrostis* have this name. [AGROSTIS.]

BENTI'VI, or **BIENTI'VEO**, the Brazilian name for the *Tyrannus sulphuratus* of Vieillot. [SHRIKES.]

BENZOIN, the name of a resin yielded by a species of Styrax. [STYRAX.] Benzoic Acid is procured from this substance. The word *Benzoin* has also been given by Hayne to the plant which yields the resin.

BERAUNITE, the name of a phosphate of the peroxide of Iron which has a hyacinth-red colour, becoming darker on exposure to the atmosphere. (Dana, *Mineralogy*.)

BERBERIDA'CEÆ, *Berberids*, the Barberry Tribe, a natural order of plants belonging to the class of Exogens or Dicotyledons. It is readily known by three characters:—1, Its anthers open by reflexed valves; that is to say, the face of each cell of the anther peels off except at the point, where it adheres as if it were hinged there. 2, Its stamens are opposite the petals. 3, Its flowers are usually formed upon a ternary plan, there being three or six sepals, and a like number of petals and of stamens. This last character is more liable to exception than the two others. The remarkable structure of the anther is found in no European plants except *Berberidaceæ* and the Laurel Tribe [LAURACEÆ]; and as the latter has neither petals nor a ternary arrangement of the parts of the flower, it can never be mistaken for these. The relations of this order are with *Fumariaceæ*, *Vitaceæ*, and *Ranunculaceæ*. The present order consists of bushes or herbs, extremely dissimilar to each other in appearance, inhabiting the cooler parts of the world, being unknown in the tropics except on the tops of lofty mountains. They are not met with in Africa or the South Sea Islands. Their juice usually stains yellow, and their bark or stems if not woody are bitter and slightly astringent. The bitter leaves of *Epimedium alpinum* are said to be sudorific. The seeds of *Caulophylum Thalictroides* have been employed as a substitute for coffee. The leaves of *Bougardia chrysogonum* are eaten in the East like sorrel. The tubers of *B. Rauwolfii* are eaten in Persia. *Leontice Leontopetalum* contains in its roots a sufficient quantity of alkali to render it a substitute for soap in Aleppo.



Common Barberry (*Berberis vulgaris*).

1, An expanded flower; 2, the calyx without the petals; 3, a petal, with a stamen in front of it; 4, a stamen by itself, with the valves of its anther reflexed; 5, an ovary cut through, showing the position of the ovules; 6, a ripe seed; 7, a section of the latter, showing that the embryo lies in albumen; 8, an embryo separated from the seed.

BE'RBERIS, a genus of plants belonging to the natural order *Berberidaceæ*, among which it is immediately known by its shrubby habit, berried fruit, and the presence of glands upon its petals. It is also remarkable for the irritability of its stamens, which, when the filament is touched on the inside with the point of a pin or any other hard instrument, bend forward towards the pistil, touch the stigma with the anther, remain curved for a short time, and then partially recover their erect position: this is best seen in warm dry weather. After heavy rain the phenomenon can scarcely be observed, owing, in all probability to the springs of the filaments having been already set in motion by the dashing of the rain upon them, or to the flowers having been forcibly struck against each other. This irritability of the filament is affected differently by different noxious substances. It has been found by Messrs. Macaire and Marcet, that if you poison a Barberry with any corrosive agent, such as arsenic or corrosive sublimate, the filaments become rigid and brittle, and lose their irritability; while, on the other hand, if the poisoning be effected by any narcotic, such as prussic acid, opium, or belladonna, the irritability is destroyed by the filaments becoming so relaxed and flaccid that they can be easily bent in any direction. This property is also lost under the influence of the vapour of ether and chloroform. This motion seems to depend on the same property which gives to the free cells of the lower plants so great a power of motion

The species of this genus are interesting both for their utility and beauty. The value of the bark and root of the Common Barberry for dyeing leather and linen of a yellow colour is well known. Dr. Royle has shown that this property exists in the species of India, especially in *Berberis aristata*; and it has been ascertained by Vauquelin that a plant found on the Nilgherries of Hindustan (*B. tinctoria*) is inferior to few woods for dyeing yellow. The acid quality of the fruit has rendered all the species more or less esteemed; that of *B. aristata* and *B. Nepalensis* is dried by the mountaineers of India as raisins, and sent to the plains for sale. The bitterness and astringency of the bark has caused them to be received into the list of useful medicinal plants; and it has been ascertained by Dr. Royle that the *Λύκιον Ινδικόν* (Lycium Indicum) of Dioscorides, concerning which so much doubt has always existed, was an Indian species of Barberry now called *Berberis Lycium*. (Royle's 'Illustrations of the Botany of the Himalayan Mountains,' &c. p. 63.)

The species of *Berberis* are obviously divided into two great groups, of which the first has undivided leaves like the Common Barberry, and the others are pinnated, after the manner of the leaf of an ash-tree. Botanists call the latter Mahonias. Ash-Barberry may be taken as their English designation.

Section I. *Leaves simple.*—TRUE BARBERRIES.

1. *Leaves thin, deciduous; Flowers solitary.*

B. Sibirica, Siberian Barberry.—Leaves obovate, obtuse, deeply and irregularly toothed; flowers solitary, shorter than the leaves; spines deeply divided into from three to seven shining partitions. A small shrub found on exposed rocks on the hills and lower mountains of Altaic Siberia, where it is very common. The berries are, according to Pallas, obovate, and of a red colour. This species does not thrive in England, but is always a scrubby bush of inelegant appearance.

2. *Leaves thin, mostly deciduous; Flowers in racemes.*

B. Cretica, Candian Barberry.—Spines in three or more divisions; leaves small, obovate, acute, nearly free from toothings; flowers in very short compact racemes. Not uncommon on the mountains of Candia and Greece, whence it has been brought to our gardens. It is a dwarf scrubby bush, looking like a starved specimen of the Common Barberry. Its berries are said to be black, ovate, 2-seeded, and austere rather than acid.

B. vulgaris, Common Barberry.—Spines in three deep divisions; leaves obovate, with fine spiny toothings; flowers in drooping racemes, which are longer than the leaves. This common species appears to inhabit equally the north of Europe, Asia, and America, in woods and thickets, especially in limestone countries. De Candolle remarks that it extends in Europe from Candia to Christiania, and that while in northern latitudes it is a valley plant, it becomes in the south exclusively a mountaineer, climbing so high on Mount Ætna as to be the most alpine of the shrubs of the sterile belt of that mountain at the height of 7500 feet. Like all such plants it has in the course of ages formed numerous varieties; these are however chiefly confined to the fruit, there being a great similarity in the foliage of all except one.

This species is usually a bush from four to six feet high; but in Italy it becomes as large as a plum-tree, living a couple of centuries or more. The wood is hard but brittle, and is chiefly employed by the dyers for staining yellow. The acid qualities of this fruit render it unfit to eat raw, but it makes one of the most delicious of preserves.

B. Canadensis, Canadian Barberry.—Spines divided into three equal lobes; branches covered with little elevated points; leaves oblong, distantly and coarsely toothed; flowers in corymbose racemes, nodding. Found in the northern states of North America. It is generally considered the same as *Berberis vulgaris*, because the specimens called *B. Canadensis* both in gardens and herbaria certainly are so; but this, the true plant of Miller and others, appears to differ from the common species in the characters here assigned to it; its leaves are moreover of a thicker texture.

B. cratægina, Hawthorn Barberry.—Spines simple; leaves oblong, strongly netted, with a straggling serrature here and there; flowers in dense, drooping, many-flowered racemes, which are scarcely longer than the leaves. Described by De Candolle from specimens collected in Asia Minor.

B. Iberica, Iberian Barberry.—Spines often simple, but sometimes 3-cleft; leaves nearly undivided; flowers in loose nearly erect racemes, much longer than the leaves. A native of Spain. The berries are dark purple.

B. Sinensis, Chinese Barberry.—Spines 3-parted or none; leaves lanceolate, very acute, much netted, entire, or regularly toothed; flowers numerous, in drooping racemes, which are not much longer than the leaves. A native of the north of India and of China.

3. *Leaves leathery, evergreen; Flowers solitary, or in clusters.*

B. Wallichiana Wallich's Barberry.—Spines long, slender, 3-parted; leaves oblong, lanceolate, deep-green, sharp-pointed, finely serrated; flowers very numerous, in clusters shorter than the leaves. A native of Nepaul, and apparently of the higher part of the country. *B. atroviridis* is another name for this species.

B. dulcis, Sweet-Fruited Barberry.—Spines long, slender, simple, or 3-parted; leaves obovate, obtuse, with or without a bristly point, quite entire, glaucous on the under side; flowers solitary, on slender stalks, twice as long as the leaves. A native of the south-western part of South America, from the Strait of Magalhaens to Valdivia, where it forms a small evergreen bush. Its fruit is round, black, about as large as a pea; it is said to be sweet and well suited for making tarts or preserving.

B. heterophylla, Various-Leaved Barberry.—Spines strong, 3-parted; leaves obovate, lanceolate, acute, either entire or with from three to five spiny teeth, very deep green; flowers solitary, on stalks about twice as long as the leaves. An inelegant bush about three feet high, bare of leaves, and having nothing but its rarity to recommend it; it is a native of the Strait of Magalhaens; in the gardens it is usually called *B. ilicifolia*; there is a figure of it in Hooker's 'Exotic Flora,' vol. i., t. 14.

B. Empetrifolia, Crowberry-Leaved Barberry.—Spines slender, long, in three or five deep divisions; leaves linear, with a spiny point, rolled back at the edge, collected in bundles in the axils of the spines; flowers solitary, growing on stalks about as long as the leaves. A very curious and pretty plant, found wild from the Cordilleras of Chili to the southern point of the American continent, over the whole of which country it appears to be very common. In general aspect it is much more like a Heath than a Barberry.

Besides these species there are several of great beauty as evergreen shrubs in South America.

4. *Leaves leathery, evergreen; Flowers in racemes.*

B. floribunda, Many-Flowered Barberry.—Spines very stiff, and 3-parted; leaves oblong or oblong-lanceolate, nearly entire or toothed in various degrees, sometimes very deeply and coarsely veined; flowers in long loose slender racemes. Apparently extremely common in the whole of the north of India, where it forms a tall bush, varying considerably in the size and form of the leaves, and in the degree in which they are toothed, but always well marked by its slender, pendulous, or erect racemes of flowers, which are much longer than the leaves, and in no degree corymbose. It is to be found occasionally in the more choice collections of this country. Out of accidental variations in its mode of leafing and flowering, the spurious species called *B. affinis* and *B. ceratophylla* have been constituted.

B. Asiatica, Raisin Barberry.—Spines small and weak, simple or 3-parted; leaves oblong or obovate, acute, somewhat glaucous beneath, either entire or coarsely or even finely toothed; flowers in short compact racemes not longer than the leaves. Found in Nepaul and Kamaon very abundantly, forming a tall bush with the habit of the common European Barberry. The fruit is round, covered over with a thick bloom, and has altogether the appearance of the finest raisins. It is produced abundantly in this climate, where the plant is now not very uncommon. The very short racemes are the principal distinction of this species when in flower.

B. dealbata, Whitened Barberry.—Spines scarcely any; leaves roundish, coarsely-toothed, rather glaucous, white beneath; racemes very short and compact, pendulous. A native of Mexico. It is a tall slender evergreen bush, with deep-brown branches and scarcely any spines. The leaves are sometimes wedge-shaped and 3-toothed, but more frequently nearly round, with two or three spiny teeth on each side. It is sometimes called in the gardens by mistake *B. glauca*, which is a different species.

B. aristata, Bristle-Leaved Barberry.—Spines 3-parted, simple, or wanting; leaves obovate, acute, shining on both sides, with a few bristle-pointed teeth on either edge; racemes always more or less compound and corymbose. A native of the mountains of Hindustan, extending from the Himalayas down the Nilgherry Hills as far as Adam's Peak in Ceylon. It is a hardy sub-evergreen bush in the gardens.

Section II. *Leaves pinnated; all evergreen.*—ASH-BARBERRIES.

B. fascicularis, Californian Ash-Barberry.—Leaflets ovate, finely-toothed, not shining; flowers in short compact clusters; stem tall and woody. Found in the moutainous parts of California and Mexico. A very handsome evergreen shrub, with pinnated leaves which are by no means shining, and of a paler green than several of the others.

Mahonia diversifolia of the gardens seems to be the same as this; and the story of its having been brought from Monte Video is probably not true.

B. Aquifolium, Holly-Leaved Ash-Barberry.—Leaflets ovate-lanceolate, flat, deeply and regularly toothed, remarkably shining; flowers in long narrow racemes; stem tall and woody. A native of North-West America from California to Nootka Sound, growing in woods, where it forms a rich and thick underwood. Its foliage is of a rich deep shining green, becoming purple in the winter; it bears fruit in some abundance, which consists of clusters of roundish black berries, having their surface covered with a rich violet bloom. They have no merit as fruit, but would probably be greedily sought by game, for the protection of which in coverts this species seems well adapted, if it could only be obtained in sufficient quantity. The difficulty of propagating it has hitherto made it a scarce plant; but seeds might be easily obtained from the Hudson's Bay Company's settlements in North-West America. It most resembles *B. fascicularis*, from which its large shining leaves at once distinguish it; and it is perfectly hardy, which that species is not: flowers in May and June. It has been figured in the 'Botanical Register,' vol. xvii., plate 1425.

B. repens, Creeping Ash-Barberry.—Leaflets few, somewhat glaucous, especially on the under side, oblong, when old rounded at the point, with shallow toothings; flowers in crowded compound erect racemes; stem very dwarf; runs at the root. Found wild on the east side of the Rocky Mountains of North America, and perfectly hardy in our gardens. Its stems do not grow above six or nine inches high, and are loaded with a profusion of rich yellow flowers, which constitute the principal beauty of the species. Its fruit is unknown. A good figure of it has been published in the 'Botanical Register,' vol. xiv., plate 1176. Nothing can be more unlike *B. Aquifolium* than this is, although the two have occasionally been most unaccountably confounded.

B. glumacea, Long-Leaved Ash-Barberry.—Leaflets numerous, ovate-lanceolate, coarsely toothed, of a dull glaucous green; flowers in long narrow erect racemes; stem very dwarf; scales of the leaf and flower-buds stiff and glumaceous. A native of North-West America, growing in shady grassy places in woods. The stem of this species does not grow more than six or eight inches high, and is in fact shorter than its leaves, which consist of about six pairs with an odd one, and are jointed at every pair of leaflets in the manner of a bamboo stem. The fruit is roundish and insipid, of a fine glaucous purple. This is less rare than *B. Aquifolium*, and is an object of curiosity more than of utility. It loves to grow in a shaded American border, where it is protected from the fiercer rays of the sun. It is figured in the 'Botanical Register,' vol. xvii., plate 1426. *Berberis* or *Mahonia nervosa* is another name for this species.

In addition to these there are the following species:—*Berberis Leschenaultii* (the *B. Acanthifolia* of some), a fine pinnated plant with round black fruit, found on the Nilgherry Mountains of India at the elevation of 8000 feet. *Berberis Nepalensis*, a native of the mountains of the north of India, where, according to Dr. Royle, it grows twelve feet high in shady places, at 5000 and 6000 feet of elevation: this is a noble species, and ought to be obtained from India at any cost, as it would in all probability succeed in this climate. *Berberis tragacanthoides*, with not more than one or two pairs of leaflets, found along the banks of the river Kur, near Tiflis; and *Berberis caraganæfolia*, a Chinese plant very like the last: both the latter have the points of the leaves hardened into spines.

BERCHEMIA, a genus of plants belonging to the natural order *Rhamnaceæ*. Two species *B. volubilis* and *B. lineata* are used in medicine.

BERENGELITE, a mineral resin from South America, soluble in alcohol.

BERENICE. [ACALEPHÆ.]

BERENI'CEA, a celluliferous Coralline Fossil, of which *B. diluviana* is an example, in the Oolite of Wilts.

BERGAMOT. [CITRUS.]

BERGERA, a genus of plants belonging to the natural order *Aurantiaceæ*. *B. Königii* possesses stomachic and tonic properties, and an infusion of the leaves is used against vomiting. The green leaves are used raw in dysentery; the bark and roots are stimulant.

BERGIA, a genus of plants belonging to the natural order *Elatinaceæ*, and named by Linnæus in honour of Peter Jonas Bergius, Professor of Natural History at Stockholm. It has a 5-parted calyx, 5 petals, 10 stamens, 5 styles, approximate capsules, 5-celled, and 5-valved. The species are insignificant weeds inhabiting moist places. *B. Ammanoides*, according to Dr. Wright, is an inhabitant of the East Indies and bears the Tamool name of Neer-mel-neripoo, or Water-Fire. Dr. Lindley calls attention to this name as resembling our Water-Pepper, a name given to the *Elatine*, the type of the order to which Lindley has referred *Bergia*. Two other species are natives of the Cape and one of Java. (Lindley, *Vegetable Kingdom*; Don, *Dichlamydeous Plants*.)

BERGKALK, in Geology, the German term for our Mountain Limestone.

BERGMEHL (Mountain Meal), a name given in Sweden to an earth which the inhabitants of the districts where it occurs have from time immemorial regarded as nutritious. It occurs in Sweden on the shores of Lake Letnaggsjohn near Urnea and mixed with flour this substance has in times of scarcity been used for bread. It was examined by Ehrenberg, who found it to contain the remains of several species of *Diatomaceæ*. He considered this fact would account for its nutritious properties. The vegetable matter however contained in the silicious frustules of these minute plants must be exceedingly small, and further evidence would be required to demonstrate that this substance really contributed to the support of those who ate it. The occurrence of the *Diatomaceæ*, owing to the indestructible nature of their frustules or skeletons, is very common. [DIATOMACEÆ.]

BERGYLT, the name of a Fish, also called the Norway Haddock, the *Sebastes Norvegicus* of Cuvier. [SEBASTES.]

BE'RIS, a genus of Dipterous Insects, of the family *Xylophagidæ*. The species of this genus are small metallic-coloured flies, which frequent the leaves of plants. Their larvæ feed on putrescent wood. The generic characters are as follows:—Body narrow; palpi minute, the third joint thickened a little at the extremity; the two first joints of the antennæ equal, third elongate subulate; eyes pubescent; the scutellum with 4, 6, or 8 points; abdomen with 7 distinct segments; the first joint of the posterior tarsi incrassate in the male; the wings have four posterior cells, and sometimes the indication of a fifth.

The ova of one of the species of this genus (*Beris clavipes*) are said to be ejected from the ovipositor in the form of a little chain, about an inch long, consisting of a single series of oval eggs, which are glued to each other in an oblique position. Most probably the eggs of the other species are ejected in the same manner.

BERKELEYA, a genus of *Diatomaceæ*, named by Greville in honour of the Rev. M. J. Berkeley, distinguished for his researches in cryptogamic botany. It belongs to the suborder *Naviculeæ*, and is characterised by having linear frustules included within tubular submembranaceous filaments, which are free at one extremity, but have the other immersed in a gelatinous tubercle. *B. fragilis* is found parasitic on *Zostera marina*, and some of the smaller marine *Algæ* on the British coasts. *B. Adriatica* has been found on the coasts of the Adriatic at Triesto.

BERNICLE GOOSE or CLAKIS, the vernacular name for the *Bernicla* of Ray, *Anser Bernicla* of Fleming; the *Bernicle, Bernacle Goose*, and *Barnacle Goose* of authors. This bird affords an instance of the credulity with which those who in their generation were held wise and learned, accepted the most absurd traditions, and handed them down to posterity with the additional weight of their authority. A cirrhipod, a marine testaceous animal, the *Pentelasmis anatifera* of Leach, *Anatifa lævis* of Bruguières, *Lepas anatifera* of Linnæus, the Duck Barnacle of collectors, was long asserted to be the parent of the Bernicle Goose. This common shell is fixed to a long fleshy peduncle, and is frequently found attached to floating timber and even sea-weed. The tentacula, which proceed from the anterior opening of the valves, have an appearance that recalls to the mind of a casual inaccurate observer the recollection of a feather, and hence, in all probability, the fable took its origin. "Some," writes Nuttall, "even described these supposed embryos as fruits, in whose structure already appeared the lineaments of a fowl, and which, being forthwith dropped into the sea, turned directly into birds. Munster, Saxo Grammaticus, and Scaliger even, asserted this absurdity. Fulgosus affirmed that the trees which bore these wonderful fruits resembled willows, producing at the ends of their branches small swelled balls containing the embryo of a duck, suspended by the bill, which when ripe fell off into the sea and took wing. Bishop Leslie, Torquemada, Odericus, the Bishop Olaus Magnus, and a learned cardinal, all attested to the truth of their monstrous generation. Hence the bird has been called the Tree Goose, and one of the Orkneys, the scene of the prodigy, has received the appellation of Pomona."

Not to weary the reader with names, and some of great reputation might be added, we will proceed to trace the fable as told by Gerard, merely adding by the way, that one of the other worthies is recorded to have opened 100 of the goose-bearing shells, and to have found in all of them the rudiments of the bird completely formed. Gerard, then, as if determined that no sceptic should have the slightest ground whereon to rest a doubt, thus gives his evidence in his 'Herbal':—

"But what our eyes have seene and hands have touched we shall declare. There is a small island in Lancashire, called the Pile of Foulders, wherein are found the broken pieces of old and bruised ships, some whereof have been cast thither by shipwracke, and also the trunks and bodies with the branches of old and rotten trees, cast up there likewise; whereon is found a certaine spume, or froth, that in time breedeth unto certaine shells, in shape like those of the muskle, but sharper pointed, and of a whitish colour; wherein is contained a thing in form like a lace of silke finely woven as it were together, of a whitish colour; one end whereof is fastened unto the inside of the shell, even as the fish of oisters and muskles are; the other end is made fast unto the belly of a rude masse or lumpe, which in time commeth to the shape and form of a bird; when it is perfectly formed the shell gapeth open, and the first thing that appeareth is the foresaid lace or string; next come the legs of the bird hanging out, and as it groweth greater it openeth the shell by degrees, till at length it is all come forth and hangeth only by the bill; in short space after it commeth to full maturitie, and falleth into the sea, where it gathereth feathers, and groweth to a fowle bigger than a mallard and lesser than a goose, having blacke legs and bill or beake, and feathers blacke and white, spotted in such manner as is our mag-pie, called in some places a pie-annet, which the people of Lancashire call by no other name than a tree-goose; which place aforesaid, and all those parts adjoining, do so much abound therewith, that one of the best is bought for three-pence. For the truth hereof, if any doubt, may it please them to repaire unto me, and I shall satisfie them by the testimonie of good witnesses." This edifying deposition is illustrated by a cut of the goose and of its parent shell.

Now, after this, can we wonder at the melancholy catalogue of human beings who have expiated the supposed crime of witchcraft at the stake on the testimony of their deluded and deluding prosecutors? Here is a man of learning and of considerable accuracy in many points, the author of a valuable work containing much information, who gravely and deliberately, on the authority of two of the most acute of his senses, asserts a downright falsehood and courts investigation. He may moreover be acquitted of any intention to deceive; but his mind was filled with previous assertions and preconceived opinions, and his excited imagination, like that of the majority of the witnesses against the unfortunate witches, gave a colour and a form to all he saw and felt.

Gerard published this celebrated romance in 1636. If we now turn to Ray's edition of Willughby, published in 1678, we shall see what a progress had been made towards truth, even in that short space of time. "What is reported concerning the rise and original of these birds, to wit, that they are bred of rotten wood; for instance, of the masts, ribs, and planks of broken ships, half putrified and corrupted, or of certain palms of trees [the catkins of the willow] falling into the sea; or lastly, of a kind of sea-shells, the figures whereof Lobel, Gerard, and others have set forth, may be seen in Aldrovand, Sennertus in his 'Hypomnemata,' Michael Meyerus, who hath written an entire book concerning the tree-fowl, and many others. But that all these stories are false and fabulous I am confidently persuaded. Neither do these want sufficient arguments to induce the lovers of truth to be of our opinion, and to convince the gainsayers. For in the whole genus of birds (excepting the phœnix, whose reputed original is without doubt fabulous) there is not any one example of equivocal or spontaneous generation. Among other animals indeed, the lesser and more imperfect, as for example many insects and frogs, are commonly thought either to be of spontaneous original, or to come of different seeds and principles. But the greater animals and perfect in their kinds, such as is among birds the goose, no philosopher would ever admit to be in this manner produced. Secondly, those shells in which they affirm these birds to be bred, and to come forth by a strange metamorphosis, do most certainly contain an animal of their own kind, and not transmutable into any other thing, concerning which the reader may please to consult that curious naturalist Fabius Columna. These shells we ourselves have seen, once at Venice, growing in great abundance to the keel of an old ship; a second time in the Mediterranean Sea, growing to the back of a tortoise we took between Sicily and Malta. Columna makes the shell-fish to be a kind of *Balanus marinus*. Thirdly, that these geese do lay eggs after the manner of other birds, sit on them and hatch their young, the Hollanders in their northern voyages affirm themselves to have found by experience."

Here we see the clouds that had obscured the subject nearly cleared away, though there is still a little lingering error in the tacit admission of the spontaneous generation of the frogs and insects.

It is no small praise to Belon and some others that, even in their early time, they treated this fable of the duck-bearing tree with contempt. There has been much confusion in the nomenclature of this bird. Linnæus considered it as the male of *Anser erythropus* (White-Fronted Wild-Goose), and treated *Anser Brenta* (the Brent-Goose), and *A. Bernicla* as synonyms. Succeeding writers continued the mistake till Temminck and Bechstein, instead of restoring the name given to it by the older ornithologists, called it *Anser leucopsis*, but did not refer the specific name *Erythropus* to the *Anas albifrons* of Gmelin and Latham.

Bernicle-Goose (*Anser Bernicla*).

Dr. Fleming, in his 'History of British Animals,' set this right, and has properly described the Bernicle-Goose as *Anser Bernicla*, and the White-Fronted Wild-Goose as *Anser erythropus*.

The summer haunts of the Bernicle reach high into northern latitudes. Iceland, Spitzbergen, Greenland, Lapland, the north of Russia and of Asia, and Hudson's Bay, are recorded as its breeding places. Sir John Richardson notes it as accidental on the Saskatchewan (53° 54′ N. lat.) as a passenger in spring and autumn, and gives the southern states of the North American Union as its winter quarters. It visits Britain in the autumn, appearing in great numbers on the north-western coasts, and in the north of Ireland. On the eastern and southern shores of Britain it is comparatively rare, and the Brent-Goose occupies its place.

The weight of a Bernicle is about five pounds, the length rather more than two feet, and the breadth about four and a half with the wings spread. The bill, about an inch and a half long, is black, with a reddish streak on each side, and between it and the eyes is a small black streak. Irides brown; head (to the crown), cheeks, and throat white; the rest of the head, neck, and shoulders black. Upper part of the plumage marbled with blue, gray, black, and white; belly and tail coverts white; tail black; flanks ashy gray; legs and feet dusky.

The eye-streak is much broader in the young of the year than in the adult; the under parts are not of so pure a white, and the upper plumage is darker.

The flesh is excellent.

BE'ROE, a genus of marine animals established by Müller, belonging to the *Ciliograde Acalephæ*. Some of the species, as the common *B. Pileus*, are now referred to *Cydippe*. The species, which are gelatinous, transparent, and either oval or globular, float in the ocean, where they are widely diffused. Lamarck says that they are very phosphoric, and that they shine at night like lamps suspended in the sea, their brilliancy becoming vivid in proportion to the rapidity of their motions. Their breathing is carried on by means of cilia, which extend longitudinally and at equal distances along the surface from the mouth to the inferior opening. Fabricius observed minute crustaceans in the digestive organs, and that when one of these animals was broken to pieces those pieces still continued to live and swim about by the action of the cilia, which was still continued. The Beroes have a rotatory motion, and Bosc observed that they also had another, produced by an alternate contraction and dilatation.

Messrs. Audouin and Milne Edwards have given a description of the organisation of the globular *Beroe* (*Beroe Pileus*, Lam.; *Pleurobrachia* of Fleming; *Eucharis* of Péron and of De Blainville), and Dr. Grant, in the 'Transactions of the Zoological Society,' has given an account of its structure. Cuvier mentions it as being common in the north—where it is said to be one of the aliments of the whale (*Balæna*)—and in the channel on the French coast. It is found very commonly on the British coasts. Dr. Grant found it in the harbour of Sheerness, in which latter locality he says "the boatmen, who seemed to be familiar with it under the name of the spawn of the sea-egg (*Echinus*), which it somewhat resembles in its globular and ribbed form, assured me that often in hot and calm weather the water swarms with the little medusæ in such numbers as to cover the surface in all this part of the æstuary of the Thames. The animal has a regular oval form, with its longest diameter from the mouth to the anus, about six lines, and its breadth about four lines. The general texture of the body is quite transparent and colourless." [ACALEPHÆ.]

BERO'SUS, a genus of Coleopterous Insects belonging to the family *Hydrophilidæ* (Leach). These beetles inhabit ponds, in which they may often be seen swimming in an inverted position. They most probably feed upon vegetable substances. The common colouring of the species is dusky yellow varied with markings of a black or dark metallic bronze hue; their form is nearly oval, and the principal generic characters are, eyes prominent, clypeus entire, antennæ nine- (?) jointed, thorax narrower than the elytra.

BERRY, in Botany, a term confined to such soft and succulent fruits as have their seeds lying loosely among pulp. The gooseberry, the currant, and the grape are therefore genuine berries; but plums, rose-heps, haws, &c., in which the seeds do not lie among the pulp, are excluded from the definition, although they are all comprehended under the same name in common language. [FRUITS.]

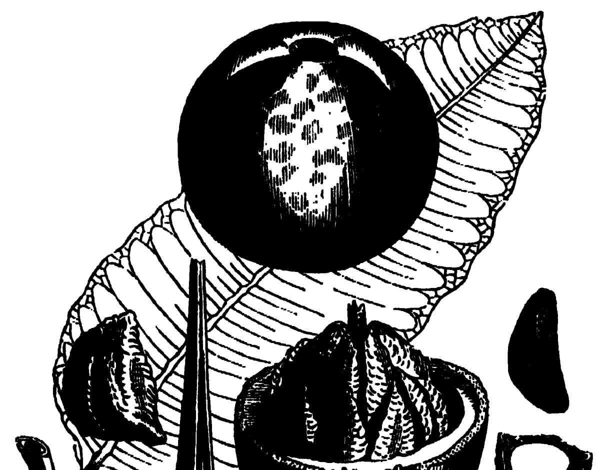
BERTHELLA, a genus established by De Blainville for a Marine Mollusk, found though rarely on the British coasts. It is the *Pleurobranchus plumula* of Montague, and is thus defined by De Blainville:—Body oval, sufficiently protuberant (*bombé*) above, and recurved below, when in a state of repose, so as completely to hide the head and the foot, which last is large and oval, but much less than the mantle. There is a kind of veil at the anterior border of the head, prolonged on each side into a sort of appendage cleft laterally. The two tentaculiform occipital auricules are cleft and striated within at their termination, and approach each other very nearly at their base, which is thinned out as it were. The eyes are sessile, placed upon the posterior root of the tentacula. There is but one pectiniform branchia, which is lateral, attached anteriorly, and in great measure free behind. The organs of generation terminate in one large tubercle, situated before the root of the branchia; the shell is internal, very delicate, and oval, with a summit hardly to be distinguished. Forbes and Hanley, in the 'History of British Mollusca,' place it in the family *Pleurobranchidæ* of the *Gasteropoda*. Although seldom taken it appears to have a wide range. It has been found at Exmouth, Guernsey, Salcombe Bay, Milford Haven, Isle of Man, Sound of Skye, Scarborough, coast of Northumberland, and Malbay on the west coast of Ireland.

Berthella porosa.
a, side view; *b*, view of back, to show internal shell.

BERTHIERITE. [ANTIMONY.]

BERTHOLLE'TIA, a genus of plants belonging to the natural order *Lecythidaceæ*, and named after Berthollet the celebrated chemist. The only species is a tree of large dimensions, and forms vast forests on the banks of the Oronoco. Its stem averages 100 feet in height and two feet in diameter, not branching till near the top, whence its boughs hang down in a graceful manner. Its leaves are undivided, arranged alternately upon the branches, about two feet long and five or six inches wide, of a brilliant green. Its flowers are yellowish white, with a calyx having a deciduous border divided into two pieces, a corolla of 6 unequal petals joined together at the base, and a very great number of white stamens joined into a thick fleshy ring. The fruit is figured and described by Humboldt as a spherical case as big as a man's head, with four cells, in each of which are six or eight nuts; its shell is rugged and furrowed, and covered with a rind of a green colour. The nuts are irregularly triangular bodies, having a hard shell, which is very much wrinkled, and which is fixed to a central placenta by their lower end; their seed, as is well known, is a firm oily almond of a pure white colour. They are sold in the shops of London under the name of Brazil Nuts.

"The Portuguese of Para," says Humboldt, "have for a long time driven a great trade with the nuts of this tree, which the natives call Iuvia and the Spaniards Almendron; they send cargoes to French Guyana, whence they are shipped for England and Lisbon. The kernels yield a large quantity of oil well suited for lamps." The same traveller describes himself and his companion Bonpland as having found those nuts a great luxury when they were following the course of the Oronoco. For three months they had lived upon bad chocolate, rice boiled in water, always without butter, and generally without salt, when they met with a store of Bertholletia nuts. It was in the course of June, and the Indians had just gathered in their harvest of them. The kernels were found delicious when fresh, but unfortunately they are apt to become rancid on account of the great quantity of oil which they contain.



Fruit and Seeds of *Bertholletia excelsa.*

BERYL, a mineral, among the varieties of which are found two of the most beautiful and costly gems with which we are acquainted, namely, the *Emerald* and the *Precious Beryl*.

They belong to the rhombohedral system of crystallisation, usually occurring in regular hexagonal prisms which occur variously modified, sometimes by the truncation of the lateral edges of the prism, at other times by the simple truncation of the terminal edges; but the prism is sometimes terminated in a much more complicated manner, of which a remarkable instance has presented itself in a crystal in the possession of Professor Naumann of Freiberg, who has observed in them the faces of no less than six other forms of the rhombohedral system. Its general aspect is always that of a hexagonal prism, and when the terminal edges are modified there will generally be found a plane inclined to the lateral planes of the prism under an angle of 119° 58′.

The crystals admit of cleavage in the four directions parallel to the faces of the regular prism, that parallel to the terminal plane being perfect, the others imperfect and more difficult to be obtained. The fracture is conchoidal and uneven; the lustre is vitreous, and it possesses various degrees of transparency. According to Mohs the hardness varies from 7·5 to 8, the specific gravity from 2·678 to 2·732. The following are its chemical characters before the blow-pipe, as stated by Berzelius.

Alone it is not easily acted upon, but when thin fragments are for a long time submitted to a powerful flame the edges become rounded, and a colourless vesicular scoria is produced. The transparent varieties become milky.

With borax it forms a clear and generally colourless glass, which effect is also produced by soda. With the phosphor salt it is with difficulty dissolved without the formation of a silicious skeleton.

Of this mineral we possess several analyses, of which the following are three: the first being an Emerald from Peru, by Klaproth; the second a Beryl from Siberia, by the same chemist; and the third a Beryl from Broddbo, near Fahlun, in Sweden:—

	Emerald.	Beryl. Siberia.	Beryl. Broddbo.
Silica	68·50	66·45	68·35
Alumina	15·75	16·75	17·60
Glucina	12·50	15·50	13·13
Oxide of Iron	1·00	0·60	0·72
Oxide of Columbium .	0·00	0·00	0·27
Oxide of Chromium .	0·30	0·00	0·00
Lime	0·25	0·00	0·00

This species contains several varieties, of which the two known among lapidaries under the name of Emerald and Aquamarine, or Precious Beryl, are the most worthy of attention. These varieties, though distinguished by some mineralogists as forming distinct species, differ however only in colour, the term Emerald being applied to those possessing the peculiar rich deep green so well known as the emerald-green, while all the other varieties are comprehended under the name of Beryl; those which are clear, transparent, and possess a good colour, present various shades of sky-blue or mountain-green, being the Aquamarine or Precious Beryl. The colour of the Emerald is attributed to the small quantity of green oxide of chromium which has been found in the specimens from Peru; while the varieties in the tints of Beryl may be considered to be produced by admixtures of the oxides of iron, the yellow being the colour of the peroxides of iron, and the mountain-green and the various shades of blue being the effect of varying quantities of the protoxide, to the presence of which the common bottle-glass owes its tint.

The following localities produce the finest Emeralds:—The mines in the Tunca Valley, situated in the mountains between New Granada and Popayan, and not far from the town of Santa Fé de Bogota, where, according to Humboldt, they are found in veins traversing clay-slate, hornblende-slate, and granite; the Heubach Valley, in the district of Pinzgau, Salzburg, where they occur imbedded in mica-slate, and are inferior in colour to those from Peru; varieties have also been lately found in some old mines in Mount Zabarah, in Upper Egypt, from which spot the ancients are supposed to have derived their emeralds.

The varieties known by the name of Beryl are found principally in Siberia and Brazil: in the former country it occurs in the granite district of Nertschinsk and also in the Uralian and Altai Mountains, sometimes in very large crystals, prisms having been found upwards of a foot in length. In the granitic mountains of Odon Tchelon, in Daüria, three very interesting mines occur at different elevations in the mountain; in the lowest are found, irregularly disseminated through a mass of semi-decomposed granite mixed with ferruginous clay and nodules of Wolfram, prismatic crystals of Beryl of a greenish-yellow colour, rarely exceeding one inch in length. Some hundred feet higher occurs the second mine in a vein of micaceous clay, from which the most valuable crystals are obtained; their colour is of a pale but pure green, and their size frequently considerable. The third mine is situated in a vein of white indurated clay on the summit of a mountain; in this mine the varieties are usually of a pale greenish-blue, but sometimes they are found of a pure but pale sky-blue. They are here remarkably transparent. Imbedded crystals and massive varieties are also found at Limoges, in France; near Zwiesel, on the Rabenstein, in Bavaria; at Fimbo and Broddbo, near Fahlun, in Sweden; and likewise in some of the tin-mines in Saxony and Bohemia.

An enormous specimen is also described in Silliman's 'Journal' as having been found at Acworth in New Hampshire, United States. Its dimensions are stated to be 4 feet in length and 5½ inches across the lateral planes, and the weight to be 238 pounds.

Specimens of Beryl have also been found in several of the primary districts of Ireland; those from the granite of the Mourne Mountains, in the county of Down, are the finest. In this locality they are associated with topaz, black quartz, felspar, and mica. In Scotland it is found in the granite at Rubeslau quarry, near Aberdeen, and also in broken pieces in the sand of the rivers of that county.

The value of the Emerald depends not only on its size, colour, and brilliancy, but also on its being free from flaws, by which this gem is frequently greatly deteriorated in the eye of the jeweller. The following is the rate at which varieties of a fine colour and free from fissures may be procured, as stated by Beudant:—

A stone of 5 grs. from 100 to 120 francs.
„ 8 „ 240 francs.
„ 15 „ 1500 „
„ 24 „ 2400 „

BE'RYX, a genus of Fishes of the order *Acanthop[illegible]ygii*, and belonging to a little group of the family *Percidæ*, in which the species possess more than seven branchial rays, whereas all the other genera included in the first division of this order (in which division the cheeks are not defended by indurated plates) possess seven or less.

Cuvier, in his 'Règne Animal,' mentions three other genera belonging to this group: namely, *Holocentrum*, *Myripristis*, and *Trachichthys*.

The other characters of Beryx are as follows:—Ventral fins, with one spine and ten soft rays; the back furnished with but one slightly-extended fin, and some indistinct small spines on its anterior edge.

Several species are fossil. *B. ornatus* occurs in the Chalk of Sussex. Mantell figured it, under the title of *Zeus Lewesiensis*, in the 'Geology of Sussex.' Two other species occur in the British Chalk.

BESHAN, a name given to the Balm of Mecca, the produce of *Balsamodendron Opobalsamum*. [BALSAMODENDRON.]

BE'TA, a genus of plants belonging to the natural order *Chenopodiaceæ*, among which it is known by its having large succulent roots, and a green calyx united halfway to a hard rugged nut. The species are found in Europe, the north of Africa, and the western parts of Asia; four are cultivated as esculents, the others are mere weeds.

B. vulgaris, Common Beet, is said to be found in a wild state along the whole of the sea-coast of the Mediterranean, and in Egypt; it is however chiefly known as a plant cultivated in gardens, for its carrot-like sweet and tender roots. Several sorts are mentioned by writers on gardening, varying in the size, form, colour, and sweetness of their roots: of these however two are much more worth cultivating than the others, namely, the small red variety and the long yellow variety; they are the most delicate, the sweetest, and have the richest colour when served at table.

B. altissima, Mangel Wurzel, is a much larger and coarser plant than the Common Beet, from which it is principally known by its roots being marked internally with zones of red and pink or white. Its native country is unknown; by some it is reckoned a mere variety of the Common Beet, but this is scarcely probable, considering that it is permanently reproduced from seed; others state that it is a hybrid between the Common and Chard Beet, our third sort, of which however there is neither proof nor probability. Mangel Wurzel is an object of extensive cultivation for feeding cattle; its leaves afford a very nutritious food for all kinds of live stock, and the roots, from their extreme sweetness, are by many farmers considered the most valuable of all the agricultural plants upon which cattle are fed in winter. Independently of their use for cattle, Mangel Wurzel roots have been extensively employed in the manufacture of sugar. They are still employed in France in the manufacture of sugar; and an attempt has lately been made in Ireland to use them for the same purpose. For this, the common red and white Mangel Wurzel will perhaps be found best suited in this country, in consequence of its hardiness, and the great weight per acre which it will afford; but the French have preferred a perfectly white kind, which is said to exceed the former in nutritive properties, in the proportion of two to one; they also grow a sort with white roots and a purple crown, and another white within, and yellow on the outside. The yellow Field-Beet, which has been a good deal cultivated in this country, is apparently a variety of *B. vulgaris*, and is too unproductive in most situations to bear comparison with the others.
